The practical utility of the method resides in the possibility of its application for following the general effects of the irradiation treatment, with its succession of degenerative and destructive changes in the nucleus and protoplasm day after day by a simple, innocuous and rapid method of examination until that time when all neoplastic elements have disappeared. In this sense the apposition method is superior in most respects to biopsy.

JOHN W. BRECKMAN, M.D.

Peridural Anesthesia in Gynecology Technique and Experience. (*Periduralanästhesie in der Gynäkologie. Technik und Erfahrungen.*) GUTENBERGER SCHMIDT *Geburtsh. & Frauenh.*, 94, 8, 549.

A 2/1000 solution of pantocain in water is injected, with the precautions peculiar to this method and the precautions common to ordinary lumbar anesthesia into the space between the ligamentum flavum and the spinal dura, that is, the peridural space. The amount injected is usually 45 c.c., and the lumbar interspace chosen for the needle puncture

is usually the third or fourth. Injection through the fourth interspace will usually be sufficient for perineal procedures, while the third lumbar interspace is usually utilized for laparotomies.

In the presence of technical difficulties, such as the accidental perforation of the dura in the third interspace, or for the removal of very large tumors, the second interspace may be used. The anesthetic solution is usually injected in 10 c.c. fractions at 10 minute intervals and in 25 minutes after the last injection the anesthesia is usually advanced to the point where the operation can be started. The anesthesia as a rule lasts from 3 to 5 hours.

The advantages of this method of anesthesia are its long duration (from 3 to 5 hours) which enables several patients to be prepared at one time, enables the operation to be delayed while some emergency operation is done, or the operation itself may be extended if conditions demand it. The manual relaxation of the abdominal muscles together with the almost complete maintenance of intestinal tone renders the gynecological abdominal field more approachable and the manipulations less traumatizing. Following the operation the patient may be placed in any position in bed and does not need someone in constant attendance. The anesthetic is not followed by headaches or vomiting. Bowel and kidney functions continue undisturbed and respiratory sequelae have not been observed.

The only contraindications to peridural lumbar anesthesia are local inflammatory processes and extreme deformity of the lumbar vertebral column (the ordinary grades of scoliosis are not contraindications) diffuse peritonitis, nephritis, flux, or other conditions tending markedly toward circulatory collapse.

Since the author finds that this method of anesthesia has all the advantages of intradural lumbar anesthesia without its disadvantages, and since the method is safe and easy of application, peridural lumbar anesthesia is warmly recommended for extensive use in the smaller gynecological institutions where personnel is scarce and convenience is at a premium.

JOHN W. BRECKMAN, M.D.

Cystitis of the Trigone in Women (*La cystite du trigone chez la femme*) GUINAY T. HENRIOT. *Ides obs. gyn. acad.*, 94, 18, Supp. 2.

The author reviews the literature on cystitis of the trigone in women, following which he reports the results of his clinical experience in 300 cases. His anatomical material consisted of 68 biopsy specimens from the vesical trigone, 115 from the mucous membrane of the cervix, and also 83 postmortem specimens from the vesical trigone.

Contrary to existing theories, an analysis of the clinical results showed that hyperemia of the trigone of gynecological origin does not produce any disturbance of urination even in patients with longstanding hyperemia, and it is believed that the trigonal hyperemia caused by pelvic disease does not give rise to trigonitis.

It was ascertained that the true incidence of polypoid protuberances at the neck of the bladder was 24 per cent, which indicates that the presence of these protuberances bears no relation to trigonal hyperemia or urethritis. The author emphasizes the fact that there has been no evidence in the present material which would indicate that the polypoid protuberances give rise to urinary symptoms. Every third woman suffered from chronic urethritis which had no relation to trigonitis or polyps at the neck of the bladder. A generalized hyperemia of the urethral mucosa which seemed to be a part of the urethrotigonitis was observed half as frequently. This form of the condition does not give rise to contractions of the bladder neck. The author states that while pelvic disease and genital activity cause bladder irritability there is no clinical evidence that it may cause trigonitis nor is increased urinary infection noted in these cases.

Histologic examination revealed a great increase in subepithelial lymph follicles in the vesical trigone and it is believed that their presence is increased in patients with trigonitis. The author has observed also a squamous metaplasia of the transitional epithelium of the trigone showing a marked resemblance to the epithelium of the vaginal mucosa. Experiments with estrogen indicate that the trigone may present the same cyclic phases as those occurring in the vaginal epithelium. Cystoscopic examinations of iodine-stained epithelium of the trigone show the presence of glycogen in these squamous cells of the trigone and there seems to be a relation between the extension of the metaplasia and the pattern of the trigonal hyperemia. In view of the rich flora of bacteria in the urethra, the author believes that this same pavement epithelium of the trigone is particularly liable to infectious effects.

In conclusion the author states that in his opinion trigonitis is the pathologic reaction to infectious and hormonal influences to which the trigone is submitted. Urinary symptoms other than those caused by urethritis seem to be explained by trigonitis as such, or by a state of irritation in the adjacent internal sphincter the latter developing as a result of the trigonitis. JAMES C. MACMILLAN, M.D.

Bladder and Ureteral Malformation in Genital Prolapse (Les déformations vésicales et urétrales dans les prolapsus génitaux) G. GUNDELIN and H. CAVALIER. *Rev. fr. gyn. obst.* 1948 43 93.

The authors present a very interesting and practical article concerning the changes in position of the urethra, bladder and ureters in the various degrees of prolapse with 9 roentgenograms and diagrams. They have carried out complete urological studies on 60 patients with genital prolapse and have evaluated their findings.

They found that the changes in position of the urethra, bladder and ureters depended on whether there was a primary prolapse of the uterus with secondary vaginal inversion or a primary vaginal prolapse with secondary progressive elongation of the

cervix. They found two types of cystoceles: a type in which the cystocele was developed at the expense of the preureteric and interureteric zones by their gradual attenuation and a second type in which the cystocele was formed by the floor of the bladder, the cervix, and the ureters swinging around the lower border of the symphysis. In this second type particularly, all of the organs rotated below the symphysis. The meatus descended a little, the bladder more, the ureteral orifices and the terminal portions of the ureters likewise, and the uterus descended to the greatest extent. The greater the descent, the more variation in the site of the urethra, which had a greater and greater tendency to become vertical. In introducing a cystoscope it had to be passed downward from above.

Cystograms of the anterior and lateral views showed the shadow of the bladder to be in the form of a pear with the broad side uppermost and completely exteriorized below the symphysis when the prolapse was exteriorized. If the prolapse was reduced, cystography often showed a very large bladder rounded like a small balloon. Sometimes, at the level of the lower pole of the bladder, irregularities could be seen resulting from folds of the bladder wall.

The cystoscope showed important changes in the base of the bladder. It was seldom easy and often very difficult to visualize the base of the bladder. If the prolapse was protruding it was usually impossible to find the ureteral orifices. The ureters often resembled the mouth of a gland and it was only after injections of indigocarmine that blue dye could be seen coming from the invisible part of the base of the bladder. Upon reduction of the prolapse the ureteral orifices became plainly visible.

The ureters were generally elongated and completely exteriorized beyond the pelvis in roentgenograms made with ureteral sounds in place. Although it was often difficult to catheterize when the prolapse was reduced, the ureters were very easily entered at the moment when the prolapse was produced as the patient strained.

Uroselectan was employed in every case to evaluate the degree of ureteral and kidney pelvis dilatation and at the same time to study the renal function in the aged women. In contrast to most autopsy reports the authors found no case of ureteral constriction with dilatation above. Bilateral hydronephrosis was only present in 1 woman of 72 years with a total prolapse, while another patient had a slight hydronephrosis on the right side due to angulation of the lumbar ureter with renal ptosis.

In all 60 cases observed the renal function was normal.

These studies suggest certain operative dangers in the treatment of prolapse. There is danger of injury to the urethra at the time the anterior vaginal wall is opened, danger of injury to the bladder when the bladder is freed from the cervix, and, especially, there is danger of injury to the ureters when the lateral attachments of the bladder are freed.

CRAIG W. MUCKLE, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Death Following an Autotransfusion (Todesfall nach Refusion) E. E. MANUELIDIS. *Geburts & Frauenk.*, 94, 3, 43

The author reports the case of a death which followed an autotransfusion. The patient had suffered a massive intraperitoneal hemorrhage from the rupture of an ectopic pregnancy. The blood was recovered from the peritoneal cavity mixed with sodium citrate and Ringer's solution, filtered, and administered by venoclysis. The patient soon became jaundiced, anuric, and dyspneic. Stupor and death with anoxemia followed. The complete autopsy protocol revealed only a tubular blockage by acid hematin as the cause of death.

Only 3 other similar cases have been found in the literature, according to Manuelidis. He suggests that in some cases the blood leaving its normal intravascular habitat, may undergo degenerative changes which release hemoglobin. From a clinical viewpoint, there is no rapid way of determining which bloods have been so changed. It is implied that, although this accident is rare autotransfusion is not a procedure of choice.

WILLIAM C. BECK, M.D.

LABOR AND ITS COMPLICATIONS

Cesarean Section at the Boston City Hospital, from 1934 to 1944. DANIEL J. McSWENNEY and ARTHUR J. HARRIS. *J. England J. M.* 1948, 239, 54.

Hemorrhage and sepsis are the most common causes of mortality following cesarean section. Whole blood given early rapidly and copiously is the only way to combat hemorrhage. Too often, transfusions are given too late, too slowly and in too small amounts. Cesarean section must not be done in the presence of shock. Shock must first be treated as expeditiously as possible. One must be sure there is no chance for secondary hemorrhage either from uterine atony or from improper hemostasis before the abdomen is closed.

Cesarean section has a distinct place in the treatment of toxemia and does not add to the risk particularly if it is done under local or sodium pentothal anesthesia.

There is no limit to the number of cesarean sections that a patient may undergo provided sufficient attention is given to the uterine scar both before and at operation.

The danger in cesarean section after rupture of the membranes and prolonged labor is sepsis. Therefore every patient in whom cesarean section is probable when given a test of labor should receive sulfonamides and penicillin prophylactically after the first 12 hours. In the frankly infected cases the extraperitoneal operation should be done.

Cesarean section in women with heart disease offers no advantage over delivery through the pelvis and should not be done unless there is some other indication.

Anesthesia for cesarean section must be administered by a trained anesthetist, especially if spinal anesthesia is used.

With proper attention to these suggestions the mortality for cesarean section should be kept below 1 per cent.

CHARLES BABCOY M.D.

PURPERIUM AND ITS COMPLICATIONS

Secondary Effects of Penicillin During Pregnancy and the Puerperium (Efectos secundarios de la penicilina durante el embarazo y el puerperio) G. COLMEIRO-LAROT. *Rev. esp. obst.*, 94, 3, 44.

On administering various forms and quantities of penicillin to the pregnant patient for different causes, the following secondary effects were recorded.

1. Of 11 patients in the first trimester 4 experienced light pains (1 with a slight hemorrhage), 6 showed no disturbance and 1 aborted. Eight of these patients had gonorrhea, 2 had pyogenic infections and the patient who aborted was hectic.

2. Of 5 patients in the second half of gestation, 4 experienced no effects and 1 patient had slight pains.

3. Of 10 patients treated during delivery and the puerperium 4 had no untoward results, 3 experienced major hemorrhage in the lochia, 2 had a diminished milk secretion and 1 patient had metrorrhagia. These patients were treated for infections of the genital organs, puerperal parametritis, and mastitis.

From the study it is believed that penicillin therapy is capable of producing uterine contraction in some instances, and this possibility must be reckoned with to avoid abortion. Furthermore, it is stated that the lochia is increased and the secretion of milk is diminished by the administration of penicillin.

NEWBORN

Diaphragmatic Hernia as a Problem of the Obstetrician. Diaphragmatic Hernia in the Newborn (Ueber die Zwerchfellbrüche als Problem des Geburtshelfers. Ueber die Zwerchfellbrüche bei Neugeborenen) OLAVI KINNUNEN. *Ann. Chir. gyn. fenn.*, 94, 37, 93.

The author reviews the embryology, classification, clinical picture, diagnosis, and treatment of congenital diaphragmatic hernia. When there is a diaphragmatic defect which permits the abdominal contents to enter the thorax, the condition is known as a false diaphragmatic hernia when there is merely

Fig. 1 (Ginglinger) Fetography by amniography. a, Fetus, third month stomach and small intestine. b Fetus, fourth month lungs, small intestine, stomach. c, Fetus,

fourth to fifth month stomach, small intestine, lungs. d Fetus, fifth to sixth month cecum and colon (thorotrast and umbrathor)

a weak spot with sac formation a true diaphragmatic hernia is present. Among 1,363 newborn infants who were examined after death during the years from 1928 to 1947, 11 had false diaphragmatic hernias often with other anomalies. All of the infants were stillborn or died soon after delivery.

One should consider such a diagnosis in cyanosis of the newborn. Roentgenologic confirmation is necessary for the establishment of a definite diagnosis but with the heart clinically displaced to the right, tympanic percussion note and faint breath sounds over the left hemithorax, sucking in of the lower thorax and epigastrium with inspiration and hepatomegaly diaphragmatic hernia must be considered.

The author suggests that if the diagnosis can be made early and the general condition of the child permits operative correction may be feasible in some instances.

WARREN R. LANG, M.D.

MISCELLANEOUS

Radiodiagnosis in Gynecology and Obstetrics.

Radiodiagnosis in Obstetrics (Le radiodiagnostic en gynécologie et en obstétrique. Le radiodiagnostic en obstétrique.) A GINGLINGER. *Gyn. obs.*, Par 1948, 47: 481.

The author presents a comprehensive report of the use of roentgenography in normal and pathologic pregnancy.

Except in cases of excessive obesity the fetus can be recognized in the roentgenogram with certainty in the sixteenth week of pregnancy although, in favorable cases, roentgenologic diagnosis is possible as early as the twelfth week. Roentgenography following the injection of lipiodol in the uterine cavity gives a characteristic picture as early as the sixth week of pregnancy. Although the risk of abortion seems to be small hystero-graphy should be performed only in cases in which interruption is in-

dicated. The author believes that roentgenography during the first half of pregnancy is of little practical interest in view of the dependability of the biologic tests.

During the second half of pregnancy roentgenography has been used to determine the presentation, position, attitude, age, and sex of the fetus; however, because of individual variability, determination of the age according to the development of the ossification centers around the knee is not free of error. Another method of the determination of age is measurement of the fronto-occipital diameter. Some authors have attempted to determine the sex of the fetus by roentgenography of the fetal pelvis shortly before term.

Whereas all these methods are of little practical value, roentgenography is more helpful for the diagnosis of multiple pregnancy especially in cases of polyhydramnios although errors of diagnosis may occur even with the most modern equipment.

Furthermore it is believed that fetal malformations and monsters can be recognized in the roentgenogram as well as other defects such as hydrocephalus, anencephalus and spina bifida. Death of the fetus can be diagnosed by abnormal flexion, lordosis, gibbus of the vertebral column or abnormal position of the extremities caused by hypotony of the skeletal muscles. Another sign of death is the aureola around the skull due to separation of the skin and adipose tissue from the cranial bones.

The differential diagnosis of tumor and pregnancy or the coexistence of both can be seen in the roentgenogram as well as ectopic pregnancy in its later stages. In certain cases of hydatid mole hystero-graphy after the injection of lipiodol is an aid in establishing the diagnosis.

The injection of opaque substances in the amniotic sac is without danger and permits visualization of the placenta and the soft parts of the fetus, es-

pecially the lungs and the gastrointestinal tract. The injected contrast substance is rapidly eliminated by the maternal kidneys.

The injection of opaque substances in the maternal circulation as a means of visualizing the placenta is still in the stage of animal experiment. In cases of low insertion of the placenta or suspected placenta previa, direct roentgenography of the uterus after filling the bladder either with air or with contrast substances will confirm the diagnosis. The author states that roentgenographic study has increased considerably our knowledge of the mechanism of birth, and of descensus and expulsion in the different presentations. The injection of barium sulfate in the umbilical vein immediately after delivery permitted study of the mechanism of separation of the placenta.

In conclusion the author states that great progress has been made in pelvimetry. Several methods of measuring the obstetrical diameters directly by roentgenography are described. Stereoscopic radiography has become very valuable in the diagnosis of dystocia of bony origin and enables the obstetrician to decide early between cesarean section and forceps delivery. WERNER M. SOLMITZ, M.D.

Comparative Physiology of Fertilization and Its Application to the Study of Sterility in Man
(Physiologie comparée de la fécondation et applications. Étude de la stérilité humaine) R. MORECARD
Gyn. et obs. Par. 948, 47 4

This article is a brief summary of our knowledge concerning the physiology of fertilization, especially the influence of chemical substances and hormones on maturation and fertilization.

The oocytes of plants and certain lower animals (echinoderms) produce a substance "fertilizin," which attracts specifically the spermatozoa. In echinoderms, frog and rabbit proliferation of the nonimpregnated ovum can be produced with testicle extract or certain chemical compounds.

Experiments in mammals (dog, rat, guinea pig and monkey) prove that the pituitary is necessary for normal spermatogenesis. In hypophysectomized animals the injection of pituitary gonadotropin hormone restores normal spermatogenesis, whereas chorionic gonadotropin fails to re-establish maturation. Vitamins E and A seem to play a role in spermatogenesis.

A certain concentration of spermatocytes in the semen is necessary to secure fertilization. In the

rabbit, at least 1,000,000 spermatozoa per cubic centimeter are required for constant fecundation; if the amount is less than 10,000 per cubic centimeter sterility occurs. In addition to normal spermatogenesis normal secretion of the prostate is necessary for fertilization. Among the different substances of prostatic secretion hyaluronidase seems particularly important. In the rabbit, the addition of hyaluronidase to diluted semen permits fecundation. In mammals fertilization occurs in the tube generally; the nature of the tropism causing the ascent of the spermatozoa is unknown.

Zondek showed in 1926 that it is possible to provoke follicle development in the prepubertal mouse by implantation of pituitary tissue. In female rats, hypophysectomy and the injection of gonadotropin produce analogous effects on maturation of the oocytes, as was described for the male. Rupture of the follicle is caused by the influence of gonadotropin, the contraction of the smooth muscle of the follicle wall under the possible influence of estrogen and a proteolytic ferment which permits the opening of the follicle.

Little is known about the penetration of the spermatozoon into the ovum in spite of many experiments in vivo after artificial ovulation, or in vitro. The author succeeded in cinematographing the entering of rabbit spermatozoa in the cluster of periovular cells in vitro but failed to observe the passage through the vitelline membrane.

Our knowledge of the physiology and pathology of fertilization in man is quite limited. Penetration of the sperm cell in the ovum has never been observed either in vivo or in vitro. Normal human semen contains 100,000 cells per cubic millimeter, 80 per cent of which are movable. Less than 60,000 cells per cubic millimeter are considered as presenting the condition of oligospermia. In pathologic cases the cells may be immovable, the time for the reduction of methylene blue may be prolonged, and the amount of hyaluronidase diminished.

Various conditions may prevent the ascent of the spermatozoa: changes of the vaginal pH which cause rapid loss of motion, increased viscosity of the cervical mucus, endometritis, and occlusion of the tubes.

In conclusion the author discusses very briefly the treatment of human sterility by artificial insemination, hormonal therapy and the administration of hyaluronidase.

WERNER M. SOLMITZ, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Renal Trauma. KENNETH M. LYNN, JR. *J. Urol.* Balt. 1948, 60: 371

During a 7 year period 23 patients with renal injury were admitted to the Charlotte Memorial Hospital Charlotte North Carolina. Operation was performed in 30 per cent of the cases and there were 3 deaths in the series.

Pain was the presenting symptom in 83 per cent of the cases and the severity of the pain was more or less correlated directly with the severity of the injury. All of the patients presented hematuria. About three fourths of the group were found to have tenderness in the flank. Rigidity on the affected side was found in 69 per cent of those having ruptures and in 12 per cent of those with contusions. One-third of the patients having renal rupture presented a palpable mass in the flank. Shock was present in 53 per cent of the patients with rupture and in 33 per cent of those with contusion.

Intravenous urography was performed on 15 patients. There was no function from the injured side in 2 cases, poor filling was observed in 7 and good filling in 6. Seven patients were operated on—nephrectomy being done in 4 cases, drainage in 2 and repair and drainage in 1 case.

The author states that the ruptured kidney which is not explored is subject to a number of sequelae, such as secondary hemorrhage, urinary extravasation, infection, hydronephrosis, stone formation and calcified cysts of the kidney. He believes that all cases of renal rupture as established by flat film excretory urography or retrograde pyelography should be subjected to exploration and emphasizes that this should be done early.

JOSEPH E. MAURER, M.D.

Immediate and Remote Descending Pyelography in Renal Contusion (La pìelografia discendente nel decorso immediato e negli esiti tardivi delle contusioni renali) GIORGIO DI MAIO. *Arch. ital. urol.* 1948, 22: 301

Observations on 16 cases of contusion of the kidneys proved to the author the diagnostic value of descending pyelography. Only in rare cases was it necessary to resort to ascending pyelography.

The employment of the method as soon as possible after the injury offers suggestions as to the choice of surgical procedure and the treatment of complications. In the great majority of cases the early employment of descending pyelography avoids the necessity of using chromocystoscopy or cystoscopy with catheterization of the ureters. A repetition of the method at certain intervals offers the opportunity of studying the anatomic and functional evolution of the ureteropyelorenal lesion.

The early employment of the method is not connected with any danger. It discloses the existence

if any of malformations or other pre-existing lesions such as lithiasis or hydronephrosis.

The limited number of observations does not allow any definite conclusions as to the effect of contusion of the kidney on the rapidity of appearance of the contrast medium, intensity and duration of the secretion. In many instances the contrast medium appeared within 3 to 5 minutes after the intravenous injection in the presence of a grave renal contusion. In cases of medium gravity the elimination of the dye was abnormally prolonged.

Renal ptosis, periureteropyelonephritis, pyelocaliasis and other conditions may be disclosed by pyelography at certain intervals after the injury and thus may contribute to the employment of conservative surgical measures.

In many instances the roentgenologic exploration obviates the necessity of a surgical exploration.

JOSEPH K. NARAT, M.D.

Pyelitis Glandularis. GEORGE L. TORASSA, JR. *J. Urol.* Balt. 1948 60: 393.

The fourth case of pyelitis glandularis is reported. It was discovered in a 46 year old negro who underwent nephrectomy for a nonfunctioning kidney which contained a staghorn calculus. Histologic study revealed the presence of mucous glands in the renal pelvis, similar to those in the colon. Goblet cells actively secreting mucin were present. Lymphoid follicles were numerous.

In all 3 previously reported cases calculi were present. The question is raised as to whether this condition is a metaplasia or whether pre-existing fetal cell rests have been stirred to activity. Metaplasia can be seen in the same microscopic section in some cases of cystitis glandularis showing the change from transitional to columnar and then to true glandular epithelium. Squamous anaplasia may also be present. Many workers believe that chronic irritation is the cause of the metaplasia.

The cell rest theory also has appreciable evidence in its favor for the ureteric bud arises from the cloaca. This common origin of the epithelium of the urinary tract and the bowel makes very real the possibility of a dormant fetal rest being stirred into activity by chronic irritation.

The author considers the danger of this glandular lesion undergoing malignant degeneration whether it be in the kidney, ureter or bladder.

JOSEPH E. MAURER, M.D.

Renal Decapsulation in Mercury Nephrosis. C. W. VERMEULEN and C. R. SWEAD. *J. Urol.*, Balt. 1948 60: 216

The present study was made in order to determine the value of renal decapsulation in anuria and uremia due to experimentally induced mercurial poisoning.

Female dogs were used in the study. After an initial determination of the function of each a solution

of mercuric chloride was injected intravenously in doses varying from 1.8 to 4.4 mgm per kilogram of body weight for 1 or 2 days. One or two days later the right kidney of the animal was decapsulated under ether anesthesia. The capsule was split along the convexity of the kidney and the capsular flaps were allowed to retract. The function of each kidney was studied daily until either death or recovery of the animal took place.

The authors describe the surgical technique they use to collect the urine and estimate the function of each kidney.

A total of 35 dogs were poisoned with mercury. Fifteen animals showed significant changes in renal function and they survived both poisoning and decapsulation for a sufficient length of time to draw conclusions as to the effect of unilateral renal decapsulation. In none of the fifteen animals was there any evidence that the decapsulated kidney functioned better than its control mate.

Following mercury poisoning, the excretion of phenolsulfonphthalein by each kidney in every dog was almost identical day by day even though one of the kidneys had been decapsulated.

The observations made indicated that in a dog (at least if renal function became impaired to the extent that the excretion of the phenolsulfonphthalein had been decreased and the blood urea nitrogen became elevated) the ordinary course of events was death due to uremia.

In no instance did a comparison of the renal function of a poisoned dog suggest that the decapsulated kidney was able to excrete urine of better quality or quantity than the undecapsulated control kidney.

The authors suggested that there was nothing to indicate that the human kidney behaves differently from that of the dog in this respect.

They concluded that in their opinion this experiment did not lend support for the clinical use of decapsulation in uremia due to mercury poisoning.

CONRAD A. KUBICKY M.D.

Wounds of the Ureter Caused by Firearms (*Les blessures de l'uretère par armes à feu*). L. KOJIC and S. PERKOVIC. *J Urol Med.* Par 1944, 54, 8.

Trauma to the ureter is rare because of its small size, elasticity and great mobility. Subcutaneous rupture of the ureter is encountered from time to time in civil practice. Wounds made by sharp instruments are also exceptional and are seldom observed in time of peace. Wounds by bayonet have given way to wounds caused by firearms. Wounds of the ureter are uncommon in times of peace, and very few cases have been found in the literature between the interval of the two wars.

The author was not able to observe a sufficient number of cases following the war to have a great deal of personal experience with this type of injury. During the war of 1914-1918, Decoulx collected 15 cases of wounds of the ureter. Leguen cited 5 cases of Marion, 2 cases of Cathelin and 1 case of Rochet and the author adds 3 of his personal cases.

Walker found 2 cases of isolated wounds of ureter in the American Army and 2 cases in British Army during the war of 1914-1918. Feinstein and Epstein found 4 cases of urinary fistula in the Russian Army resulting from wounds of ureter complicated by intraperitoneal wounds which rapidly resulted in death, reported as having occurred in the German Army during the 1914-1918 war. Kuemmel, Fritsch, Rehn, Koerte, Stueck and Gundelfinger, Kolb and Laewen each observed a patient with a ureteral wound. Recently Gross saw a biliary and ureteral fistula following a gunshot wound. Kimbrough described 3 cases in the American literature, Prather 3 and Lewis 1 case of wounds of the ureter caused by firearms, during the past war.

The ureter is a very small organ and is rarely wounded. Its great mobility permits it to escape the projectile of a certain velocity. Wounds of the abdominal organs from firearms are frequent enough so that wounds of the ureter are bound to be more frequent than published reports would indicate. In this regard wounds of the ureter are like wounds of the kidney during war.

In the front line surgical ambulances, wounds of the kidney are more frequently found than they are found in the hospitals in the rear. Wounds of the kidney as well as of the intraperitoneal organs are very dangerous. The wounded die on the battlefield or in the front line ambulances.

On the contrary isolated wounds of the kidney or those complicated by less serious wounds are seen in the hospitals to the rear. A large number of cases of wounds of the ureter are accompanied by wounds of the abdominal aorta and the inferior vena cava, and result in immediate death.

The author groups the wounds of the ureter caused by firearms during the time of war as follows:

1. Wounds of the ureter complicated by gunshot wounds of the large vessels, abdominal aorta, inferior vena cava, intraperitoneal organs (liver, spleen) or intrathoracic organs. The complications of these wounds result in immediate death on the battlefield.

2. Wounds of the ureter associated with wounds of the hollow intraperitoneal organs or of the peritoneum which mask the wound of the ureter. These ureteral wounds are diagnosed at emergency operation because of the intraperitoneal aspect of the wound. Sometimes the operation reveals the wound of the ureter and at other times the wound of the ureter escapes notice. It is only when a urinary fistula develops that the wound is discovered.

3. The solitary wound of the ureter is rare and most interesting to the urologist. This injury is seen 1 or 2 days after the accident or later when a urinary fistula develops.

The author believes that the experience of any urologist is very limited with this type of case. Therefore accumulated cases should be studied in order to determine the best operative procedure.

The circumstances surrounding the trauma, the pathology of the ureter and the operative possibilities

ties are very different if the injury is due to an operative involvement of the ureter or if the injury is acquired on the field of battle. On the one side we find the operating room the aseptic wound the early diagnosis in the case of dissection of the ureter during the course of operation, and on the other we have the field of battle, the infected wound, and complication of the pelvic organs. Late diagnosis suggests the essential difference between the two types of ureteral wounds.

The author concluded that wounds of the ureter are rare in time of war as well as in time of peace. Very often they are masked by wounds of neighboring organs or by the pelvic wound. They are discovered at a later date when a urinary fistula develops in the lumbar region.

The author reported 3 cases of injury to the ureter.

In the first case a man of 30 years of age was wounded on April 15, 1945 by a machine gun bullet in the left side of the perineal region. He developed a urinary fistula with pain in the flank and after noon fever. A left nephrectomy was performed on September 27, 1945.

The second case was that of a patient 19 years of age who was wounded by mortar fire on December 12, 1944. The wound involved the right lumbar region. The patient developed pus in the urine and a small lumbar fistula. A retrograde pyelography showed the projectile at the tip of the ureteral catheter with a functionless right kidney. On September 15, 1945 a right nephrectomy was done.

The third case was that of a 19 year old man wounded September 28, 1944 by a machine gun bullet which entered the right buttock. Cystoscopic examination showed stenosis 4 cm. above the bladder on the right side and a functionless right kidney. On September 29, 1945 a right nephrectomy was done.

The author included diagnostic pyelograms of the cases presented and discussed each case at length.

In discussing the treatment, he observed that it was difficult to apply conservative treatment in this type of injury because it was almost impossible to make an early and exact diagnosis. The late alteration of the wall of the ureter and the periureteral tissues and also the suppuration of the renal parenchyma do not permit hope for a good result from conservative treatment. He outlined the following methods of treatment:

1. Indwelling ureteral catheter
2. Suture of the incomplete ureteral tear
3. Suture of the wall of the complete tear in the ureter
4. Implantation of the superior end of the ureter into the bladder
5. Débridement—simple or extensive without disturbing the ureter
6. The radical operation, nephrectomy

The indwelling catheter may help to close the ureteral fistula. Desnos and Le Fur have reported a case in which this type of treatment was used but they did not make a follow up examination.

Suture of the incompletely severed ureter can rarely be done. Late suture is impossible and it may be better to use an indwelling ureteral catheter. This will permit the urinary fistula to close and also maintain the caliber of the ureter.

Suture of the completely severed ureter has been recommended by some authors but again without much success. Late diagnosis and alteration in the wall of the ureter and the periureteral tissues are the principal factors that contraindicate this type of treatment.

Some authors report successful suture of the ureter and give as proof the closure of the urinary fistula but this closure is at the same time associated with atrophy of the kidney. The proof of the success of suture of the ureter is not complete without ureteral catheterization, pyelography and evidence of good elimination of the urine from that side.

The reimplantation of the torn ureter in the bladder is an excellent procedure but the diagnosis must be made very early. Later the alteration of the structure does not always permit sufficient mobilization of the ureter for this type of operation. Lewis on the contrary implanted the superior end of the ureter into the bladder 6 months following injury and obtained proof by intravenous urography of good kidney function and recession of the hydronephrosis on the wounded side.

Nephrectomy is the treatment applied most frequently. It is done at the time as an emergency procedure. Later it may be done because of alterations in the kidney as well as in the ureter. Often there is no chance to save the organ because nephrectomy is done as an emergency procedure in a gravely injured patient. Later the operation is again rendered difficult and dangerous because perinephritis and periureteritis compress and surround the organs.

The complete débridement of the wound is necessary the first day or two after the wound has been made. Later it is of value to do this procedure in the treatment of urinary phlegmon.

In résumé the author stated that conservative treatment of the wounded ureter can rarely be applied. There is little chance for anatomical and functional conservation of the organ. Nephrectomy is often the only surgical procedure for emergency treatment as well as delayed treatment of the ureteral injury from firearms. CONRAD A. KUEHN, M.D.

BLADDER, URETHRA AND PENIS

Operation for Excessive Bladder Hypertrophy. E. C. CRABTREE and S. RICHARD McFILLER. *J. Urol.* Balt. 1945 60 593.

The authors consider the persistence of bladder atony with retention of large amounts of residual urine after adequate prostatectomy. Such poor clinical results are puzzling and further excisions of tissue in the posterior urethra or at the bladder neck are often futile.

In the absence of neurogenic vesical disturbance such failures it is contended are due not to con-

timed obstruction, but rather to a changed bladder muscle. Loss of detrusor tonus is due to marked proliferation of fibrous tissue at the expense of the smooth muscle. Two major histological changes are found (1) an increase in the pre-existing fibrous tissue which normally surrounds the muscle bundles, and (2) new areas of connective tissue which replace degenerating muscle either wholly or in part. The cause of such scarring is not clear.

In nonsurgical rehabilitation of such bladders, prolonged catheter drainage is suggested in less severe cases. The administration of large doses of testosterone enhancing the tonus of the bladder muscle may shorten the drainage period. As a surgical measure an operation excising two-thirds of the mobile part of the bladder is described and it is hoped that the islands of smooth muscle may regenerate in the remarkable way that bladder musculature does. The small remaining bladder is closed around a cystotomy tube and the obstructive factor is dealt with appropriately. The viscus tends to regenerate to normal size and empty fairly satisfactorily.

Several brief abstracts of cases are cited in support of the points brought out.

ALLAN K. SWERSE, M.D.

The Importance of Information Furnished by Pre-operative Urethrography and the Results of Urethrotomy on the Immediate Repair of the Urethra, in the Course of Diffuse Perineal Phlegmon (Importance des renseignements fournis par l'urographie pré-opératoire et résultats de l'urétroromie et de la réfection immédiate de l'urètre cours des phlegmons diffus du périnée) L. SARA
DEUT. MON. Acad. Chir. Pa. 945, 74-5

The frequency of diffuse or circumscribed perineal phlegmon is high in Algeria. It is no wonder "the author stated that urethral pathology is given so much attention in our country. He regarded the so-called "classic treatment as insufficient, incomplete routine and old fashioned.

The usual treatment for diffuse perineal phlegmon was described as follows:

After a brief history is taken to determine if the patient has stricture or not or if he has had a urethritis or stricture, he is placed on the operating table. A long incision is made from the root of the penis into the scrotum. It bisects the scrotum and thus opens the perineum. The finger explores all of the various tracts and tissue planes. If the tissue is copper colored, gaseous, or edematous, and the process extends to the abdomen, suprapubic incisions are also made.

Following surgery treatment with local anti-infectious agents, antisyphilitic serum, sulfonamides, and penicillin is instituted.

The scrotoperineal incisions are dressed. Local and general intense antibiotic treatment is indicated.

After the operation the patient often voids through the perineum and he is continually wet with urine. The tissues heal very slowly with numerous fistulas, and it usually takes many weeks for com-

plete healing. The acute phase then subsides, but a chronic periurethritis with stricture formation still exists.

The author makes a preoperative urethrogram, contrary to the present accepted procedure in all cases of perineal phlegmon diffuse or localized, gangrenous or not. He stated that urethrography from a practical viewpoint shows:

1. The site and extent of the stricture.

2. The extent of the infiltration, whether it is a simple periurethral infiltration or a large one extensively involving the perineum.

3. The site of the periurethritis (and thus the site of the lesion can be demonstrated by this method). This provides an important sign for the operator, for it shows him whether the lesion is in the angle of the penis or in the bulb.

These observations are important for one can see the causal lesion and determine its extent. Through the information thus gained in the course of surgery it can be seen that the usual simple operative opening in the perineum may result in a fatality because it is not adequate for the amount of drainage that is necessary.

From a speculative viewpoint, the preoperative urethrography in the course of perineal phlegmon tends to prove Vollemier's contention that there is an infiltration of urine into the perineum and pelvis which is associated with a diffuse perineal phlegmon. This is demonstrated by the diffusion of the contrast media during a perineal phlegmon. The diffuse invasion of the perineum by urine follows the efforts of the bladder working against an obstruction to force out urine drop by drop into the periurethral openings. The site of the pelvic cellulitis has for a long time been thought to be associated with the infiltration of urine following either a perineal phlegmon or a periurethritis.

In practice the urethrography permits one to see the signs of pelvic infiltration of urine visible at the same time as the perineal infiltration of urine. By this method, one is able to see how the pelvioperineal diffusion is produced. The pelvic floor and the perineal aponeurosis are not a partition. In the perineum and pelvis there are openings for vessels, nerves, and lymphatics and these openings provide a way for the infection to spread.

At surgical intervention one is surprised to find the bulb, the anobulbar raphe, the rectourethral space, the site of the edema, and lacerated gangrenous and sanious tissues all involved in this destructive process. Here again, urethrography in the course of perineal phlegmon gives important information concerning not only the site of the lesion but its possible diffusion as well. It suggests the operative procedure.

The author first makes a urethrogram before any surgical intervention is done and then continues as follows:

1. In the case of a diffuse perineal phlegmon confined to the perineum a cystotomy with retrograde catheterization of the urethra is primarily done. An

Fig. 1 (Sabadini) Preoperative urethrograms. Urethral opening: massive perineal diffusion of contrast media.

Fig. 2 (Sabadini) Urethrogram showing the healed urethra.

incision is made from the penoscrotal angle to the anobulbar raphe with the electric bistoury. The scrotum is separated into two halves. The infected gangrenous, blackish tissue is removed with the electric knife. The urethra is splinted with a catheter. If it is not possible to catheterize the urethra with one catheter it may be necessary to use two catheters: one catheter placed by the retrograde method through the cystotomy incision and the other through the urethra by means of an incision over the strictured area between the two catheters. In this way the patency of the urethra can be established. The postoperative treatment consists of the administration of antigangrenous serum and large doses of penicillin for several days after the temperature has subsided and there is a general amelioration in the patient's symptoms. Locally dressings with antigangrenous serum immediate injection of penicillin through the drain and later on Dakin's solution provide the local treatment. After the patient has recovered completely, his care is the same as that of any other patient having a urethrotomy.

2 In diffuse perineal phlegmon spreading to the hypogastrium and the abdomen the technique differs as to the establishment of the cystotomy. The risk of dissemination of the hypogastric infection into the prevesical tissue must be considered. The perineal intervention is then conducted as indicated with more incisions and counter incisions for adequate abdominal drainage. To avoid the constant passage of urine from the urethral opening a Malecot or a de Pezzer catheter is placed in the bladder. In

5 or 6 days, or in a week, it is possible to traverse the abdominal wall without risk of disseminating the prevesical infection. It is advisable then to do a cystotomy to divert the urinary stream and replace the catheter by a rubber splint so that the urethra can reform around it. The author warns that the usual antibiotic medication should not be discontinued with this type of delayed cystotomy for the danger of disseminating the infection does not pass for 3 or 4 days.

3 In the diffuse perineal phlegmon that is associated with pelvic phlegmon the preoperative urethrogram is of great advantage for the invasion of the pelvis is then always recognized. The operative intervention is conducted then with greater precision. The vesical perineal and urethral steps are the same as in all diffuse phlegmons. They permit the bulb and the anobulbar raphe to be opened with the escape of foul serous drainage. The rectoprostatic space is widely opened for this space is distended by the same edema that is present in the rest of the tissues and it represents a serious complication. The fingers explore all of the tissue planes. It is very important to pay particular attention to the side of the rectum and the base of the bladder. The exploration of the lateral sides of the prostate and of the entire membranous urethra should receive special attention. Wicks and drains are left in the retroprostatic cavity and the incision should remain open in its entirety. The postoperative care is the same as that for any perineal phlegmon. It is important to establish pelvic drainage with intermittent

irrigations of penicillin and, after 3 or 4 days to change the penicillin to Dakin's solution.

The author summarizes his experience with more than 30 cases of perineal phlegmon in which he did immediate urethrotomy and in which he made urethrogram prior to surgery. He reported 7 deaths. These deaths usually occurred from 3 to 5 days after surgery, and they usually occurred in those patients who had diffuse gangrene and a very poor general condition with marked toxicity.

In the patients that survived the general condition improved rapidly with local excision of the gangrenous tissue and the large operative incisions healed rapidly. The urethra reform spontaneously over a rubber tube. Occasionally this process could be hastened by suturing of the newly formed tissue about the tube. Usually the healing of the perineum and urethra took place about the same time, from 45 to 60 days. The small fistula in the bulb persisted occasionally. If the fistula persists for a long time the caliber of the urethra should be increased by replacing the tube by means of passage of a sound following the closure of the bladder and if the patient is then unable to void, a sound should be passed 2 or 3 times a day with great precautions to insure asepsis and gentleness. The catheter can be replaced during the night if the nocturnal micturitions are frequent. After healing these patients should return in 3 months for urethral calibration.

GENITAL ORGANS

Blastomycosis Involving the Prostate. *Mo K S*
Balt and LAR, VET K HALL, J. *Urol*
Balt 945, 60 or

The thought that blastomycosis might be a causal agent in disease of the prostate rarely presents itself. In 1911 Shepherd and Rhea reported prostatic involvement in a generalized systemic spread of the infection discovered at autopsy. Later several other authors described evidence of blastomycosis in the prostate found at autopsy. Prior to the present report 3 cases were cited in which this disease was discovered during life to involve the genital tract by the presence of characteristic fungus cells in the sediment of centrifuged urine, or in the material from the prostate and seminal vesicles. In both instances, urological complications were preceded by characteristic expectoration of mucopurulent blood tinged material and cutaneous lesions.

The authors present 2 cases of their own. In the first case the initial symptoms were prostatic and the patient was treated with massage. Following this stimulation of a prostatic focus, cutaneous lesions developed. Blastomycetes were identified in examinations of prostatic secretion of urine and in the dense inflammatory infiltrate of tissue blocks from verrucous lip lesions. In the second case a prostatectomy was done for urinary complaints. Sections of the gland were reported to contain numerous focal abscesses. The patient, who presented a

serious cardiac condition had a downhill course. At autopsy histological studies showed blastomycosis in several organs. A review of the previously examined sections of the prostate revealed that the focal abscesses contained zygomycetes dermatitidis, the cause of blastomycosis. The authors stress the importance of examining sections containing abscesses or tuberculous formation with higher magnifications in order to discover or rule out infecting organisms, especially fungi.

It is conceivable that prostatic blastomycosis, in the absence of cutaneous lesions or characteristic cough with blood tinged expectoration may go unrecognized.

ALLEN K. SWENET, MD.

Considerations on the Present State of Prostatic Surgery (Conferenza sullo stato attuale della chirurgia prostatica). *VITTORIO CIULLO, Polidoro*
Sexa prat 194 55 1048.

Seven hundred patients with prostatic conditions were received at the Ospitali Civili di Brescia, Italy, in the period from August 1, 1946 to May 31, 1948. Of these, 3 refused operation and 1 was adjudged inoperable; the remaining 70 were operated upon. The method of Freyer was used in 4. These were from 55 to 84 years of age. Preoperative azotemia was 0.60 per thousand and the largest adenoma weighed 200 gm. Epididymitis occurred in 2 cases, and the average time of incapacity was 40 days. All of the results were good. If a operation was utilized in 3 cases. The patients were from 65 to 71 years of age with preoperative azotemia of 0.60 per thousand. The adenomas weighed 10, 15, and 17 gm. respectively. There was 1 case of epididymitis and the period of incapacity averaged 18 days. The results were excellent.

The Wildbolz perineal prostatectomy was employed in 20 patients. These patients ranged from 71 to 83 years of age with azotemia of 0.85 per thousand. The largest amount of tissue removed weighed 80 gm. There was one rectoperineal fistula which developed on the ninth day after the operation and closed spontaneously on the forty first. The average incapacity was 20 days. Nineteen of these patients were cured entirely and 1 was left with urinary incontinence. Millin's retropubic prostatectomy was chosen in 16 of the patients. These ranged from 55 to 70 years of age with azotemia of 0.80 per thousand. The heaviest adenomas removed weighed 105 gm. In 6 cases urine continued to escape from the suprapubic region and the catheter had to be reintroduced for from 4 to 6 days. In 1 case turbid urine persisted for 4 months after the operation. The average period of incapacity was 21 days. All of the patients were cured. Finally the transurethral resection was done in 13 patients. These ranged in age from 47 to 86 years. The average azotemia was 0.93 per thousand. The largest amount of tissue removed by this method weighed 48 gm. There were no complications, and the average incapacity was 15 days. All of these patients left the service urinating easily with a residual urine of from

0 to 20 gm. There was not a single death in the entire group.

As might be expected the Freyer method was chosen for the largest prostate glands and those most difficult to manage the aseptic method of Hey and the retropubic method of Millin being reserved for those patients with smaller more easily enucleable tumors and in the absence of infection. Wildbolz's method was reserved for the smaller adenomas and for the older patients representing a poorer risk and for those patients in the younger group in whom enucleation by this route seemed practicable and who did not object to the greater threat of permanent sexual impotence.

The author believes that the generally good results attained in these cases are due to the fitting of the various procedures to the pathological conditions encountered and that the constant adherence to one method would result in the necessity for a greater selectivity (in this group operation was done in 98.6 per cent of all cases) in the choice of cases for operation or the results would not be so good.

JOHN W. BRUNSWAN, M.D.

Undescended Testes. EDWARD W. BRACE, *J. Urol.*
Balt. 1948, 60: 623.

The author surveys the subject of undescended testes comprehensively and stresses the importance of early recognition of the problems involved and of the application of intelligent hormonal and surgical measures as indicated.

Differentiation is made between the larger group of undescended testes in which the retention is caused by anatomic or mechanical obstruction and the relatively small group in which descent arrest along the normal route is due to hormonal disturbance. To the end of obtaining healthy spermatogenesis it is necessary to have the testis reposing in the bottom of the sac prior to the onset of puberty. After that stage is reached the retained gonad undergoes atrophic changes.

Hormonal therapy in the form of chorionic gonadotropin at the age of 7 or 8 years is advocated. Henderson is quoted as recommending a dosage of 500 international units three times weekly for 6 weeks then 1,000 international units twice weekly for 2 weeks if descent is manifest. If no progress is noted the hormone must be stopped because of danger of an irreversible precocity syndrome and surgery should be considered. The author discusses developmental history of testicular descent, including the role of the gubernaculum as a continuous cord connecting the lower pole of the testicle to the bottom of the scrotum. This structure tunnels through the abdominal wall and fashions the inguinal canal in advance of the gonadal descent. The testicle is pulled down "like a log upon a sledge" into the scrotum.

Anatomic factors associated with testicle retention include spermatic cord difficulties which vary with position of the testis the greatest problem with elongation being experienced when the organ is

lodged in the internal ring. No single cord component was at fault in this series of 46 cases since diffuse bands and adhesions usually matted the various structures together. As a whole the cord was always adherent to the peritoneum and had to be freed from it on the posterior and lateral walls of the abdominal cavity. The author feels it permissible to cut the vas if necessary, to gain length. The spermatic artery however should not be cut for that purpose because testicular atrophy frequently follows. Some degree of hernia or potential hernia existed in almost every case. In the repair of simple indirect hernia to avoid shortening of the cord the Ferguson technique was used, which brought the cord beneath all muscle layers to emerge near the external ring. Coexistence of direct hernia worsened matters because of the necessity of reinforcement of the posterior canal. In these cases the Wyllys Andrews technique of overlapping the external oblique behind the cord was employed.

Orchiopexy was performed 32 times with the use of various standard methods. Orchiectomy was done 17 times always in the presence of a sound contralateral organ. In these cases it was not possible to carry out an adequate orchiopexy and it was believed that removal of the testicle obviated the greater danger of malignancy in maldescent. In unilateral involvement if the testicle showed gross atrophic changes after the age of 18 it was removed. In bilateral involvement, every effort was made to preserve at least one gonad.

ALLAN K. SWERDLE, M.D.

Testicular Atrophy Accompanying Liver Cirrhosis
(Atrofia testicular de la cirrosis hepática) M
México. *Dis. Méd.* 8: 119, 1948, 20: 2006.

The observation has repeatedly been made that patients with cirrhosis of the liver develop an atrophy of the seminiferous tubules with alterations of the interstitial cells. Apparently some relations exist between the hepatosplenic apparatus and the endocrine glands. According to another theory the process of fibrosis may involve in addition to the liver also other organs. Such a condition is called "sclerogenic diathesis." The fibrous alterations may be found in the pancreas, genital organs, the thyroid and adrenal glands. Other theories have been advanced to explain the simultaneous occurrence of cirrhosis of the liver and atrophy of the testes, e.g., hypofunction of the testes caused by a constitutional dysfunction, an untoward effect of the liver on the endocrine glands functionally connected with the testes, and an effect of the diseased liver on the areas of the central nervous system regulating the sex life.

The concomitant occurrence of cirrhosis of the liver and testicular atrophy is not a pure coincidence. Zondek maintains that inactivation of sexual hormones by the liver is caused by the enzyme estrinase. This enzyme is able to destroy the biologic activity of certain estrogens in vitro. The latter may inhibit the testicular function by impairing the gonadotropic effect of the anterior lobe of the hypophysis.

The testicular atrophy usually develops during the histologic activity of the hepatic lesion

JOSEPH K. NARAY, M.D.

Orchiopexy. LEONARD PAUL WERNER. *J Urol* Balt., 1948, 60: 631

A critique on orchiopexy is presented which emphasizes the regional anatomical features and the advantageous aspects of accepted surgical procedures and recent modifications.

Reference is made to McGregor's principle of a "third inguinal ring" which plays an important part in the retention of the testis in the scrotum. This is a gateway to the scrotum and is stated to be situated to one side of the midline $\frac{1}{4}$ to 1 inch below the upper border of the pubis and external inguinal ring in the adult. Clinically when one invaginates the scrotum with the finger to feel the external ring, the finger passes through the third ring. Medially the boundary is the root of the penis and suspensory ligament, and laterally it is the ligament of Scarpia. The pursestring suture placed at the neck of the scrotum through the deep skin fascia and aponeurosis of the external oblique after placing of the testicle in the lower part, approximates or reconstructs the ring.

The formation of a loose scrotal sac particularly in those cases in which the sac is small requires more than blunt finger separation of elastic connective tissue fibers in the scrotum. Vermooten's recently published modification of the Bevan technique in preparation of the scrotal bed is approved. To obtain a bed that will permit the testis to remain it is suggested that the elastic fibers be divided by knife over a sponge stick, evaginating the most dependent portion of the scrotum into the wound. The normal elasticity of the scrotal tissue which tends to push the testis out, is thus counteracted. Anchorage of the testis by the tying of a gubernacular suture outside the scrotal wall is advocated. Traction with an elastic band may be used if desired but if there has been adequate preparation of the scrotal bed and freeing of the cord from adhesions with sufficient lengthening, and pursestring suture at the neck of the scrotum this should not be necessary.

The author prefers the Bevan technique with modifications utilizing applied anatomical factors.

ALLAN K. SWERDLE, M.D.

MISCELLANEOUS

Surgical Indications in Genitourinary Tract Infection. ROGERS DEANER. *J Pediatr* St. Louis, 1948, 33: 357

The present article deals with the author's concept of pediatric urologic problems based upon 25 years of experience in the management of urological problems in children observed in the St. Louis Children's hospital. The prevention or elimination of infection is a frequent concern to both the pediatrician and the urologist in a great many cases that present urological problems.

Urinary tract infections in infants and children that require urological investigation and surgery constitute about one-tenth of those that are encountered. The remaining 90 per cent, predominantly pyelitis or pyelonephritis, respond to chemotherapy sufficiently well to recover unless repeated recurrences take place. Malnutrition and a history of longstanding or repeated urinary infections are the rule in those cases that do not respond to chemotherapy.

The investigation of a child suspected of having a surgical infection in the urinary tract begins with a careful microscopic examination of the urine. The microscopic and cultural methods of urinary examination are of considerable importance in the management of a child with urinary tract infection.

The presence or absence of residual urine must be determined early in those cases. The initial determination of the amount of residual urine is an important examination, and great care must be taken so that it is accurately done.

Cystograms furnish a permanent record of the bladder contour and capacity. The amount of fluid introduced into the bladder for this purpose will vary with the size and the age of the child. The pictures of the bladder obtained by intravenous urograms may eliminate the need for cystograms in some cases because the former frequently outline diverticula, distortions of the bladder, or vesical foreign bodies. They do not, however, disclose regurgitation into the ureters in the same diagnostic way that a cystogram does. If no residual urine is present, the amount of opaque fluid comparable to that expelled in an average voiding can be used in performing the cystogram.

Intravenous urography is a useful agent for diagnostic purposes. Too much cannot be expected from intravenous urography in all cases. If the renal function is good and no obstruction or stagnation is present, the media may be excreted so rapidly that little information about the kidney architecture can be obtained. On other films the radio-opaque material will be of insufficient concentration to be of diagnostic importance. The most serious disadvantage of intravenous urography is that the films frequently fail to show minor defects in the kidney defects that are readily demonstrated by retrograde studies. Intravenous urography is of great value if cystoscopy and retrograde pyelograms cannot be made.

The improvement made in infant cystoscopes in recent years greatly facilitates the urological investigation of children. The superiority of cystoscopy and retrograde pyelography over intravenous urography lies in (1) actually seeing within the bladder and the urethra, (2) being able to catheterize the ureters and to obtain separate specimens of kidney urine, (3) securing differential functional tests from each kidney and (4) repeating retrograde pyelograms when necessary.

Routine enemas are not used by the author to eliminate intestinal gas. If fluoroscopy or a scout film before radiographic studies reveals too much gas

for satisfactory films the intravenous or retrograde pyelograms may better be postponed until another time. Intestinal gas does not interfere with retrograde pyelograms as a rule because of the greater density of the radio-opaque media.

In certain patients in whom these diagnostic procedures and the exercise of the best clinical judgment still leave the diagnosis in doubt it may be necessary to perform a surgical exploration of the mass in the flank, and to inspect and take a biopsy of the questionable lesion.

The fundamental principle in the management of all surgical complications of infections in the genitourinary tract is the prompt establishment of free drainage and the elimination of all stasis. Every effort must be made to preserve tissues and structures and to restore them to normal function. Plastic or restorative surgery plays an important role in the management of these cases.

Bladder neck and posterior urethral obstructions are divided into those in which the basic factor of the obstruction is neurogenic in origin and those in which a mechanical defect at the bladder neck causes the obstruction. Examples of the neurogenic group include children who have spina bifida occulta, men ingocele, cord tumors or injuries to the spine resulting in paralysis of the lower extremities with loss of vesical and anal control.

A conservative program of therapy is usually employed in these cases with particular emphasis upon the control of infection.

The types of obstruction which are most common in children are contracture of the vesical outlet, congenital valvular obstruction of the prostatic urethra, congenital hypertrophy of the verumontanum, ureterocele, prostatic lobes and neuromuscular disease.

In both types of obstruction, the same serious complications i.e. stasis and infection are present with renal insufficiency as the eventual outcome if these two factors are not successfully combated. The mechanical obstructions are more amenable to surgical correction and therefore offer a better prognosis if they are not too far advanced before operation.

Transurethral resection of bladder neck obstruction can be done by using miniature instruments. At the risk of having to repeat the operation one or more times, it is wise to proceed cautiously and with extreme consideration of these tiny structures rather than to try to remove too much tissue at one time.

Cystostomy does provide adequate drainage and may be advisable if diverticula of the bladder requiring removal are present. The scalpel removal of bladder neck obstruction via a cystostomy is notoriously inaccurate and difficult. Cystostomy has the added disadvantage of delaying the evaluation of vesical neck surgery until the bladder has again become a closed viscus. It has not been proved that an open and therefore a contracted bladder may not in fact contribute additional obstruction to the ureters by the pressure of the thickened bladder wall upon the intramural portion of the ureter.

Unexplained ureteral dilatations of a severe degree are sometimes identified as megaloureter or congenital hydroureter. These ureters are usually infected and as a rule the kidney and ureter are so badly damaged as to necessitate a nephroureterectomy if the condition is unilateral.

Dilatation of the ureter due to mechanical causes falls into two general classifications: (1) those due to extrinsic factors and (2) those due to intrinsic factors. Those due to extrinsic factors consist of aberrant vessels and fibrous or scar tissue bands and they are usually found at the ureteropelvic junction. This type of obstruction produces constriction of the ureter resulting in urinary obstruction and dilatation which in turn causes stasis, infection and renal damage.

Intrinsic obstruction to the ureter implies a disturbance within the ureteral wall or lumen itself such as stricture, constriction, stenosis, foreign body such as a stone or a ureteral tumor.

A wide variety of technical operations have been devised to relieve ureteral obstruction. The chief handicap to a successful operation is that many of these ureters have been stretched to almost paper thinness and this makes any form of plastic repair difficult with an unfavorable prognosis.

Regurgitation of urine upward in the ureter is an interesting phenomenon both because of its frequency and because of the uncertainty of its origin. A patulous orifice might suggest a purely mechanical origin for the regurgitation yet urinary regurgitation can occur with orifices that are not patulous and appear quite normal. Many dilated and patulous ureters regain their normal tone and lose their dilatation if a bladder neck obstruction is successfully relieved. There seems to be some relationship between the response of the bladder wall and the response of the dilated ureter to an operation on the bladder neck. Both the ureter and the bladder respond to the operation in about the same degree.

The ordinary anomalies of the kidney are single or polycystic renal disease, horseshoe and ectopic kidney. All of these conditions are associated with infection and pyuria is the presenting sign that leads to the discovery of the anomaly. The surgical intervention in these cases, either in the presence or absence of infection, will depend upon whether surgery will be helpful. Each case has to be handled individually.

Renal tuberculosis in children usually is accompanied by tuberculosis elsewhere. If a proved case of unilateral tuberculosis is encountered, nephrectomy should be seriously considered. It may be, however, that further experience with streptomycin in tuberculosis will warrant a nonsurgical approach to this type of case in the future.

Calculus disease in children is more often a medical or a metabolic problem than a surgical one. Both kidneys are usually involved and whether the kidney substance itself is riddled with calcium material or the pelvis and calyces are full of stones, surgery is likely to be impracticable and of no avail. If a frag-

ment of stone breaks away and lodges in the ureter surgical removal of the calculus may be necessary. Rather than risk further mutilation of the kidney by surgery, the control of infection and correction of the metabolic disorders as far as possible may be advisable before surgery is attempted.

Whenever the urologist is confronted with a choice of either sacrificing a kidney or perhaps a more difficult task of trying to repair it, he should remember that the genitourinary structures of a child exhibit amazing inherent reparative properties, and this may be the determining factor in choosing a more conservative treatment in the individual case. There must be favorable assurance that before the nephrectomy is done the remaining kidney will support life. On occasion a heminephrectomy or a calycectomy may be done to remove the diseased portion of the kidney with retention of the normal part.

An incision made downward through the strictured area and sutured across the course of the ureter at right angles to the incision has proved to be a popular plastic technique for the repair of ureteral strictures.

As a rule no definite plastic procedure can be planned until the kidney or ureter has been exposed and the exact nature of the obstruction determined. Two principles must be kept in mind to construct free drainage to the kidney that will permit no ac-

cumulation of urine and to provide adequate drainage for the parts during the convalescent period.

A nephrostomy may have to suffice on occasion when it is imperative to establish immediate drainage of an infected kidney with the minimum of surgical shock. A dilated ureter is a good site for drainage in hydroureter or hydronephrosis. The conventional T-tube is a very satisfactory drainage tube in this location.

Diversion of the urinary stream by means of ureterointestinal anastomosis or ureterocutaneous transplant with or without cystectomy is an established procedure in children as well as in adults.

The drugs most commonly used at the present time as urinary antiseptics are the various sulfonamide derivatives penicillin streptomycin, mandelic acid methenamine and the various alkalizing agents. The preoperative use of chemotherapy is advisable and should be continued during the postoperative period as long as fever or pyuria persists.

Too much benefit should not be expected of any antibacterial agent as long as a mechanical problem of stagnation or stasis exists. The most potent aid that can be given drug therapy is the restoration of a normal current of urine through the urinary passages.

The article is well illustrated with pyelograms of many interesting pediatric urological cases.

CONRAD A. KUBER, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS MUSCLES, TENDONS ETC.

Anatomoclinical Study of 2 Cases of Primary Tuberculous of Striated Muscles (Considerazioni anatomocliniche su due casi di tubercolosi primaria dei muscoli striati) RENZO CORREI and GIORGIO VENTURI *Arch Ital chir* 1948, 70 216.

As a rule, tuberculosis of the muscles is secondary to a specific process in other organs. A primary lesion of the muscles is very rare. Tubercle bacilli may reach a muscle either through the blood stream or by contiguity. Tuberculosis of hematogenous aspect may assume one of two forms (1) miliary in the form of grayish nodules which may show a tendency to confluence and caseinization or (2) circumscribed with casein formation in the center and a large fibrotic peripheral zone. Fungus or abscess formation with complete liquefaction of the center may result.

The involvement of a muscle by contiguity is observed more frequently and may follow pleurisy, osteoarticular lesions or lesions of the lymph nodes.

The authors apply the term primary tuberculosis to a lesion which is of hematogenous origin. He refers to reports in the literature of 92 cases of primary tuberculosis, and reports 2 cases of his own.

A cystic tumor was removed from the left pectoralis muscle in a woman 48 years of age. The Ziehl stain of the specimen failed to reveal tubercle bacilli but the presence of Langhans cells and other typical findings established the diagnosis.

There was no history and no evidence of a specific lesion in any other organ. The skin reaction after the operation was positive.

A man 22 years of age with a previous history of a right exudative pleurisy developed a swelling over the right latissimus dorsi muscle which was diagnosed as either a sebaceous cyst or a granuloma of unknown origin. Although no tubercle bacilli could be detected in the specimen the presence of giant cells and other typical findings established the diagnosis of tuberculosis.

The general condition of both patients was good.

The preoperative diagnosis of such lesions is very difficult unless changes in other organs can be detected. In the differential diagnosis, one should consider various neoplasms, tumefactions of parasitic origin and specific inflammations caused by syphilis, lepra, actinomycosis, sporotrichosis, anthrax.

Three types of tuberculosis of the muscles may be distinguished (1) nodular (2) sclerofungous and (3) abscess.

Early and radical surgery is indicated and should be followed by postoperative x-ray therapy. Medical dietetic, and hygienic measures should supplement local treatment. JOSEPH K. NARAY, M.D.

Cavernous Angioma of Striated Muscle (Sull'angioma cavernoso dei muscoli striati) PIERO FORCINI and ALESSANDRO FICAT *Gior Ital chir.*, 1948 4 347

The authors describe a case of angioma of the flexor muscles of the forearm and analyze the clinical characteristics and the histopathology of the classification. They believe that the case they describe must be considered as an angioblastoma according to the classification proposed by Costa. This tumor has no relationship to trauma, and the inflammatory processes must be considered as congenital on the basis of a disturbed mesenchymatous tissue proposed in a sense by Albrecht.

The authors give a detailed report of an adult male age 20 whose personal history was essentially negative. For a period of 5 years the patient had noticed a double tumefaction of the middle third of the right forearm. The tumor was about the size of a walnut and produced no incapacity of the arm. Some pain was produced by pronation of the forearm and flexion of the fingers. The mass was surgically removed without difficulty and healing was by primary intention. Sections of the tumor mass are shown in the article.

The authors have collected over 300 cases of angiomas from the literature and have presented a résumé of the subject. CARLO SCUDERI, M.D.

Calcifying Tendinitis of the Shoulder NEWTON C. MEAD, Q. *Bull Northwest Univ M School* 1948 22 270.

Calcifying tendinitis is the commonest cause of pain and disability of the shoulder. Although frequently called 'bursitis' the calcium occurs and remains in the substance of the tendon until it points and ruptures. The bursal floor becomes inflamed as a result of this but this bursitis does not resemble the process so commonly met with in other bursae of the body in which the bursa following overuse or direct injury becomes tender, painful and distended with fluid. A similar calcifying process occurs in tendons and ligaments elsewhere in the body as in Pellegrini Stieda's disease in which no bursa is present.

The etiology is uncertain. It is commonly stated that it is a degenerative condition resulting from trauma of the tendon. There is no reason to doubt this but it is interesting to note that only 12 of 180 patients studied gave a clear-cut history of a traumatic origin of the condition. No relation of the disease to the occupation of the patient could be found. Overhead workers such as painters and plasterers do not appear to be frequent sufferers. In the male the distribution between the right and left shoulders in this series is exactly even. Surprisingly in the female patients there is a marked

preference for the right shoulder over the left a ratio of 67 to 31. No explanation for this is apparent.

The best available information of the pathology of this condition is given by Codman. He found degenerative areas in many shoulder tendons which appeared to be due to traumatic rupture of a few of the internal fibers. He also found ovoid bodies similar to rice bodies occupying the defect in the tendon and believed them to be the precursors of the calcified mass. What occurs to cause the calcification and inflammation is not known but at times there is a definite relationship to additional trauma. The truly disabling severe symptoms do not occur until the calcified mass has expanded and is protruding under the acromial floor of the bursa. It thus produces a bursitis of a definite inflammatory nature. However the bursa rarely becomes distended with fluid. Codman pointed out that if the subdeltoid bursa is distended, it is very good evidence that there is a rupture of the musculotendinous bursal floor and a communication with the shoulder joint proper. The calcium itself is not chemically irritating, as is proved by the relative absence of pain in patients in whom the bursal sac is full of a calcified suspension. The excruciating pain is directly related to the tension within the calcified deposit while it is still imbedded in the tendon.

The author divides his cases into four types.

1. Acute calcifying tendinitis (63 cases). In this condition the onset is sudden and the slightest motion of the shoulder is agonizing. The patient is completely disabled. The acute symptoms last from 3 to 7 days without treatment. There is gradual recovery without disability in several weeks or months. Roentgenograms taken during the height of the symptoms will show a mass of imbedded calcium in the fibers of one of the tendons of the musculotendinous cuff which makes up the floor of the subacromial bursa. After the severe pain has subsided, calcium is seen in a much less dense form in the dependent portion of the bursa itself but the calcium in the tendon will not have changed greatly in appearance. Roentgenograms a month later will, in favorable cases show complete disappearance of the calcium from the area.

2. Chronic calcifying tendinitis with acute exacerbation (43 cases). If untreated, the acute attack will end spontaneously after a few days or weeks, but the calcium will not disappear from the tendon and the symptoms of chronic tendinitis persist.

3. Subacute calcifying tendinitis (17 cases). The onset is gradual and there is never the intensity of pain seen in the acute type. The condition does not subside spontaneously except after very long periods.

4. Chronic calcifying tendinitis (37 cases). The calcium seen in the roentgenogram has a hard dense appearance and may vary from a small speck to a very large mass. The shoulder will not rotate easily and abduction is limited usually with pain as the greater tuberosity passes beneath the acromion.

Surgical decompression, either by needling or open incision of the mass is a logical and very effective

method of treating patients with acute cases and an acute flare-up in chronic cases. It is not indicated in chronic cases as the deposit is not under tension. In these cases symptoms result from the tendinitis itself and the bursitis associated with it. The pain is at its worst when the degenerated tendon is under tension or when its insertion is brought into contact with the acromion as in abducting the arm. In the latter case the tip of the acromion may be removed. The technique of needling and surgical decompression is described in detail.

JOHN J. CRANLEY, JR., M.D.

Subcutaneous Rupture of the Extensor Pollicis Longus Tendon (*Rottura sottocutanea del tendine del lungo estensore del pollice*). *Libero Vercelli, Policlinico, sez. prat.* 1948, 55: 550.

The author reports a case of subcutaneous rupture of the extensor pollicis longus tendon that was diagnosed one month after an injury to the thumb with out any fracture or breaking of the skin.

The patient was operated upon and repair was accomplished by suture of the distal portion of the extensor pollicis longus tendon to the extensor pollicis brevis tendon. The result was excellent.

The author reviews the literature and proposes a classification based on the mechanism of the rupture.

The first case was reported in 1876 by Duplay. Eighty five cases were reported in the literature up until 1932.

CARLO SCUDERI, M.D.

Anatomical Studies on Lumbar Disc Degeneration. *STEIN FARRER, Acta orthop scand* 1948, 17: 14.

One hundred lumbar vertebrae together with the sacra were removed as soon as possible after death, and permitted the study of 500 intervertebral discs and 1,000 intervertebral joints. The sacrum was fixed in a vice and the specimens were flexed and extended without force, and so roentgenographed. After a short period of formalin fixation, the discs were cut horizontally and macrophotographed. The intervertebral joints were removed separately and decalcified. These investigations have not yet been concluded, and an effort will be made to study the relation between disc and joint changes.

Histological examination of disc material shows that regressive changes in the nucleus occur early. These are interpreted as signs of a normal age involution rather than pathologic degeneration. As the age increases, the amount of fluid in the nucleus decreases, fibrosis increases, and the borderline between the disc and the annulus becomes less distinct. This occurs without clinical signs or degenerative symptoms. When fissure formation is found in the annulus, degeneration has occurred.

Anatomical investigation of the degeneration shows variations according to the disc level in the lumbar spine. In the upper lumbar region the disc degeneration showed a concentric arrangement, and fissure formation was observed all around the disc. In the two lower discs the degeneration was situated mainly in the lower portion. A sagittal path ex

tended from the nucleus dorsally to the posterior longitudinal ligament, running out on both sides in the form of a T and often extending to a point slightly lateral to the intervertebral foramen. Schmorl, Junghans, Guentz and others have pointed out that in the thoracic region the anterior portion of the disc is affected owing to the greater anterior pressure after the disappearance of the nucleus. The author believes that the lumbar lordosis contributes to the specific type of lower lumbar disc degeneration.

Disc degeneration was found in the backs of 32 patients and disc prolapse was found in 11. In those with prolapsed disc, extensive degenerative changes also were present. It was found that in all cases in which a disc showed roentgenological instability without other roentgenographic indication of disc degeneration (reduction in the height of the disc, osteophytes, and sclerosis) fairly widespread fissure formation was nevertheless present in the annulus especially posteriorly.

Disc prolapse is the result of previous disc degeneration the trauma playing the part of the liberating factor. A negative roentgenogram does not preclude the existence of fairly advanced changes in the disc.

The author favors lumbosacral fusion early as soon as instability is diagnosed. His studies have shown that in cases in which extensive laminectomies have been performed previously lumbosacral fusion has given unsatisfactory results.

DANIEL H. LEVINTHAL, M.D.

Eighteen Observations of Bilateral White Tumors of the Knee (A propos de dix huit observations de tumeur blanche bilatérale du genou) P. INGELBLOOM, A. VERDUREUX and NICOL. *Lille chir.*, 1948, 15, 115

During a period of 28 years the authors have observed 69 unilateral and 18 bilateral tuberculous tumors of the knees. In other words, the bilateral lesions occurred in 2.53 per cent of the patients—7 males and 11 females—and the youngest patient was 2 years of age. Six patients were younger than 10 years the ages of 7 patients ranged from 10 to 21 years the ages of 3 ranged from 21 to 25 years 1 patient was 34 years, and 1 was 54 years of age.

In 7 cases other osteoarticular lesions were present, in 3 the pleura and the lungs were involved and in 2 specific visceral conditions were discovered.

As a rule, one side was affected to a higher degree than the other. Not infrequently the patient suffers osteoarthritis on one side and synovitis in the opposite knee and during treatment of the osteoarthritis a clinical recovery of the synovitis is effected and the patient resumes his activity but after awhile a recurrence of the synovitis takes place. The remission may last a few years in children but is usually shorter in adults.

Inasmuch as roentgenographic examination frequently fails to give sufficient information and the symptomatology of synovitis may be very scanty

other diagnostic methods are necessary. The use of various culture media and even inoculation may give negative results. Successive passages through a few guinea pigs may be necessary to reveal the presence of tubercle bacilli. Biopsy of the synovia is of great diagnostic value.

The establishment of the correct diagnosis is essential because positive findings suggest a resection. This is a grave decision because a bilateral ankylosis of the knees results from the operation.

The authors have discontinued treatment by synovectomy because it produced unsatisfactory results.

In spite of a bilateral ankylosis of the knees some times accompanied by an ankylosis of the hips the functional results may be more or less satisfactory. The authors were able to obtain 8 cures, while 1 patient succumbed to pulmonary complications.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Resection of the Lower Extremity of the Ulna (La résection de la extrémité inférieure du cubito) HEBERT CAGNOLI and JORGE GARCIA NOVALES. *An. chir. bras.*, 1948, 1, 69.

Although mutilating from the anatomic point of view from the functional viewpoint resection of the lower extremity of the ulna offers chances of restoration or preservation of the movements of pronation and supination.

The operation should be considered when one of the following conditions is present:

- 1 Recent fracture (a) fracture of the lower end of the radius with dislocation of the ulna, (b) fracture of the lower end of the ulna, irreducible by closed methods with lower radioulnar dislocation and (c) comminuted fracture of the lower ulnar epiphysis.

- 2 Old fracture and its sequelae (a) metaphysio-diaphyseal or diaphyseal fracture of the radius with dorsal or radial angulation causing a palmar or dorsal subluxation of the ulnar epiphysis, (b) fracture of the lower end of the radius with angulation, (c) fracture of the lower end of the radius with shortening of the bones responsible for a dislocation of the lower radioulnar articulation, (d) fracture of the lower extremity of the radius, well reduced from the anatomic point of view but distorting the lower radioulnar articulation and (e) sequelae of a fracture of the lower ulnar epiphysis.

- 3 Sequelae of a fracture of the lower extremity of the radius causing functional disturbances such as pain and limitation of supination.

- 4 Traumatic dislocation of lower end of ulna.
- 5 Tumors of the lower end of the radius or ulna.
- 6 Arthrosis or ankylosis of the lower radioulnar articulation.

- 7 Madelung's congenital deformity.
- 8 Sequelae of acute subacute, or chronic arthrosis of the radiocarpal articulation if arthrodesis is indicated.

p. Arthrosis of the radiocarpal articulation of traumatic origin, usually following the pseud arthrosis of the navicular bone If surgical arthrodesis is indicated

The authors illustrate the value of the method with reports of 21 cases.

The bone is resected with a Gigli saw through a longitudinal incision over the lower end of the ulna.

JOSEPH K. NARIT, M.D.

Osteotomy of the Vertebral Column; Smith Peter sen Operation (Osteotomie de la colonne). *Arch. de Neurologie. P. neurolog. argent.* 1948, 35, 536

The author describes an operation for the correction of the simian type of posture created by the various types of spondylitis especially the rheumatic form.

In a staged procedure the author removes the intravertebral fibrocartilaginous disc between the second and third lumbar vertebrae after forceful maneuvering of the vertebral column into an upright position as shown in Figure 1. The results obtained have been gratifying.

A lateral approach, and the use of an disc graft including both hip joints in a corset permits early ambulation with the assurance that there will be no recurrence of the flexion. It is believed that these steps have greatly simplified the operation for curvature of the spine.

STEPHEN A. ZIEGLER, M.D.

Fig. (Numerata)

A Procedure of Foot Disarticulation with Partial Conservation of the Calcaneus (Sur un procédé de disarticulation d pied avec conservation partielle du calcaneum). *L. Ricard. Lyon M.* 1948, 47, 299.

The author discusses the disadvantages of the different classical methods of foot amputation (Chopart, Symes, Pirogoff and others). He devised a modification of the Symes operation in which a part of the calcaneus is saved and mortised between the malleoli, with or without resection of the Achilles tendon. With this procedure the drawbacks of the Symes operation—undue shortening of the leg, and weight bearing by the leg bones—are avoided. At the same time it provides ample skin covering for the stump.

WERNER M. SCHWARTZ, M.D.

FRACTURES AND DISLOCATIONS

Treatment of Simultaneous Fractures of the Two Bones of the Forearm, Particularly in Children (Traitement des fractures simultanées des deux os de l'avant bras, en particulier chez l'enfant). *Mat. et Clin. Chir. Rev. orthop.*, P. 1948, 34, 243.

Fractures of the diaphyses of the radius and ulna in children are usually less serious than those in adult. However this fact is no excuse for any neglect because all of the complications are encountered at all ages and many poor results are not helped by growth and some even become worse.

In addition to the correction of deformities and the maintenance of good reduction it is necessary to avoid pseudarthrosis and exuberant callus in fractures of the forearm. The correction of deformities includes correction of length, which necessitates clinical and roentgen examination not only of the two bones but also of their articular extremities. Preservation of the pronator curve of the radius and of the width of the interosseous space and correction of displacement. The maintenance of the fragments in good position requires supervision by successive roentgen examinations because secondary displacements are particularly frequent in the forearm. Pseudarthrosis can be prevented by immobilization for a period of at least 6 weeks which must sometimes be increased especially after surgical intervention. To prevent the formation of excess callus and synostosis, all causes of osteoperiosteal irritation must be eliminated. Massage must therefore be rejected and long continued immobilization assured.

Greenstick fractures which have been neglected because of their supposed benignancy are sources of disappointment if they are not perfectly reduced with complete fracture of the cortex and immobilization for an average of 6 weeks.

Most fractures in children respond to proper orthopedic treatment. Irreducible and some intracapsular fractures require surgical treatment. Simple replacement of the fragments is often enough. Among the classical methods of fixation, the author prefers central pegging preferably with fresh bone and Ombredanne external synthesis with screws and

connecting plate. This requires only one operation and the apparatus adapt themselves well to the phenomena of growth. If only one bone is fixed it is best to choose the radius as its shortening is much more serious than that of the ulna if necessary the ulna is fixed after the radius.

The insertion of a stainless steel pin into the medullary canal instead of Kuntscher's nail tends to replace the old methods of synthesis in children. Its ease of introduction into the ulna makes this the operation of choice for this bone. The operation is somewhat more complex for the radius. The pins must respect the epiphyseal cartilages. It is logical to begin with the bone which is easiest to handle, (the ulna) the radius is then often reduced spontaneously if not, it is also fixed. Fluoroscopy should be available in the operating room to control the reduction. The method should not be regarded as a panacea that can be used without all the precautions required by bony synthesis. RICHARD KENZEL, M.D.

Dislocation and Fracture Dislocation of the Pelvis F. W. HOLDSWORTH, *J. Bone Surg.* 1948, 30-B 461

The author's article is based on a study of 50 cases of fracture of the pelvic ring. Two types of fracture are listed: (1) dislocation of the sacroiliac joint, and (2) fracture of the ilium or sacrum adjacent to the sacroiliac joint. In both types there is separation of the symphysis pubis or fracture of both pubic rami. In both there is outward displacement of one half of the pelvis.

Forty-two patients survived and were followed up (27 with dislocation of the sacroiliac joint and 15 with fracture of the ilium or sacrum near the joint).

Visceral complications and injury to the bladder and urethra were rare in this series: there being only 4 cases of injury to the bladder and urethra. Two patients had large extraperitoneal tears in the bladder and both died. Retroperitoneal hemorrhage was a more frequent complication and was the cause of death in 4 cases. Fractures of the pelvis were treated by suspending the patient in a canvas sling. Both lower extremities are placed in Bucks extension with slight flexion at the hips. Manipulation may be necessary if there is a rotation displacement. Fixation is maintained for 12 weeks.

The average period of follow-up is 5 years and no case is followed for less than 2 years. About one half of the patients with sacroiliac dislocation were able to return to reasonably heavy work and practically all of the patients with fracture were able to do so. The frequency of persistent sacroiliac pain after dislocation suggests that early sacroiliac fusions should be suspected.

RICHARD J. BENNETT JR., M.D.

Pathologic Dislocation of the Hip Joint. A. T. BRY 807 *J. Bone Surg.* 1948, 30-B 449.

The author reports 17 cases of pathologic dislocation of the hip—a short leg and a limp—observed at varying ages of childhood and adolescence. Fourteen of these patients have been traced and re-examined.

Among these 17 cases reconstruction of the Colonna type was performed in 1 case, subtrochanteric osteotomy was done in 4 cases, and arthrodesis of the hip in 11 cases. 1 patient was not treated surgically.

The patients were followed for a period of 10 years after operation. Subtrochanteric osteotomy was done in 4 cases with success in only 1 case. In the cases in which subtrochanteric osteotomy was performed as a secondary operation the results were excellent. In 1 case arthroplasty was attempted at the age of 8 years with failure. The best results were obtained with arthrodesis of the joint which gave a stable strong and painless hip. Among 11 patients so treated, good bone fusion was secured in 7. Union occurred in all 4 patients who were operated upon after the age of 12 years while only 3 of 7 patients operated on before the age of 9 years obtained satisfactory fusion.

The author believes that arthrodesis should be delayed in cases of this type until the age of 12 or 13 years. Only 1 patient in the present series complained of pain in the back after arthrodesis. Shortening is combated by bringing the trochanter down as nearly as possible to its normal level.

RICHARD J. BENNETT JR., M.D.

Ununited Fractures of the Neck of the Femur JAMES A. DICKSON, *J. Am. Med. Ass.* 1948, 137 1199

In spite of the increased number of united fractures which internal fixation has yielded from 35 to 50 per cent of intracapsular fractures of the femur are functionally unsuccessful.

The present article is devoted to a study of ununited fractures. From the findings in this study it seems possible to restore anatomic and physiologic function to the hip joint. Once nonunion is recognized, the earlier the operation is performed the better will be the results. An understanding of the basic principles of causation makes earlier recognition and rational repair possible.

The mechanical factors of the angle of the fracture and of circulation are most important. Fracture lines which tend towards the vertical not only inhibit union by shearing action, but facilitate aseptic necrosis by depriving the femoral head of contact with the medullary circulation.

The aim of treatment then must be to secure impaction at the fracture line and to re-establish circulation to stimulate osseous repair.

The numerous techniques involving one or the other of these principles are critically reviewed and failure of operation occurred in from 35 to 50 per cent of all the cases in this category. The author presents his technique of a controlled high osteotomy which changes the inclination of the fracture line from about 65 degrees to less than 30 degrees. A bone graft from the ilium is added to aid in revascularization and osteogenesis. The procedure has yielded solid union with equalization of leg length in 9 out of 10 patients operated upon.

Conservatism is urged in handling the dead femoral head since such heads may become re-

vascularized and functional if weight-bearing is prohibited while regeneration is taking place. Perhaps a more careful selection of the primary procedure in these fractures might reduce the incidence of non union, and surely the earliest possible surgery must be undertaken when nonunion is known to exist as waiting permits degenerative changes which militate against a favorable outcome.

FRANCIS E. BRIDGEMAN, M.D.

Trochanteric Fracture. MATTHEW CLEVELAND D M BOWORTH, and F R THOMPSON. *J Am Med Ass* 1945, 37, 80.

The concept that the trochanteric fracture is a simple one to handle and always will give a good result is erroneous and disregards the frequent sequelae of disability and discomfort which often plague patients with this condition for life. A study of 133 consecutive cases observed at St. Luke's Hospital, New York shows that the lesion is not simple and does not routinely come to a good result.

The average age of the patients is more than 75 years and 90 per cent of them are women. Commonly they have numerous physical mental or both types of changes in addition to the fracture so that they are not "good risks" for any care.

The injury initiating these fractures is usually slight, the result of stumbling or a slight fall but often dissolution of the bony structures prior to the injury is really the cause of fracture. The response to rapid and definitive treatment for relief of pain and spasm is good if procedures are carried out rapidly and the patient is well supported.

The choice of treatment depends on the ability and experience of the medical personnel as well as on the type of trochanteric fracture. However the various levels at which fracture occurs influence the treatment less than they do the end result and the length of time required to secure union. Modes of conservative treatment are reviewed and of them, Russell's balanced traction is recommended over any other than internal fixation when that can be competently carried out.

A survey of 133 consecutive cases with 94 per cent follow-up was conducted. A group of 38 patients treated by balanced traction was compared with a group of 95 patients treated by internal fixation. The numerous complications arising in spite of excellent hospital care of the "traction" patients led to the trial of internal fixation with a Jewett type of nail made of vitallium. With nails of assorted angles and lengths at hand and a speedy surgical and roentgen team for accurate rapid work, the results were good.

Postoperatively light traction is maintained temporarily followed by a Thomas brace with pelvic band and knee lock. Crutch ambulation with minimal weight bearing is permitted early but the brace must be worn until union is solid. This takes from 3 to 7 months.

Complications occurred but less frequently than in the traction-treated group. The most annoying

complication was gradual progression of the nail through the femoral head and into the acetabulum. Too long a nail and early or too active weight bearing predispose to this complication. The symptoms are minimal, and removal of the nail has been done readily and without further complications.

Conservative care netted a hospital mortality of 36 per cent, while in the operative group of patients it was 12.6 per cent. Senile psychosis occurred in 11 per cent of the "traction" patients and in only 2.1 per cent of those subjected to nailing.

The survival rate of these patients is not high in any case but 1 year after fracture, 32 per cent of the group treated by traction and 79 per cent of those subjected to nailing were alive. After 4 years the survivals were 13 per cent and 30 per cent, respectively. Now all intertrochanteric fractures are nailed according to this technique.

FRANCIS E. BRIDGEMAN, M.D.

Treatment of Pertrochanteric Fractures (Zur Behandlung der pertrochanteren fracturen) H. B. BRACK and W. J. PROFFERT. *Helvet. chir. acta*, 1948, 15, 509.

The present treatment of pertrochanteric fractures by extension for several months or by the application of a plaster cast is a difficult experience for the patient who is usually old. It also entails much time and some care. Therefore the authors have used internal fixation of the fracture by passing several Kirschner pins through the skin and the fragments in the following manner.

After preparation of the skin the patient is placed on the orthopedic table and the fracture is carefully reduced. Special attention is given to the correction of external rotation. The soft tissues lateral and caudal to the trochanter are anesthetized. To determine the direction of the pins during their insertion, a wire screen (anteroposterior direction) a water level and a protractor (axial direction) are used. After the first two or three pins have been inserted, roentgen films are taken in the anteroposterior and axial directions. If one of the pins is in the correct position, the direction and depth of penetration of the others are patterned accordingly. Further control films are taken and the necessary corrections made after each insertion of three pins. Good position of the pins in the axial direction is usually the greatest problem. An effort is made to place the pins so that their whole course lies inside the femoral neck. Any pin that pierces the articular cartilage is pulled back to a subchondral position. The arrangement of the pins and their number depend on the fracture and especially on the size of the lateral spur of the shaft fragment. Usually from 6 to 8 (rarely 10) pins are used. In intertrochanteric fractures, or in cases in which the fracture line runs, without strongly lateral convexity from the tip of the great trochanter to the lesser trochanter the pins are inserted convergently up to the femoral head. The shorter the spur the more caudal the insertion of the pins on the femoral shaft and the steeper their

course. The pins are often allowed to cross one another. The portion of the pin which protrudes through the skin is cut off as deeply as possible while an assistant depresses the soft tissues with two flat instruments. A dry dressing is applied and the leg is kept between sandbags for 14 days, when slight active movements may be started.

This method was used in 53 cases during the last 2 years. The majority of patients were women in bad general condition, 9 of them were between 70 and 88 years old, to avoid pulmonary and cardiovascular complications the insertion of pins was performed frequently on the second or third day and even immediately after admission. Movements in bed were started after from 4 to 15 weeks (average, 8 weeks) and the patients were taken out of bed and began to use the extremity after from 10 to 27 weeks (average, 14 weeks). In several cases the pins were removed before the extremity was used (average, 13 weeks) because they were about to pierce the skin. Healing occurred in all cases despite severe senile osteoporosis in many of the patients. Loosening of pins occurs rarely and never to such a degree that the roentgen picture shows clearing around the pin. One case was observed in which the faulty insertion of the pins led to heat damage of the bone, thus demonstrating the danger of the use of drills and circular saws in bone surgery. RICHARD KEMEL, M.D.

Aseptic Necrosis of the Femoral Head CARL E. BADGLEY and R. H. DENTHAM *J Am Med Ass* 1948 137: 1193.

The term "aseptic necrosis" has been too loosely used to make comparable studies of end results so classified and various phases of degenerative arthritis. Avascular necrosis may be used more specifically to define death to part or all of the femoral head due to vascular damage primarily of the posterior and anterior circumflex femoral vessels.

Although the bone necrosis quickly follows severe vascular damage it cannot be demonstrated (by its relative density) roentgenologically for from 2 to 3 months. Subcapital and transcervical fractures are suspects of avascular necrosis particularly when manipulation or open surgery upon the capsule further jeopardizes the supply of blood to the femoral head.

The frequency of avascular necrosis in fractures in which internal fixation has been followed by bony union is rather high about 40 per cent in one study. Although the internal fixation itself does not produce avascular necrosis it does produce a high per cent of united fractures in spite of a dead femoral head.

Four main types of complications are noted in the process of repair of fractures of the femoral neck.

1. Bony union with a period of functional use followed by pain, roentgen changes in density and contour of the femoral head from collapse of the weight bearing surface. The term aseptic necrosis should be restricted to this entity.

2. Bony union followed by decreasing function, pain, loss of joint space but maintenance of the con-

tour of the femoral head. To this state the term degenerative arthritis may be accurately applied.

3. Nonunion of the fracture may be associated with a dead head.

4. Nonunion of the fracture in the presence of a viable head.

Phemister's contributions to the clinical and pathologic knowledge of these complications are reviewed, and a résumé of the means of avoiding unnecessary damage to the vascular supply is offered. Of major importance is avoidance of weight-bearing until the viability of the head and union are ascertained with roentgenograms. In spite of careful treatment, avascular necrosis is a serious complication which may result in a poorly functioning hip.

Choice of operative therapy depends upon the degree of degeneration and the type of patient chiefly and ranges from a vitallium mold arthroplasty to arthrodesis of the hip. Various reconstruction operations are useful in certain instances and in experienced hands.

FRANCES E. BROCKFELCE, M.D.

Surgical Treatment of Uncomplicated Knee Dislocation (*Traitement chirurgical des luxations non compliquées du genou*) BASTIEN and VANHELLE. *Lille chir* 1948 14: 53.

In appropriate cases early surgery in dislocations of the knee is advisable. It permits thorough evacuation of the hemarthrosis and tears of ligaments, capsule and muscles can be explored and repaired. The meniscus can be resected partially or completely, if necessary. Furthermore in cases in which reduction is impossible because of interposition of parts of the capsule between the articular surfaces, open reduction is imperative. Effective repair of the cruciate ligaments is, in most cases impracticable and unnecessary. The authors suggest removal of the torn portions without suture of the cruciate ligaments. Perfect suturing of the lateral ligaments to insure the greatest stability of the joint is important. Surgery should be performed within 4 or 5 days after injury.

The approach to the different ligaments and the technique of operation are discussed in detail. For repair of the internal lateral ligament the authors suggest a horizontal incision a little superiorly to the joint, which is continued proximally and posteriorly in a vertical direction. This approach exposes the ligament in its entirety and at the same time permits perfect exploration of the joint. The branches of the saphenous nerve are spared by this incision and no sensory disturbances are observed postoperatively. The external lateral ligament is exposed by an oblique straight incision beginning at the condylar tuberosity and ending at the head of the fibula.

For exposure of the cruciate ligaments different techniques are employed. The authors prefer the transtuberous route for the anterior ligament and part of the posterior ligament. A U-shaped incision is made the horizontal portion of which crosses a little inferior to the tuberositas tibiae. The tuberosity is dissected and the patella and patellar liga-

ment are turned upwards this permits wide exposure. The inferior insertion of the posterior cruciate ligament is approached by a vertical incision in the popliteal space between the semimembranosus and gastrocnemius.

In old or neglected cases symptoms of instability and muscular atrophy may be present. Arthroscopy may reveal lesions of the menisci and cruciate ligaments. In these old or neglected cases suturing of the ligaments is not successful and autoplasmic operations with the use of tendons must be performed.

WERNER M. SOLMITS, M.D.

ORTHOPEDICS IN GENERAL

Total and Subtotal Sacrococcygeal Agenesis (Agenesia sacrococcygea, totalis y subtotalis) JOSEF M. JOROK and HECTOR JOROK. *Rev. A. med. gen.* 1945, 62: 350.

The authors review 8 cases of total and 27 cases of subtotal sacrococcygeal agenesis reported in the world's literature. They add one case of their own, that of total absence of the sacrococcygeal segment, the clinical history of which has been followed for a period of 20 years.

The boy was first seen at the age of 4 and at this time the condition was diagnosed as congenital absence of the lumbosacrococcygeal segment. Bilateral luxation of both hips, and bilateral equinovarus. There was a gibbus formation in the lumbosacral articulation to which the aponeurosis and ligaments were attached. Twelve years later the boy was able to get about dexterously on crutches, and had grown, although he was small of stature for his 16 years. His chest and arms were large and well developed, whereas his waist, hips, and legs were atrophic and of the paralytic type. There was complete incontinence of urine and for the most part absence of any sensation of defecation.

The patient was examined periodically from 1928 to 1947 the various changes were recorded and the roentgen ray views were compared.

STEPHEN A. ZIEGLER, M.D.

The Nutrition of the Articular Cartilage and the Formation of the Synovial Fluid under Various Functional Conditions. Experimental Research on Rabbits with Concurrent Observations on the Compressibility of the Articular Cartilage With and Without a Fluid Supply Approaching Physiologic Conditions (Ueber die Ernährung des Gelenkknorpels und die Bildung der Gelenksflüssigkeit unter verschiedenen funktionellen Verhältnissen. Eine experimentelle Untersuchung an Kaninchen unter gleichzeitiger Berücksichtigung der Kompressibilität des Gelenkknorpels bei bzw. ohne Flüssigkeitszufuhr) BO E. THIELMANN and JOSEF SÄLLER. *Acta physiol. scand.* 1945, 7: 303.

Experiments were carried out on 40 (8 months old) rabbits. Both shoulder joints were used, the right and left shoulders being scattered throughout the various groups without reference to right and left sides and without regard to the individual ani-

mal. However, a number of these shoulders were used as controls in the various manipulations involved so that only about 60 of these joints were employed in the true study. With the exception of one living control rabbit the work was done on killed animals. The total material was divided into 4 groups. In every case the removed shoulder joint was encased up to the cartilage in Wood's metal, and mounted in an apparatus, constructed by Ingelman, for measuring the compressibility (changes in thickness in the cartilages). In every case the blood was washed out of the experimental field by a perfusion fluid (dextran) which was developed by A. Groenell and B. Ingelman (*Acta physiol. scand.* 1944, 7: 97, 1945, 9: 17) and which is used extensively in local medical practice as a substitute for blood serum. For histologic examination the tissues (cartilage, capsule, synovia, joint fluids) were mounted on smears or sections stained with iodine in a solution.

In the first group of experimental animals the arteries leading to articular regions was perfused with dextran containing a suspension of rice starch granules (about 1,000 granules per cubic centimeter). In this group the starch granules were later found distributed in the articular cartilage about three-fourths of them in the basal third, a fourth in the middle third, and none in the upper third of the cartilage; that is, the third adjoining the joint cavity.

In the second group the starch suspension was suffused into the marrow cavities adjoining the scapular and the humeral articular cartilages. Here one-half of the granules were found distributed within the basal third, a third within the middle, and a sixth within the superficial third of the thickness of the cartilage.

In the third group the procedure was the same as in the second except that during the injection into the marrow cavity the joint surfaces were repeatedly pressed together and as often the pressure released, attempting in this manner to imitate the vital function of the joint during the life of the animal. In these joints, about one-fourth of the starch granules were later found distributed within the basal and middle thirds respectively while the other half of the granules were distributed in the superficial third of the cartilaginous thickness.

In the fourth group the treatment was the same as for the third group, except that the medullary cavity was perfused with the dextran, without the starch granules, and before the start of the experiment 0.5 c.c. of the suspension of rice starch was injected into the articular cavity through the articular capsule. Here the cartilage was later found to be devoid of starch granules, except in a few instances in which there were a few granules in the superficial layers of the cartilage.

In this last group an interesting finding was the greater number of granules per volume unit of cartilage substance in the cartilage of the glenoid cavity than in that of the humerus. This is explained by the authors on the assumption that the starch granules would find greater difficulty in penetrating that

part of the cartilaginous substance comprising the cellular tissues in the rabbit the glenoid articular cartilage has been shown to have a lesser cellular content than that of the humerus. On the whole there were more starch granules per unit of volume in the cartilages of the third group than in the others and this is interpreted as due to the greater perfusion of fluid through these cartilages from the functional strain put on them during the experiment.

With regard to the effect on the amount of synovial fluid as a result of experimental manipulations no method was found to measure accurately the amounts of joint fluid present however the impression was that the physiological stress put on the joint resulted in an increase in the amount of joint fluid present. The fluid in the first and second groups did not contain starch granules. In the first group granules were found in the capillaries of the synovial membrane and this finding is thought to demonstrate the presence of anastomoses between these capillaries and the vessels of the medullary cavity. In the third group there were no granules in the synovial capillaries and therefore it is thought that those found in the synovial fluid passed from the medullary cavity into the cartilage and from there into the joint cavity.

In the second group the cartilage was found to increase in thickness soon after medullary perfusion was started and this is regarded as a result of the replacement from the medullary cavity of the fluid lost sustained during the period between the killing of the animal and the starting of the perfusion. This swelling phenomenon was even more pronounced in the third group and seems to postulate an increase in the fluid circulation in the cartilage under physiologic stress. This fact together with the tendency of the cartilage to resume its initial volume following the compression (this tendency being stronger in the joints with medullary perfusion) suggests that the conditions under which these experiments were carried out closely resemble those present during life and that the results obtained would apply closely to those obtained in the living subject.

JOHN W. BRENNAN, M.D.

Experimental Research for Promoting Longitudinal Growth of the Lower Extremities by Irritation of the Growth Region of Femur and Tibia. G. CHAPPEL and J. ZELDENRUST. *Acta orthop scand.*, 1948, 17, 371.

Shortening of one of the lower extremities may occur after poliomyelitis, joint destruction in childhood malunited fractures, congenital hypoplasia and other affections. In the treatment of adults there are two methods of correction—either lengthening the short extremity or shortening the longer extremity—or an elevated shoe may be prescribed for the shortened extremity. Elongation of the shortened extremity is the most logical procedure but its application is rather limited and it is frequently attended by complications. Shortening of the normal limb presents certain technical and physio-

logical difficulties. One of the most successful operations is that of epiphyseodesis described by Phipps later which arrests the growth of the longer limb.

When the epiphyseal cartilage of the shorter limb is intact, it is possible to stimulate the growth. Various efforts in this direction have been described by Stanley Paget, von Bergmann, von Lagenbeck, Helferich, Helger, Königswieser, Riedinger, Weinlechner, Schott, Rauch, Schüller, Reschke, Ruschberg and others. Ollier was the first to propose a correction of genu valgum by one-sided destruction of the epiphyseal cartilage. Roentgen therapy has been used in attempts to arrest bone growth however the authors consider that this may be harmful.

In the authors' experiments bone growth has been stimulated by inserting ivory pegs into the metaphyses of growing bones of animals. They state that this lengthening is minimal and is not suitable for human practice on account of its uncertainty and because of resulting deformities. Phipps's epiphyseodesis or the Hass wire-loop growth restraint is preferable.

DANIEL H. LEVINTHAL, M.D.

Sciatica Caused by Herniation of Intervertebral Disc. Late Results of Operation in 115 Cases (Les sciatiques discales. Résultats éloignés de 115 cas opérés). DECOULX and SOULARY. *Lille chir.* 1948, 16, 137.

The author discusses the symptomatology, diagnosis and treatment of sciatica caused by herniation of an intervertebral disc, and reports the late success of surgery in 107 of 115 cases.

Only about 50 per cent of the patients remembered a gross injury like heavy lifting or a fall as the cause of their complaints. In most cases the affection starts with repeated attacks of lumbago of several days' duration, and only gradually the picture of sciatica develops in the subsequent months or years. The Lasègue sign is practically always present. Other typical signs are rigidity and scoliosis of the lumbar spine, often combined with kyphosis and torsion so-called corkscrew rachis, muscular atrophy, hypesthesia and diminution or absence of the Achilles reflex. Ninety per cent of all nuclear hernias are located either between the fourth and fifth lumbar vertebrae or between the fifth lumbar and the first sacral vertebrae. The following signs are used to differentiate between the two locations:

Herniation between fourth and fifth lumbar vertebrae. Normal Achilles reflex, atrophy of buttocks, thigh and calf, hypesthesia of the anterior malleolar region, dorsum of foot and great toe.

Herniation between fifth lumbar and first sacral vertebrae. Absence of Achilles reflex, atrophy of anteroexternal leg muscles, hypesthesia of posterior malleolar region, sole and heel.

This differentiation is, however, rather theoretical and not too dependable.

The roentgenogram reveals characteristic pictures only in a minority of cases (38 cases in the authors' series of 115). Injection of a contrast substance in the spinal canal should be considered only in excep-

tional and atypical cases when all other diagnostic methods have failed. Severe headaches, aggravation of pain fever and even more serious accidents have been reported after such myelography. If it is unavoidable to inject a contrast substance, some material which is more fluid than lipiodol should be injected and aspirated after roentgenography.

Surgery is indicated only in severe and refractory cases after medical treatment has failed. The medical treatment consists in complete bed rest for 1 month and radiotherapy.

The operation can be performed either by laminectomy or by the lateral approach. The former method gives ample exposure but is not without danger and has been abandoned by the authors after severe complications in 2 cases—in 1 case a local postoperative pachymeningitis, in the other a paraplegia which, a second intervention showed, was caused by a hematoma pressing on the medulla. The lateral approach (extraction of the herniated disc after resection of the ligamentum flavum) does not require opening of the meningeal sac and is technically not difficult. The operation does not take more than 15 to 45 minutes. In most cases one finds the sensory root stretched over the disc like a violin string. In other cases the disc protrudes with out being herniated and has to be extracted with forceps. In still other cases, nothing abnormal can be found. In these cases either the herniation cannot be visualized, or the complaints have been caused by vertebral periarthritis or by hypertrophy of the ligamentum flavum rather than by a slipped disc. Here the surgeon can either resect the sensory root or, as the author prefers, liberate the root over a large area.

The superiority of the lateral method of approach is well illustrated. Laminectomy resulted in com-

plete cure in 69 per cent of the patients as compared with 92 per cent complete cure with use of the lateral approach. Furthermore, with laminectomy the herniation could be visualized in only 39 per cent of the patients, while in the lateral approach, herniation could be visualized in 84 per cent.

WERNER M. SOLMITS, M.D.

The Bone Marrow on Sternal Aspiration in Multiple Myeloma. EDWIN D. BAYRD. *Blood*, 1944, 3: 937.

This study of the bone marrow on sternal aspiration in multiple myeloma is concerned primarily with three main points: (1) the type of cell or cells involved in the production of the disease; (2) the origin of this cell or these cells; and (3) cytologic criteria for the degree of malignancy.

The author gives a broad summary of the literature in regard to the first two headings, but finds very little on the third.

He has analyzed the sternal marrow biopsies in 71 cases at the Mayo Clinic. Differential counts and morphologic detail were studied completely in 51 cases and 43 cases had been under observation long enough to attempt correlation between the abnormal cellular structure and the degree of malignancy which was present.

All 71 cases were classified as falling into the plasma cell type of multiple myeloma. In the series he can trace all gradients from the normal plasma cell to the most anaplastic and immature myeloma cell. He believes the common origin of the cells is in the reticulum.

The study tends to substantiate the theory that the more abnormal the diseased cells, the greater the degree of malignancy.

KENNETH H. SPONKEL, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Contribution to the Biochemical Study of the Phlebitides and Their Surgical Treatment (Contribution à l'étude biochimique des phlébites et à leur traitement chirurgical) RAOUL FORTADRE, PAUL MANDEL and GEORGES APPRILL. *J internal chir. Brux.* 1948 8 778.

To prevent or abort a phlebitis it is not sufficient to lower the prothrombin level by dicoumarin or to prolong the coagulation time by heparin since despite the use of these anticoagulants, venous complications occur or continue their course. In these cases the authors have always found Lenggenghager's time (reaction of the thrombin level) shortened revealing a hypercoagulability which persists despite a prothrombinemia that has been greatly lowered by dicoumarin. Everything proceeds as if there were an excess of thromboplastin. Therefore the authors think that there are phlebitides with hyperthrombinemia, and others with hyperthromboplastinemia. As a result the biochemical control of the phlebitides should not be limited to investigations of Quick's time of the prothrombin level or of the coagulation time, but these examinations should be completed by the systematic study of the platelet level and Lenggenghager's reaction.

The therapeutic failures of the anticoagulants demonstrate that surgical treatment has a place in the therapy of the phlebitides. Embolic phlebitis should be operated upon to stop emboli.

The authors have operated upon 3 patients who had one or several previous small emboli through a small femoral or iliac phlebotomy they were able to remove long floating and only slightly adhering clots and thus to re-establish blood flow in the veins. Cure was complete without sequelae, 18 months later.

In adherent thrombophlebitis of the phlegmasia alba dolens type the danger of embolism is not as great as that of late sequelae. Operation reveals clots which adhere rapidly and intimately to the venous wall. In 3 (of 5) patients operated upon thrombectomy was performed but was incomplete in 1 case and the course of the phlebitis was unchanged, in the other 2 cases the veins were completely freed from clots and the edema regressed rapidly these 2 patients died later and at autopsy the veins were found to be without new thrombosis.

Two other patients were phlebectomized one of these died of shock and the other was cured.

Eight patients were operated upon for old phlebitis which had been present for periods of from 6 months to several years. In 3 of these the veins were freed and periarterial sympathectomy was performed but the results were unsatisfactory. Of the other 5 patients complete phlebectomy gave excellent results in 3 and incomplete phlebectomy

(in 2) gave slight improvement in 1 patient and resulted in failure in the other.

Iliofemoral phlebectomy was done for effort phlebitis with arterial spasm in 1 case and femoral phlebectomy was done for suppurative phlebitis in another with excellent results.

Simple ligation and especially of the inferior vena cava is indicated only in embolic phlebitis this is an emergency operation having no other object than that of preventing embolism. Thrombectomy is better since it eliminates the sequela of phlebitis it is the method of choice for all varieties of phlebitis and gives the best late results. If it cannot be done phlebectomy of the entire thrombosed segment should be performed. RICHARD KEMEL, M D

Surgery of Arterial Injuries and the Problem of Vein Transplantation (Ueber die Chirurgie der Arterienverletzungen und die Frage des Venentransplantats) KARL BAETZMER. *Chirurg* 1947 17-18 345

The author reports experiences in surgery in about 300 cases of arterial aneurysm most of them due to gun shot injuries. The cases were observed in the surgical department of the University at Freiburg Germany.

He emphasizes the dangers of ligation of large arteries especially the carotid and the popliteal. Ligation of the popliteal artery leads to gangrene in from 30 to 80 per cent of the cases according to different statistics. Also ligation of the anterior tibial artery may lead to gangrene of the foot, even when the posterior tibial artery is in good condition. Ligation of the common carotid artery causes cerebral disturbances, hemiplegia or death in from 20 to 50 per cent of the cases.

Therefore in two-thirds of his cases the author preferred reconstructive methods to ligation. End to-end suture after extirpation of the aneurysm is possible only in smaller injuries. Often the adjacent parts of the arterial wall, proximal as well as distal to the aneurysm are damaged for a length of several centimeters so that sutures do not hold and direct suturing is impracticable. On the other hand if larger portions of the artery are resected and the stumps joined under tension the diameter of the vessel decreases considerably and insufficient peripheral circulation ensues.

In about one-half of the cases transplantation of a vein was done successfully. It could be shown by arteriography that in a high percentage of the cases the grafts remained patent. In 1 case it was possible to examine the graft histologically 22 years after the transplantation. The wall of the grafted vein had changed to an arterylike wall and even showed typical arteriosclerosis.

Usually the long saphenous vein is used for transplantation. However frequently the lumen of

this vein is not wide enough especially for grafts in large arteries like the subclavian common carotid external iliac, and femoral. In these cases, it is preferable to use the femoral vein. As the collateral circulation is very well developed in the venous system even portions of from 15 to 20 cm. in length can be taken without danger of circulatory disturbance. In arteriovenous aneurysms vein from the surrounding region can be taken in some cases. However often in aneurysms of the subclavian and carotid arteries the veins are very thin and friable so that they are not fit for grafting.

WALTER M. SOLMITZ, M.D.

Resection of the Femoral Artery in Circulatory Disturbances of the Leg (Die Resektion der Arteria femoralis bei Durchblutungsstörungen am Bein)
In BERNHARD. *Chir. u. g.* 1948, 9, 93.

The author believes that in circulatory disturbances of the leg especially in thrombosis and aneurysm of the femoral artery, resection of the artery is the method of choice. In contradistinction to other large arteries of the body, the femoral artery often becomes obliterated in its entire length after a locally circumscribed lesion. This can be demonstrated by roentgenography. Frequently one can observe that in thrombosis of one artery, circulatory disturbances, pain, and coldness develop also in the contralateral leg. After resection pain and circulatory disturbances cease in the contralateral leg first immediately after the operation and only much later in the extremity subjected to operation. The mechanical obstruction of the artery is not the only cause of the circulatory disturbance. Irritation of the arterial wall leads to vasoconstriction of the blood vessels and to lesser degree of the contralateral leg and may also cause other disturbances of the entire sympathetic nervous system. Therefore, in some cases, lumbar sympathectomy should be added to the resection of the artery.

The operation is most successful in thrombosis and arteriosclerosis, less in arteritis of various origins. In endarteritis obliterans the outcome is less satisfactory and resection of the lumbar sympathetic trunk should be done in all these cases in addition to resection of the artery. Also in ulcers and threatening gangrene the operation sometimes leads to a successful outcome.

Of the numerous functional tests, continuous recording of the skin temperature proved the most reliable. After a water bath of 35° C. for 15 minutes the leg is put under a heat cradle at 50° C.

The oscillatory index is much less reliable.

WALTER M. SOLMITZ, M.D.

BLOOD; TRANSFUSION

Experimental Study with Blood Transfusions (Studio sperimentale sulle trasfusioni di sangue). By CENZO LAURICELLA. *Arch. Ital. Chir.* 1948 70:9

The author conducted an experimental study on dogs, to determine the fate of transfused blood, for which he received the Achille Albanese award from the University of Palermo.

He developed an internal biliary fistula in dogs. At first the gall bladder was anastomosed directly to the right renal pelvis after the common duct had been ligated, but this procedure resulted in a high mortality. He then made the anastomosis through the body of the kidney to the pelvis, and by so doing the mortality was reduced to zero. Eight dogs were operated upon in this manner. Following recovery from the operation the amount of bilirubin excreted was determined daily and a standard was set for each animal. Four dogs were then transfused with compatible blood varying from 50 to 100 c.c. The other 4 dogs were transfused with similar amounts after an amount of blood equal to that to be transfused was first removed. The amount of bilirubin was determined as previously.

From the results of these experiments, the author arrived at the following conclusions:

1. The blood transfusions were constantly followed by an increase in the bilirubin excreted. This increase began within 24 hours and lasted for variable length of time up to 20 days—an average of 16 days.

2. Blood-letting previous to the transfusion did not influence the amount of bilirubin excreted.

3. The amount of bilirubin excreted in excess of normal was proportional to the amount of blood transfused.

4. The post transfusion hemolytic phenomena of which the excess of bilirubin excreted constitutes a direct index, are proportional to the quantity of blood transfused, and indicate the destruction of an amount of blood equal to that transfused.

The destruction of transfused blood cells does not represent a normal cycle for red blood cell destruction. In the experiments, the transfused blood is apparently destroyed within 20 days, an average of 16 days for the 8 dogs. The bilirubin excretion level then returned to normal. According to the experimental work of Hawkins and Whipple as well as others, the life cycle of red blood cells in dogs is about 124 days, and hence represents a much longer period than the life cycle of transfused red blood cells, as these experiments would seem to indicate.

LEONARD J. FROST, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Prothrombin Activity RACHEL S SANDROCK and
EARLE B MAHONEY *Ann Surg* 1948, 128 531

Postoperative prothrombin activity was studied in 382 surgical patients. In this series 80 per cent of the patients did not show any signs of hyperprothrombinemia in the blood and did not give any evidence clinically of thromboembolism. In the remainder hyperprothrombinemia was detected before the onset of clinical signs of thrombophlebitis.

The authors found that in the first 3 days of recovery after operation an increase of prothrombin activity in the blood became the precursor of thromboembolic phenomena in the patient. Dicumarol was administered prophylactically to 23 patients because of the sudden increase in prothrombin activity.

The authors thought that the dilution prothrombin test was too variable therefore the prothrombin activity of whole plasma was used for the test.

It was often found that when clinical signs of thrombosis were present prothrombin activity in the blood was already reduced or normal. It was thought that the hyperprothrombinemia discovered on the third postoperative day manifested the onset of thrombosis in the small veins of the leg. The test was not considered accurate for all cases because not every patient with hyperprothrombinemia developed clinical thrombosis.

BENJAMIN G P SHAPIROFF M D

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Traumatic Lesions of the Thumb of Recent Origin
(Lesiones traumáticas recientes del pulgar) PEDRO
V PEDEMONTE. *Am orlop (traumatol)*, 1948, 1 97

Of three functions of the hand—exploration of the objects, gesticulation, and exertion of pressure—the last mentioned is the most important. The thumb is of greatest value for exerting pressure.

The author makes a plea for conservative surgical treatment of traumatic lesions of the thumb illustrating the description of various methods by examples from his own practice.

A poor stump is preferable to a complete loss of the thumb because it may be reconstructed. Various plastic procedures may transform a useless thumb into a useful organ.

In a complete avulsion of the soft parts there is a general tendency to place the torn tissues back into their original position and to suture them. However the late results of such treatment are very unsatisfactory due to necrosis of the skin. The author prefers to treat traumatic lesions by debridement, proper immobilization and replacement of the in-

jured tissues by a skin flap preferably taken from the abdomen at a later date. After transplantation the injured arm is placed in a body cast.

If a bone is crushed a subperiosteal extirpation is recommended.

The author advocates lavage of the wound with copious amounts of an antiseptic solution. In very extensive injuries if the tendons cannot be identified and properly sutured at least an effort should be made to preserve the nerves to avoid an annoying anesthesia. As a rule the cast is removed after from 6 to 8 weeks.

If an extensive defect of the skin is present one of three methods may be employed (1) the wound may be allowed to heal by second intention (2) it may be sutured, or (3) a plastic repair may be performed. The first two methods are condemned because they produce painful scars.

Loss of the distal phalanx is estimated to cause 10 per cent disability loss of the proximal phalanx 30 per cent and loss of the thumb including the corresponding metacarpal bone 35 per cent.

JOSEPH K. NARAT M D

Suppurative Fasciitis as the Essential Feature of
Hemolytic Streptococcus Gangrene. E. L. MC
CAFFERTY JR., and CHAMP LYONS *Surgery* 1948
24 438.

The term "necrotizing erysipelas" was introduced to designate a specific infection due to beta hemolytic streptococci, and characterized by subcutaneous necrosis and secondary cutaneous gangrene. Early surgical incision to the limits of the subcutaneous necrosis" were demonstrated to be effective in the control of the spreading infection.

The clinical picture of the disease is well known. It most commonly affects the extremities. The pathognomonic sign of the disease has been described as a dusky hue of the skin with or without blisters or bullae and usually appearing on the third fourth or fifth day of the infection. Before potent antistreptococcal therapy was available, multiple incisions of the bear-scratch type were lifesaving. The wounds were then dakinized and the considerable defects pinch-grafted 6 to 8 weeks later.

The authors present certain modifications in our understanding of this disease as a consequence of their experience with penicillin treated infections. The conclusion that the disease was an anaphylactic phenomenon of the Schwartzman or Arthus type has been brought forward. In studies of penicillin-treated infections the subcutaneous necrosis has been limited quite clearly to a suppurative fasciitis. Hemolytic streptococcus gangrene is an extensive cellulitis which even under modern therapy is frequently complicated by abscesses of the fascial planes.

Recognition of suppurative fasciitis as the essential feature of hemolytic streptococcus gangrene has

simplified its clinical management. The diagnosis and surgical incision should not be deferred for the appearance of the older pathognomonic sign of impending cutaneous gangrene. Recognition of persistent edema along a fascial plane in an infection otherwise subsiding under antistreptococcal therapy is indicative of a fascial plane abscess.

The bear-scratch type of incision has been discarded in favor of planned fasciotomy incisions designed to expose the entire length of the fascial plane abscess. The most effective method of avoiding long incisions is early recognition of fascial plane edema and prompt surgical intervention. After drainage a fine mesh gauze is introduced into the wound and the extremity is immobilized by a gentle pressure dressing.

Early secondary closure of these frequently considerable defects has proved practical and desirable
HARRY W. FINE, M.D.

Antibiotic Therapy EMANUEL APPELBAUM and WILLIAM A. LEFT *J. Am. Med. Ass.* 1948, 38, 9.

The authors have frequently observed that during the course of treatment with an antibiotic a complete change in the bacterial flora may occur. The pathogenic organisms that are sensitive to an antibiotic in use disappear or become less numerous and insensitive organisms may appear in large numbers and cause a new infection. The authors reported in great detail a case of pneumococcal pneumonia treated with penicillin, in which they developed a new infection due to gram negative bacilli which responded to streptomycin. They strongly emphasized the occurrence of superinfections as an important and hitherto poorly appreciated feature of antibiotic therapy in general. The importance of frequent and careful bacteriologic examinations in all patients before and during treatment with an antibiotic was stressed in order to detect the presence of superinfections.

The authors do not, however, advocate the combined use of two different antibiotics from the start of treatment of infections because first, these drugs may sensitize certain patients to their use later in life and, secondly, the incidence of the occurrence of superinfections does not appear to be high enough to warrant such a practice
ROBERT TURELL, M.D.

Penicillin Therapy N. ERCOLI, W. C. HUEPPEL, L. LANDAU, B. S. SCHWARTZ, and F. J. QUARLES *J. Am. Med. Ass.* 1948, 38, 5.

During the past few years there have been numerous investigations conducted with a view to the development of a simple and efficient method for maintaining and prolonging an effective blood level of penicillin culminated in the development by Romanovsky of a penicillin-wax-oil mixture but because this preparation has a high melting point and viscosity requiring special syringes, and in view of the occasional occurrence of painful indurations at the site of the injection, there arose a need for the development of an injectable preparation of penicillin which can be

handled at ordinary room temperature and which does not produce appreciable untoward reactions while possessing superior therapeutic properties.

The observation that small doses of epinephrine suspended in oil exert a strong delaying effect prompted Ercoli and his collaborators to incorporate potassium penicillin into a vehicle of this composition. The quantity of epinephrine added to the oil was kept sufficiently low to assure a prolonged local vasoconstrictor action without causing any systemic vasopressor effect. The authors presented evidence to show that their mixture of 300,000 units of potassium penicillin, 0.3 mgm. of epinephrine, and 1 c.c. of vegetable oil produces after the intramuscular injection and particularly after the subcutaneous injection, an effective blood penicillin level for periods of 16 to 24 hours. This preparation is easily handled with syringes and needles which ordinarily are available

Aureomycin. MORTON S. BRYER, EMANUEL B. SCHWARTZ, CAROLINE A. CHANDLER, ELEANOR A. BIRM, and FERRIS H. LONG *J. Am. Med. Ass.* 1948, 38, 117.

Aureomycin is a new antibiotic and is derived from a strain of *Streptomyces aureofaciens*. It possesses bacteriostatic and bactericidal activity against numerous gram positive and gram negative bacteria. It is supplied in acid solutions having a pH of 4.5. The activity of the antibiotic deteriorates rapidly in alkaline solutions at room temperature. Human serum also decreases its activity. The L.D.₅₀ (lethal dose for 50 per cent of test objects) on intravenous injection in mice is between 50 and 100 mgm. per kilogram of body weight. The L.D.₅₀ on subcutaneous injection in mice is between 3,000 and 4,000 mgm. per kilogram of body weight. Rapid intravenous injection of 150 mgm. per kilogram of body weight killed a dog and produced hemoglobinuria.

Repeated large doses of aureomycin were tolerated in rats and dogs, with moderate local reaction and some loss of weight associated with anorexia. Autopsy revealed no gross or microscopic abnormality in the viscera. A rabbit tolerated 2 per cent aureomycin borate administered locally in the eye. The concentrations of the antibiotic in serum ranged from 0.3 to 2.4 micrograms per milliliter. The antibiotic was not detected in the spinal fluid. High concentrations of aureomycin were noted in the urine.

Aureomycin administered to mice orally did not protect against infections produced by pneumococcus type 1, or *Klebsiella pneumoniae* type 4, but did protect against those produced by *Streptococcus hemolyticus* beta (C303). Parenteral doses gave some protection against all three infections. Penicillin afforded slightly more protection against infections produced by gram positive bacteria, while polymyxin and streptomycin were superior in experimental infections produced by *Klebsiella pneumoniae*.

Patients suffering from coliform and *Streptococcus faecalis* infections of the urinary tract,

Rocky Mountain fever (Eastern type) typhoid and brucellosis have been treated with aureomycin, which was administered orally or both orally and intramuscularly. The oral dosage employed varied from 10 to 60 mgm. per kilogram of body weight per day given in from 6 to 12 doses. Intramuscularly a total dosage of 3 mgm. per kilogram of body weight per day, divided into 4 doses, was tolerated but with signs of moderate local irritation. The 5 patients with Rocky Mountain spotted fever who were treated on the third to fifth day of their disease were afebrile and asymptomatic within from 12 to 72 hours. A patient ill with chronic brucellosis whose blood cultures were repeatedly positive for *Brucella suis* became afebrile 3 days after the institution of aureomycin therapy. Blood cultures became sterile 48 hours after treatment was begun. As of the date of reporting these had remained sterile and the patient had remained afebrile and asymptomatic for more than 2 months. Infections of the urinary tract due to *coli aerogenes* and *Streptococcus faecalis* have been sterilized, and evidence of inflammation has disappeared when patients were treated with aureomycin by mouth.

Two patients with typhoid were treated with favorable initial responses.

ANESTHESIA

The Role of Epinephrine in Analgesia E. G. GROSS
HELEN HOLLAND H. R. CARTER, and EUNICE M.
CHRISTENSEN *Anesthesiology* 1948, 9, 459.

The potent analgesic agents have been assumed to exert their pain relieving action through a depression of the thalamic region of the central nervous system. The use in various laboratories of improved methods for measuring analgesia however has revealed several indications that the autonomic nervous system may also be involved in the production of analgesia.

It is believed that the results of this study may establish that epinephrine plays a role in the mechanism of analgesia and evidence appears that this may be a vascular effect. Perhaps the vascular effect results in a hypoxic state in the nerve tissue. The exact mechanism however by which a vascular change might bring about the analgesia, and the central or peripheral nature of the analgesia requires further experimentation.

MARY FRANCES POE, M.D.

Local Sequelae of Endotracheal Anesthesia W.
ALLEN DONNELLY, ARNOLD A. GROSSMAN, and
FRANCIS M. GREGG. *Anesthesiology* 1948, 9, 490.

The types of trauma incident to endotracheal anesthesia are discussed and the findings on post-anesthetic indirect (mirror) laryngoscopic examinations in 100 cases are described. Even with residents recently introduced to the endotracheal technique the local damage following intubation was, in all

cases, moderate in degree and caused only minimal subjective complaint or functional change. No permanent damage was encountered.

It is not unreasonable to assume that in the hands of the skilled anesthesiologist, the incidence of trauma resulting from intubation will be minimal and that the occurrence of even slight injuries (noted in this series) will be less frequent. The advantages of endotracheal anesthesia which have not been discussed in this paper far outweigh any minor undesirable effects discovered in this study.

MARY FRANCES POE, M.D.

Intravenous Procaine in Thoracic Surgery N. M.
BITTRICH AND W. F. POWERS. *Current Res. Anesth.*
1948, 27, 181.

The authors report and summarize the use of continuous procaine infusion intravenously in combination with other agents such as cyclopropane ether and pentothal, during thoracic operations on 17 patients. The procaine infusion was employed in the particular attempt to control cardiac irregularities occurring in patients undergoing thoracic surgery.

Preoperative medication with nembutal morphine sulfate and scopolamine was used. The patients were anesthetized with cyclopropane nitrous oxide-oxygen-ether or pentothal nitrous oxide oxygen-ether and intubated with intratracheal tubes. Transfusion was begun and the patient was placed in the operative position. Assisted or controlled respiration was used as indicated. Before the pleural cavity was opened a continuous intravenous infusion of 1.0 per cent procaine hydrochloride in 5 per cent glucose solution was begun. Small amounts of pentothal were given intravenously from time to time to reduce the convulsant effects of the procaine.

In 5 of 17 cases arrhythmia occurred although the procaine solution was flowing at rates from 60 to 100 drops per minute. A rate of 150 drops per minute was required to correct arrhythmia in one patient. This has raised the question as to whether or not a single dose of from 50 to 100 mgm. can be expected to control cardiac arrhythmia especially if it is the result of more serious cardiac dysfunction than was present in these patients. Mild convulsions occurred during ether anesthesia in 4 patients whose disease was bronchiectasis and who had received insufficient amounts of pentothal. This appears to refute the suggestion that the susceptibility to the convulsant effects of procaine is diminished during general anesthesia. No harmful effects were seen in these cases.

The case reports emphasize the diminution of bronchospasm and coughing and the ease with which both could be controlled with the intravenous administration of procaine. The patients appeared to tolerate operations better and made easier recoveries. No patient who had been given procaine had any immediate sensation of pain upon awakening.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

The Diagnosis of Suprasellar Tumors by Pneumoencephalography N. S. SCHLESINGER and J. GEORGE TRILLICK. *Am J Roentg* 94: 60-71.

The authors reviewed the pneumoencephalographic findings in 5 patients in whom a diagnosis of suprasellar neoplasm had been made in an attempt to determine whether a conclusive diagnosis of tumor in the suprasellar region could be made early by means of routine pneumoencephalography. This survey disclosed a striking alteration in the appearance of the cisterna chiasmatica, best described as obliteration, in 4 cases in which the existence of a meningioma in the suprasellar region had been verified by operation and in another case in which the presence of a hypophyseal duct tumor is highly probable.

A control study of 150 consecutive pneumoencephalograms in which no suprasellar lesion was suspected shows 94 per cent visualization of the cisterna chiasmatica; therefore the authors conclude that obliteration of the cisterna chiasmatica warrants the presumptive diagnosis of a suprasellar tumor if a lesion in this area is clinically suspected.

FRANK L. HUBERT, M.D.

The Pathologic Gall Bladder FRANK GREENWOOD and E. SAMUEL. *Bull J Radiol* 94: 3-43.

The authors present an analysis of their cholecystographic studies of 500 consecutive cases of pathologic gall bladder. Routinely they used a single dose of dye and administered additional dye only in those cases which showed poor original concentration. Of those gall bladders thought to be normal 99 per cent required the additional doses of dye. Fluoroscopic examination with compression and spot filming was employed routinely. The authors state that with this technique they are better able to avoid overlying gas shadows. Further they believe that this part of the examination is just as important as the comparable fluoroscopic and roentgenographic examination of the duodenal cap in the erect position. Films were always made in the erect position, since this view was the only one which revealed 18 per cent of the nonopaque gall stones. When overlying gas shadows were particularly disturbing the demonstration of nonopaque stones was aided by the use of tomography.

P. W. EVLER, M.D.

Contribution to the Radiological Study of Simultaneous Skin and Bone Manifestations in the Legs (Contribution à l'étude radiologique des modifications osseuses et cutanées concomitantes dans la région des jambes) RENE GILBERT and GEORGES VOLTER. *Acta radiol* 94: 39-403.

Bony reactions accompanying soft tissue alterations in the legs have long been known to radiolo-

gists. Do they follow or precede the modifications of the soft tissues? Do they result from local or systemic reactions? After a short summary of the literature the authors elaborate their theory.

Periostosis being a constant and important finding its macroscopic and microscopic pathology is outlined. The periosteum is a conjunctive membrane which cannot be detected with x-rays even if it has been raised from the adjacent bone by a mass of blood or pus. It will be seen only if mineralized or ossified.

The first stage of periosteal reaction in repair processes consists in the production of a reticulum of osteoid calcium-free trabeculation which is radio-lucent.

In the second stage, which constitutes the first roentgenological evidence, there is mineralization of the periphery of this reticulum which leaves a clear space between it and the underlying bone. This occurs toward the twentieth day.

Finally the clear zone becomes ossified and continuous with the cortex of the bone and the roentgenogram shows it as a thickening of the cortex. This is true of acute cases.

In chronic processes, periostosis will, in most instances, be produced intermittently and show a lamellar appearance on the films. Fundamental roentgenological signs are then discussed.

1. There are morphological and structural modifications of the bone such as osteoporosis, osteosclerosis, and periostosis, alternately or simultaneously and intermingled. It is interesting to note that osteoporosis of the head and malleolus of the fibula is an early sign, although the lesions are usually closer to the tibia. This is due to the fact that the volume of the fibula is considerably less than that of the tibia. Periostosis, on the other hand, is seen almost as early in either bone. The interpretation is, of course, more difficult in the aged in whom periostosis already exists.

2. Other modifications such as calcifications of the interosseous membranes, tendons, muscles, phleboliths and even arteriosclerosis occur later in the soft tissues.

The basic condition is most likely venous stasis which gives rise to skin soft tissue, and osseous manifestations. In varicose ulcers the osseous condition does not precede the vascular alterations, but it is detected earlier. Furthermore discrete osseous reactions are usually seen in the other leg which is free of ulcer.

In primary skin conditions such as tuberculous or ulcus rodens the bony changes are localized and occur without proportion to the lesions. In osteomyelitis, the alterations are seen much earlier in the soft tissues than in the bones.

In periostosis such as is seen in varicose conditions, the first stage only is active. The two last stages are

passive and subjected to the laws of tissue growth and hormonal regulation. In this respect the process is similar to that seen in some generalized infections such as syphilis and certain types of intoxications.

JEAN P. JEAN M.D.

A Decade of Experience with Plesioroentgenotherapy in Tumors of the Skin and Mucosa (Un decennio di esperienza nella plesioroentgenoterapia dei tumori della cute e delle mucose) C. PORTA. *Tumori* Milano 1948 34 119.

Plesioroentgenotherapy (PRT) has been employed at the National Institute for the Cure of Tumors at Milan Italy in 605 cases during the period from 1935 to 1944. The apparatus used was the original type of Chaoul's (Sieman's tube). The factors for its function are 55 kv. and 4 ma. with a focal distance of 5 cm. and filtration equivalent to 0.2 mm. of copper. The field chosen for irradiation was never larger than 3 cm. in diameter. The usual dosage consisted of 6,000 roentgens in fractional doses of from 500 to 600 roentgens daily on consecutive days. In the cases of melanoblastoma the dosage was higher at times reaching 10,000 roentgens in a single course or even from 20,000 to 25,000 roentgens in two or more courses. For the recurrences which developed after some years the dosage and fractionation was the same as for the original course. In the more recent recurrences, however, the dosage was somewhat smaller (from 4,000 to 5,000 roentgens) with fractions of from 300 to 400 roentgens in some cases nevertheless in the majority of these patients the fractionation ranged from 500 to 600 roentgens.

The total rate of cure was 54 per cent. however only 416 of the patients were available for later control studies and the cures when based on this number amounted to 82 per cent. These figures however do not faithfully mirror the results of treatment since they included many patients with tumors notoriously resistant to irradiation therapy (melanoblastomas and tumors of the internal angle of the eye). Many of the latter patients, although cured locally later developed distant metastases of the lymph glands and these were unfairly perhaps included among the figures for failure of cures. Seven before and after photographic reproductions illustrate the excellent cosmetic results obtained and the absence of trophic sequelae in the irradiated skin areas.

The lesions treated included newgrowths of the buccal and nasal mucosa, the mucosa of the prepuce and clitoris tumors of the skin and tumors of the ocular and especially corneal conjunctiva. Best adapted to this form of treatment seemed to be the neoplasms of the bridge of the nose, the internal angle of the eye and the lobe of the ear. In these cases the results were satisfactory as far as local cure and freedom from recurrence were concerned and there were fewer reactions and necrotic degenerative changes of the underlying cartilage than following treatment with radium or other forms of irradiation. Excluded were the highly malignant deeply infiltrating growths

which are suitable for radium therapy. Nevertheless, the method could be applied also in some of these cases particularly for tumors developing upward from the skin surface where the protruding masses or growth could previously be removed by diathermic excision. Tumors more than 3 cm. in diameter could also be treated by contact therapy when the area could be irradiated in several contiguous fields.

The author regards plesioroentgenotherapy (contact therapy) as the method of choice for tumors of the skin and mucosa always of course on the basis of its inherent limitations and provided that the method be applied with a rigidly correct technique.

JOHN W. BRENNAN M.D.

Colloidal Lead Orthophosphate Associated with Deep Roentgen Therapy in Bone Metastases from Cancer of the Breast LAWRENCE REYNOLDS, T. LEUCUTIA, JAMES C. COOK and KENNETH E. CORRIGAN. *Am. J. Roentg.* 1948 60, 193.

The authors treated 355 cases of bone metastases chiefly from carcinoma of the breast with preliminary intravenous injection of colloidal lead orthophosphate in conjunction with roentgen therapy. The present method consists of intravenously injecting an average dose of 30 c.c. of colloidal lead orthophosphate suspension containing 120 mgm. of lead. This in 3 days is followed by a series of deep roentgen treatments. As a rule the rays obtained with 200 kv. and 1 mm. of copper are used and full erythema doses are given per field at one session. The number of fields selected for crossfiring depends on the physical measurements of the part of the body to be irradiated. Occasionally in very heavy patients supravoltage roentgen therapy is employed because of greater depth dose. The entire series is completed in a period of from a few days to 2 weeks. Hospitalization of from 20 to 30 per cent of the cases is necessary because of severe treatment reactions. The injection of the colloidal lead is repeated 2 months later and followed again in 3 to 4 days by a second series of deep roentgen treatments. The reaction is usually less severe. Additional treatment series may be given if there is additional spread of the carcinoma. In one case a total of 1,200 mgm. of colloidal lead orthophosphate was injected over a period of 10 years with twelve series of deep roentgen treatments with gradually reduced doses. The only contraindications to the administration of the colloidal lead are severe liver damage, nephritis and very marked anemia. In about 20 per cent of the cases the intravenous injection of colloidal lead orthophosphate is followed within 1 to 2 hours by a chill and a temperature elevation reading up to 103 F.

The symptomatic improvement has been satisfactory in 95 per cent of the cases. The complaints in conjunction with the invasion of the osseous skeleton by the malignant neoplasms begin to abate in about 10 to 14 days. In 3 months there is very solid reossification of the formerly destroyed area.

of the bone which permits resumption of limited activities. The average survival amounted to 3 years. In 4 per cent the survival was more than 5 years. The patient who survived longest lived 10 years but there were no permanent cures.

The preliminary intravenous injection of colloidal lead orthophosphate in conjunction with roentgen therapy leads to a three-fold effect in the malignant neoplastic invasion of the osseous system: the lead has a certain toxic action in itself; there is a direct destructive effect of the roentgen rays and the heavy lead atoms deposited within the tumor area emit, under the influence of roentgen irradiation, ionizing secondary electrons which also act on the carcinoma cells. More recently attempts were made to use radioactive lead orthophosphate to aid internal irradiation. However, further investigations especially with "tagged" lead are necessary before worthwhile therapeutic efforts can be undertaken.

FRANK L. HUMERY, M.D.

The Use of Adrenal Cortical Hormone in Radiation Sickness. FREDERICK ELLIS, JR. *Radiology* 94:8, 5-394.

The symptomatology of radiation sickness points to adrenocortical insufficiency. Irradiation of a sufficiently large volume of the body results in the release of histaminelike substances if not of histamine itself. These substances cause the anterior pituitary to secrete a corticotrophic hormone which in turn stimulates adrenocortical activity. This stimulation may well result in exhaustion of the gland.

In a recent study with mice as the test objects, the author used desoxycorticosterone acetate (DCA), a synthetic hormone of the adrenal cortex, in the treatment of radiation sickness. It was demonstrated that DCA protects the liver against radiation-induced fatty changes and that this liver-protecting action is accompanied by a decrease in the mortality rates produced by various doses of x-rays applied in total body irradiation. It was demonstrated, furthermore, that both effects are dependent on the size of the daily dose of DCA. 0.5 mgm. was found to be an optimal dose for daily administration. The lethal effect of L.D. 50 was reduced by almost 50 per cent.

The author's studies were extended to include the influence of DCA on the effects of x-rays on the spleen, bone marrow and adrenal cortex. One hundred male Swiss white mice were given total body irradiation and then killed at different intervals. The results of the study of the spleen, bone marrow and adrenal cortex in animals which were irradiated, and in those which were irradiated and treated daily with 0.5 cm. DCA were compared. The author observed no change in the x-ray induced

effects on the spleen. On the bone marrow, however, a definite and statistically relevant change was noticeable in the DCA treated group. Similarly, a decreased depletion of sudanophilic fat of the adrenal cortex was observed in the animals receiving DCA.

In a series of 50 patients who exhibited nausea or vomiting or both, 37 were completely relieved of these distressing symptoms. It is believed that DCA may prove of value not only in the treatment of radiation sickness encountered as a complication of radiation therapy but also in radiation sickness occurring as a result of accidental exposure to lethal doses of ionizing radiations.

Radioactivity and Urinary Tract Calculi. DAVID S. C. NISOL, ALBERT E. BOTHER, and PAUL W. GROSZINGER. *N. England J. M.* 1948, 38:427.

The authors report a very interesting case of radioactivity of a bladder stone.

The patient, a male 56 years of age, who had a vesical calculus as well as multiple prostatic calculi, was also afflicted with polycythemia vera. Preparatory to the operation for the calculi, orally radioactive phosphorus for the polycythemia was administered. He received a first dose of 6 millicuries, and 3 months later a second dose of 10 millicuries. During all this time the increase in size of the bladder calculus was observed by means of repeated roentgen studies and cystoscopic examinations. Sixty-one days after the second oral dose of radioactive phosphorus a suprapubic cystostomy was performed and the vesical calculus together with some of the prostatic calculi were removed.

The stones then were analyzed for radioactivity. Both the Geiger counter and the autoradiographs showed that the vesical calculus was markedly radioactive. There was a laminated layer at the periphery which represented deposited radioactive phosphorus from the urine. This layer corresponded to the increase in size of the stone during the period of administration of the drug. The prostatic calculi, which were not in contact with the urine and also were presumably not enlarging during the period of phosphorous therapy, were not radioactive.

It is the authors' opinion that the method might serve as a control of the efficacy of various proposed procedures for the prevention of additional stone formation, as, for example, the effect of an acid ash diet on the formation of alkaline stone. It also offers an opportunity for the study of the action of radioactive materials on associated infections of the urinary tract. The possible effect of the radioactive stone on the surrounding tissues must also be considered.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Some Supplementary Leads in Clinical Electrocardiography KARL ERIK GREWIN *Acta med scand.*, 1948 130 Supp 209

Considerable interest has been evidenced in electrocardiographic curves with regard to special leads. The author presents an adequate historical résumé of the subject, and reviews the contributions of many authors in Europe and the United States.

His critical evaluation of the many reports contained in the bibliography of the text are objective and interesting. The author also presents a report of his own experience in the field.

CHAUNCEY C. MAHER, M.D.

The Effects of Altered Arterial Tensions of Carbon Dioxide and Oxygen on Cerebral Blood Flow and Cerebral Oxygen Consumption of Normal Young Men SRYMOUR S. KETY and CARL F. SCHMIDT *J. Clin. Invest.*, 1948, 28 484.

The effects of the inhalation of 5 to 7 per cent CO_2 , 85 to 100 per cent O_2 , and 10 per cent O_2 were studied on the composition of arterial and internal jugular blood, on blood flow, oxygen consumption, and vascular resistance of the brain, and on cardiac output and blood pressure.

CO_2 inhaled in concentrations of 5 to 7 per cent produces an increase in cerebral blood flow averaging 75 per cent. O_2 inhaled in concentrations of 85 to 100 per cent is associated with a reduction in cerebral blood flow of 13 per cent, while 10 per cent O_2 produced an increase of 35 per cent in this function.

These changes are statistically significant. Calculation of cerebrovascular resistance indicates that in every case the change in blood flow is due to a change in the vascular resistance of the brain. Cerebral oxygen consumption is not significantly altered by changes in the composition of inspired air over the ranges studied. Mean arterial blood pressure rose significantly during the CO_2 and high O_2 inhalations and fell slightly with 10 per cent O_2 . The only significant change in cardiac minute volume was an increase which occurred during 10 per cent O_2 inhalation and resulted from an increase in rate rather than stroke volume.

WALTER H. NADLER, M.D.

The Effects of Various Amino Acids on Peripheral Blood Flow and Skin Temperature. MARTIN B. MACHET *J. Clin. Invest.*, 1948 28 454.

Skin and rectal temperatures, total oxygen consumption and blood flow through the hand were studied in 4 healthy young males before and after the oral administration of seven amino acids.

At an environmental temperature of 24 centigrade glycine produced a significant rise in the skin temperature of the hands and in the dosage used

resulted in a significant increase in blood flow through the hand. These increases generally became apparent about 30 minutes after the glycine ingestion and were most marked after about 180 minutes. Save for similar but less marked increases in toe temperature, no significant temperature changes were noted elsewhere in the body, including the rectum. At 18° centigrade and 30° centigrade no significant changes in rectal or skin temperature or peripheral blood flow followed the administration of glycine. At an environmental temperature of 24 centigrade changes similar to those produced by glycine were observed after the administration of D-phenylalanine, only a very slight and questionably significant increase in hand skin temperature and blood flow through the hand were noted after 1 (+) histidine monohydrochloride, no effect was produced upon rectal or skin temperature or on the peripheral blood flow after ingestion of 1 (+) glutamic acid, 1 (-) tyrosine, 1 (-) leucine and D-methionine.

Although five of the seven amino acids used caused a definite increase in oxygen consumption, there were no consistent quantitative relationships between total oxygen consumption and skin temperature or peripheral blood flow.

WALTER H. NADLER, M.D.

The Effects of the Rate of Administration of Amino Acid Preparations on Urinary Wastage of Amino Acid Nitrogen in Man CHARLEY J. SMYTH, STANLEY LEVY and ANDREW G. LAMICHEK *J. Clin. Invest.*, 1948 28 418.

In 15 human subjects a comparison was made of the urinary loss of amino acid nitrogen in a 4 hour period after the administration of three different amino acid preparations, each containing 5.4 gm. of nitrogen. In 5 of these subjects the amino nitrogen content of the urine was determined for the same period after an infusion of physiological salt solution. The protein hydrolysate injection rates used were those shown by previous experience to approach the maximum tolerated rate of the majority of the patients. The greatest urinary amino acid nitrogen wastage occurred with the solutions prepared by the enzymatic hydrolysis of casein, which preparation contained large amounts of peptide nitrogen. The increased loss of total amino acid nitrogen seemed to be due mainly to bound amino acid nitrogen. In a 4 hour period the per cent of the total administered amino acid nitrogen lost in the urine ranged between 16 and 19.7 per cent. After the administration of either an acid hydrolysate of casein or a mixture of amino acids under similar conditions, usually only 3 to 5 per cent of the total amino acid nitrogen was found in the urine. In contrast, there was little free amino acid nitrogen lost after the administration of any of the preparations studied regardless of the speed of infusion. Mixtures of amino acids if well

of the bone which permits resumption of limited activities. The average survival amounted to 3 years. In 4 per cent the survival was more than 5 years. The patient who survived longest lived 10 years, but there were no permanent cures.

The preliminary intravenous injection of colloidal lead orthophosphate in conjunction with roentgen therapy leads to a three-fold effect in the malignant neoplastic invasion of the osseous system: the lead has a certain toxic action in itself; there is a direct destructive effect of the roentgen rays; and the heavy lead atoms deposited within the tumor area emit, under the influence of roentgen irradiation, ionizing secondary electrons which also act on the carcinoma cells. More recently attempts were made to use radioactive lead orthophosphate to aid internal irradiation. However, further investigations especially with "tagged" lead are necessary before worthwhile therapeutic efforts can be undertaken.

It is the authors' opinion that the method might serve as a control of the efficacy of various proposed procedures for the prevention of additional stone formation, as for example, the effect of an acid ash diet on the formation of alkaline stone. It also offers an opportunity for the study of the action of radioactive materials on associated infections of the urinary tract. The possible effect of the radioactive stone on the surrounding tissues must also be considered.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Some Supplementary Leads in Clinical Electrocardiography KARL ERIK GREWIN *Acta med. scand.* 1948 130 Supp. 109.

Considerable interest has been evidenced in electrocardiographic circles with regard to special leads. The author presents an adequate historical résumé of the subject, and reviews the contributions of many authors in Europe and the United States.

His critical evaluation of the many reports contained in the bibliography of the text are objective and interesting. The author also presents a report of his own experience in the field.

CHAUNCEY C. MAHER, M.D.

The Effects of Altered Arterial Tensions of Carbon Dioxide and Oxygen on Cerebral Blood Flow and Cerebral Oxygen Consumption of Normal Young Men SEYMOUR S. KETY and CARL F. SCHMIDT *J. Clin. Invest.* 1948 28 484.

The effects of the inhalation of 5 to 7 per cent CO_2 , 85 to 100 per cent O_2 , and 10 per cent O_2 were studied on the composition of arterial and internal jugular blood, on blood flow, oxygen consumption, and vascular resistance of the brain, and on cardiac output and blood pressure.

CO_2 inhaled in concentrations of 5 to 7 per cent produces an increase in cerebral blood flow averaging 75 per cent. O_2 inhaled in concentrations of 85 to 100 per cent is associated with a reduction in cerebral blood flow of 13 per cent, while 10 per cent O_2 produced an increase of 35 per cent in this function.

These changes are statistically significant. Calculation of cerebrovascular resistance indicates that in every case the change in blood flow is due to a change in the vascular resistance of the brain. Cerebral oxygen consumption is not significantly altered by changes in the composition of inspired air over the ranges studied. Mean arterial blood pressure rose significantly during the CO_2 and high O_2 inhalations and fell slightly with 10 per cent O_2 . The only significant change in cardiac minute volume was an increase which occurred during 10 per cent O_2 inhalation and resulted from an increase in rate rather than stroke volume.

WALTER H. NADLER, M.D.

The Effects of Various Amino Acids on Peripheral Blood Flow and Skin Temperature. MARTIN B. MACHET *J. Clin. Invest.* 1948 28 454.

Skin and rectal temperatures, total oxygen consumption, and blood flow through the hand were studied in 4 healthy young males before and after the oral administration of seven amino acids.

At an environmental temperature of 24 centigrade, glycine produced a significant rise in the skin temperature of the hands and in the dosage used

resulted in a significant increase in blood flow through the hand. These increases generally became apparent about 80 minutes after the glycine ingestion and were most marked after about 180 minutes. Save for similar but less marked increases in toe temperature, no significant temperature changes were noted elsewhere in the body, including the rectum. At 18° centigrade and 30° centigrade, no significant changes in rectal or skin temperature or peripheral blood flow followed the administration of glycine. At an environmental temperature of 24 centigrade, changes similar to those produced by glycine were observed after the administration of DL-phenylalanine, only a very slight and questionably significant increase in hand skin temperature and blood flow through the hand were noted after 1 (+) histidine monohydrochloride, no effect was produced upon rectal or skin temperature or on the peripheral blood flow after ingestion of 1 (+) glutamic acid, 1 (—) tyrosine, 1 (—) leucine, and DL-methionine.

Although five of the seven amino acids used caused a definite increase in oxygen consumption, there were no consistent quantitative relationships between total oxygen consumption and skin temperature or peripheral blood flow.

The Effects of the Rate of Administration of Amino Acid Preparations on Urinary Wastage of Amino Acid Nitrogen in Man. CHARLEY J. SMYTH, STANLEY LEVY, and ANDREW G. LANCHEAK. *J. Clin. Invest.* 1948 28 413.

In 15 human subjects, a comparison was made of the urinary loss of amino acid nitrogen in a 4 hour period after the administration of three different amino acid preparations, each containing 5.4 gm. of nitrogen. In 5 of these subjects, the amino nitrogen content of the urine was determined for the same period after an infusion of physiological salt solution. The protein hydrolysate injection rates used were those shown by previous experience to approach the maximum tolerated rate of the majority of the patients. The greatest urinary amino acid nitrogen wastage occurred with the solutions prepared by the enzymatic hydrolysis of casein, which preparation contained large amounts of peptide nitrogen. The increased loss of total amino acid nitrogen seemed to be due mainly to 'bound' amino acid nitrogen. In a 4 hour period, the per cent of the total administered amino acid nitrogen lost in the urine ranged between 1.6 and 19.7 per cent. After the administration of either an acid hydrolysate of casein or a mixture of amino acids under similar conditions, usually only 3 to 5 per cent of the total amino acid nitrogen was found in the urine. In contrast, there was little free amino acid nitrogen lost after the administration of any of the preparations studied, regardless of the speed of infusion. Mixtures of amino acids, if well

tolerated can be given at exceedingly rapid rates without causing increased spillage into the urine.

WALTER H. NADL, M.D.

Is Tuberculosis Present or Not? Histologic Examination or Inoculation? (A tuberculous or non? Examen histologique ou inoculation?) Erickson. *Urolog. Med. chir. acta* 943, 5, 5.

After the inoculation of guinea pigs with the fluid obtained from 40 patients with pleurisy the author obtained positive results in only 13 instances or 30 per cent. The clinical examination left no doubt concerning the tuberculous origin of the condition. Of 30 patients with tuberculous adenitis only 6 gave positive results on inoculation of guinea pigs.

The glands removed from the aforementioned group of 30 patients were studied histologically. Of 50 sections 43 showed signs of tuberculosis. Only in 5 cases the results were negative with regard to tuberculosis. In one of them the inoculation had given a positive result in an initial stage of the tuberculosis, while in the other case the calcification was so complete that no more signs of a specific lesion could be detected. All the glands were removed from the abdominal cavity. Similar results were obtained with tuberculous cervical ganglia. In only 1 of 5 cases was the result of the inoculation positive, while histologic study established the diagnosis of tuberculosis in the 4 others. The process was in full stage of evolution in all instances.

The third series of tests dealt with tuberculous material of various origins, collected in the course of operations. In only 6 of 10 tests was the inoculation positive, while histologic examination demonstrated the presence of tuberculosis in every instance.

If a surgeon is confronted with the question, "Is tuberculosis present or not?" undoubtedly the histologic examination will furnish the most reliable reply. In 90 per cent of the cases a negative inoculation does not determine whether active microbial activity is present or not. An investigation should be made to ascertain whether as small a number of bacilli as is generally assumed is sufficient to infect a guinea pig with tuberculosis.

Effect of Oral Caronamide on Plasma Penicillin Levels Following Large Intramuscular Doses of Penicillin. ALBERT O. SEELER, HARVEY SEIDELS COLLINS, and MAXWELL FINLAND. *Am J M S* 943, 6, 24.

Because of the rapid renal clearance of penicillin, merous agents have been examined for their ability to block the tubular excretion of this antibiotic and thereby enhance the plasma levels obtainable from any given dose. While diodrast and para-minohippuric acid are effective in this regard, their usefulness is restricted because of the need of large amounts by vein. Reports concerning the value of benzoic acid or sodium benzoate have been at variance.

The present study was undertaken to determine if caronamide given by mouth significantly en-

hances penicillin blood levels in man by reversibly inhibiting its excretion following the administration of single doses of 1 million units. Seven patients over 60 years of age, and 10 patients under 60 years were studied. Only those without any evidence of cardiac and renal disease were selected. Caronamide was given by mouth in tablet form: the older people receiving 3 gm. and the younger 4 gm. every 4 hours after administration of the penicillin. Plasma penicillin levels were determined at suitable intervals before, during and after caronamide therapy. Two patients under 60, and 3 patients over 60 years of age, in whom caronamide was significantly effective, were later studied with sodium benzoate beginning with 3 gm. and repeating with 4.5 gm. after a few days.

In 6 of the 7 patients over 60 years, caronamide therapy enhanced the penicillin levels strikingly. Six hours after the penicillin was administered the levels with caronamide were about 10 times as high as those without caronamide, and after 24 hours the penicillin level with caronamide averaged about 16 times, whereas at this time no penicillin could be detected in the control plasma. While the degree of enhancement varied widely in patients under 60, the plasma penicillin levels without exception were definitely higher during caronamide therapy than in the control period. After 4 hours the average difference was about 15 fold. Without caronamide little or no penicillin remained in the plasma 8 and 12 hours after the injection, while with caronamide 3 of the 10 patients evidenced penicillin levels as late as 18 hours.

Sodium benzoate had little if any effect on the penicillin level when given in doses of 3 gm. every 3 hours. When larger doses were administered the level was somewhat enhanced in 1 patient but not in the other 3. The only untoward sequelae to caronamide therapy were nausea in 4 patients with vomiting in 2 of them. While it is probable that penicillin levels could be further enhanced by increasing the sodium benzoate dosage, 3 patients complained of nausea with the dosage used.

Thus the oral administration of caronamide, together with large intramuscular doses of penicillin, makes it possible to maintain high penicillin levels with relative ease. The effect of caronamide in prolonging penicillin plasma levels is greater than that resulting from a 10 fold increase in the penicillin dosage.

D. VID H. LIND, M.D.

Plasma Penicillin Levels After Oral Penicillin with and without Oral Caronamide. HARVEY SEIDELS COLLINS, ALBERT O. SEELER, and MAXWELL FINLAND. *Am J M S* 943, 6, 248.

Studies on the effect of caronamide on the blood levels obtained during oral penicillin administration are the subject of this report. Male patients, both young and old in whom no definite evidence of renal damage, congestive failure or other serious illness was present were selected. On tablet containing 100,000 units of crystalline potassium penicillin G

buffered with 0.5 gm sodium citrate was given perorally every 4 hours beginning at 9 a.m. on day 1 and continued through 5 p.m. of day 4. Blood samples were drawn before during and after the caronamide administration at such intervals as to provide several observations of the 4 hour level.

Caronamide tablets were also given orally the first dose at 1 p.m. of day 2 with doses repeated every 4 hours at the same time as the penicillin the final dose being given at 1 p.m. of day 3. Plasma penicillin levels between penicillin doses were obtained before the first and last doses of caronamide and again 10 hours after the last dose of caronamide. The caronamide was employed in 3 different dosages 8 patients under the age of 60 received 4 gm. every 4 hours 9 patients over 60 were given 2 gm. every 4 hours and 7 patients over 60 received 3 gm. every 4 hours. In the latter group blood caronamide concentrations were determined.

Oral penicillin when administered alone in doses of 100,000 units every 4 hours could not be relied upon to maintain significant concentrations of the antibiotic in the plasma in persons under the age of 60. Penicillin levels of 0.03 units per ml. were maintained in more than two-thirds of persons over 60 years of age on the same dosage. Presumably this is due to a reduction in the functional tubular excretory mass in older people. This also accounts for the greater enhancing effect of caronamide in the aged.

Caronamide in oral doses of 4 gm. every 4 hours in persons under 60 and in doses of 3 gm. every 4 hours in those over 60 enhanced and prolonged the levels from oral penicillin. This effect however seemed to be less marked than that observed in patients who had been given penicillin intramuscularly. In the group in whom only 2 gm. of caronamide had been administered every 4 hours the results were quite irregular and enhancement of penicillin levels throughout most of the caronamide period was noted in only 2 patients.

Determinations of plasma caronamide concentration indicate that absorption and/or excretion of orally administered caronamide varies in different individuals. This may account for the differences in the enhancing and prolonging effect of the caronamide and for the duration of its effects.

In patients older than 60 years with slightly elevated blood nonprotein nitrogen levels the enhancing effect of caronamide persisted for at least 28 hours after the caronamide was discontinued. This effect was associated with persistence of significant caronamide concentrations in the blood of these patients.

Discussion of Multiple Tumors (Considerazioni sui tumori multipli) L. BARBERA. *Tumori* Milano 1948, 34: 47

The presence of two different benign tumors in the same individual or the occurrence of one benign and one malignant tumor is relatively frequent, contrary to a concurrent or successive development of two different malignant neoplasms. Three such cases are reported by the author.

A 57 year old woman had had her left breast removed at the age of 45. The diagnosis was adenocarcinoma. Twelve years later she developed an ovoid tumefaction of hard elastic consistency in the epigastric region. The roentgenologic examination disclosed the presence of an infiltrating and vegetating tumor on the lesser curvature of the stomach.

A 75 year old woman had been operated on at the age of 50 years for adenocarcinoma of the left breast. Five months prior to her admission to the hospital she developed meteorism and pain in the right lower quadrant of the abdomen. The autopsy revealed an adenocarcinoma of the right ovary with metastases in the spleen, omentum and liver.

The third patient a woman 64 years of age had undergone an amputation of her right breast at the age of 52 years for a medullary carcinoma. Ten years later an adenocarcinoma of the left breast necessitated the removal of that organ.

In all 3 cases the family history disclosed the occurrence of malignant neoplasms in one or more members of the family. In the first case 12 years had elapsed between the first and the second tumors in the second case the period was 25 years and in the third case 10 years. In all 3 instances the first tumor was located in the breast. All 3 women had had normal menstrual function and all were multiparas.

JOSEPH K. NARAT M.D.

Benign Giant-Cell Synoviomia and Its Relation to Xanthoma M. J. STEWART. *J. Bone Surg.* 1948, 30-B: 532

The majority of benign synoviomias occur in the flexor tendons of the fingers and thumb although some are of articular bursal or tenosynovial origin. Nearly three-quarters of the 40 cases of benign synoviomias observed in the routine surgical material from 1914 to 1947 at the General Infirmary at Leeds, were from the fingers in contrast to the occurrence of malignant synoviomias which usually arise from the joints or bursae of the lower limbs (with less than 4 per cent from the fingers). The sex ratio for benign synoviomias is 1:3 male to 1 female. These tumors are rarely found in persons under 10 years of age or over 60 years of age.

Benign tumors of synovial origin are more properly called benign giant-cell synoviomias. Since there is no xanthoma cell the term xanthoma is a misnomer. Cells of varied histogenesis including histiocytes fibrocytes serosal endothelial and synovial cells as well as neoplastic cells from the synovia (i.e. differentiated histiocytes) phagocytize lipid and cholesterol esters derived from extravasated blood disintegrating tissue or secreting products to form the large lipid laden cells found in these tumors.

FRANK B. QUEEN M.D.

Clinical and Histological Considerations of Liposarcoma (Considerazioni cliniche ed istogenetiche sul liposarcoma) ATTILIO BASILE. *Arch. Ital. Chir.* 1948 70: 183.

A rare case of liposarcoma with its various phases of malignant evolution is presented.

The 60 year old patient first noted a small tumor mass on the lower right chest wall, about as big as a nut 6 years previously. This gradually increased in size until it reached the size of a fetal head but did not cause any symptoms. Three months before he was seen however the increase in size became more rapid and the tumor also became quite painful. When seen it had attained the size of a large melon. Clinical investigation, including roentgenograms of the chest and aspiration biopsy were negative. A clinical diagnosis of liposarcoma was made and the mass excised under sodium pentothal anesthesia. The superficial part of the mass was divided into two parts by a deep sulcus but these parts were covered by the same capsule. On the under surface was found another mass as large as an orange penetrating into the deeper structure and adherent to the periosteum of the rib for an area of 3 by 4 cm and also to the adjacent structures. It was also firmly adherent to the superficial mass.

The superficial portion was found to be a lipoma however the deeper portion was found to possess an incomplete capsule. It was of a reddish gray color and rubbery in consistency. The microscopic picture was that of a liposarcoma.

From the study of this case and a review of the literature the author believes that the following considerations are correct.

Liposarcomas are rather rare and they may be encountered in any part of the body wherever there is adipose tissue. They are most frequently found subcutaneously or retroperitoneally.

Their morphology varies a great deal and hence the histologic interpretation and classification are difficult.

After evaluation of the microscopic reports and clinical course many of the fibrolipomas, pseudolipomas, fibromyxolipomas, and atypical lipomas reported in the literature will be considered true liposarcomas.

DUCTLESS GLANDS

Studies on the Stilben Estrogens. Action on the Prostate (Ricerche sugli estrogeni stilbenici. Azione sulla prostata) P. LA VOTTI and V. MORTOLO. *Tumori Milano*, 94:3 36-71

Eight dogs were used in the authors' experiments because the prostate glands of the animals are the best developed of all animals used for experiments and are most responsive to the estrogen. Six of these dogs were treated for a month with daily intramuscular injections of 1 mgm. of diethyl dihydrostilbene per kilogram of body weight. Four of these were castrated one week before initiation of the injections. The 2 remaining animals were similarly treated but the injections were terminated after 15 days. These animals weighed from 4,500 to 5,500 gm. and were from 6 to 12 months of age. The dosages employed were considered equivalent to those employed in the human being in the treatment of cancer of the prostate gland.

Histologic examination of the prostate glands of these treated animals disclosed in every instance a proliferation of the prostatic stroma and a metaplasia of the epithelium of the prostatic urethra and of the periurethral glands. The glandular epithelium of the prostate, on the other hand, exhibited regressive changes. Here the normally present cubical or cylindrical polystratified epithelium of the mucosal type was replaced by a monostratified flat epithelium apparently inactive as regards secretive function. There was no notable difference between the mode of response of the castrated animals from that of the noncastrated ones.

From their studies on this material the authors feel justified in postulating a direct action of the estrogenic preparation of an elective character on the prostatic tissues which suggests that this preparation is in the nature of a sexual hormone.

ANATOMIC AND CLINICAL RE-EVALUATION OF CAMPER'S, SCARPA'S, AND COLLES' FASCIAE

CHARLES E. TOBIN Ph.D., and JOHN A. BENJAMIN M.D., Rochester New York

THE subcutaneous tissue of the ventral abdominal wall particularly that distal to the umbilicus is described in the anatomic and clinical texts as consisting of a superficial fatty layer (Camper's fascia) and a deeper membranous layer (Scarpa's fascia). These two layers supposedly fuse and continue caudally as the dartos layer around the penis and scrotum wherein

the continuity of Camper's fascia is not fatty and involuntary muscle fibers are imbedded in these fused layers. In the perineum the continuations of the two layers are described as having the same pattern as that found over the ventral abdominal wall—a superficial fatty layer in the urogenital triangle, continuous with the fat in the ischioanal fossa and a deeper membranous layer (Colles' fascia) which is adherent to the inferior rami of the pubis and ischium and to the posterior border of the urogenital diaphragm. The continuity of the membranous layer into the ischioanal fossa is not well established.

From the Department of Anatomy and Department of Surgery, Division of Urology, The University of Rochester School of Medicine and Dentistry.

This study was supported in part by funds from the Dr. Henry C. Burwell Memorial and the Field Research Fund of the University of Rochester School of Medicine and Dentistry.

Fig. 18. Kodachrome of a sagittal section through the pelvis from a male cadaver with simulated urinary extravasation from the penile urethra. The red liquid latex injected into the perforated penile urethra has infiltrated all of the subcutaneous tissue between the dermis and the layers of Buck's fascia over the components of the penis in the perineum, the tunica vaginalis in the scrotum. Buck's fascia along the shaft of the penis, the intrinsic fascia over the spongyosus of the external oblique muscle, and into the superficial part of the ischioanal fossa. Note that the simulated extravasate is not limited by an inner membranous layer (Scarpa's-Colles' fasciae) but infiltrates the entire thickness of the subcutaneous tissue. $\times 0.17$

Fig. 19. Kodachrome of a partial dissection of the subcutaneous tissue of the lower abdominal wall, the penis, and scrotum from a male cadaver with simulated urinary extravasation from the penile urethra. The skin has been removed from the areas shown. Note the red latex, within the entire thickness of the subcutaneous tissue in the scrotum and immediately above the pubic symphysis. A larger quantity of simulated extravasate would have filled the entire thickness of the subcutaneous more cephalad over the ventral abdominal wall. $\times 0.15$

Fig. 20. Kodachrome of a dissection from a simulated case of extravasation. The skin has been removed and the layers of spermatic fasciae have been opened and retracted.

The simulated extravasate infiltrated the layers of spermatic fasciae superficial to the tunica vaginalis testis and ascended retrogradely upward into spermatic cord. $\times 0.3$

Fig. 21. Kodachrome of a dissection from a simulated case of extravasation from the penile urethra. The skin has been removed from the penis and scrotum. The subcutaneous tissue has been incised in the midline and reflected laterally over the lower abdominal wall and along the dorsal shaft of the penis. The spongyosus of the external oblique muscle is opened over the rectus abdominis muscle and down through the right inguinal canal (left side of illustration). The other layers of the rectus sheath have also been opened transversely and longitudinally near the umbilicus. Note that the yellow latex used to simulate the extravasate infiltrated the spermatic cord from the lower part of the scrotum and ascended retrogradely through the inguinal canal. Also note the simulated extravasate in the subcutaneous tissue along the shaft of the penis. Some of the latex also followed along the areolar tissue surrounding the superficial vessels and nerves and entered into the layers of abdominal muscles at the points where the vessels and nerves made their exits, as shown by the latex over the rectus sheath and on the spongyosus of the external oblique muscle. The sac of an indirect inguinal hernia is shown at the left subcutaneous inguinal ring (right side of figure). $\times 0.2$

The importance of the connections of the membranous layer to the deep fascia and periosteum of the body wall, and its continuity from the perineum around the scrotum and penis and over the ventral abdominal wall has been stressed in both anatomic and clinical texts because of its role (1) in limiting and directing the course of extravasated urine blood pus or gases (2) as a surgical guide in making drainage incisions and (3) in the approximation of the edges of the membranous layer in surgical closure of incisions in the ventral abdominal wall and in the perineum. The presence of an outer subcutaneous fatty layer in many parts of the body is accepted but there is some doubt as to the presence and the continuity of a definite deeper membranous layer (Scarpa's and Colles' fasciae) which is distinct from the outer fatty layer in the regions under consideration.

In the first place there appears to be no established definition of or priority for the terms Camper's and Scarpa's fasciae. The original papers by Camper (1768 and 1801)¹ and Scarpa (1809)² which might possibly have been the source of these terms dealt primarily with the anatomy and surgery of hernia and did not describe these layers as they are currently defined in the anatomic and clinical texts but through some sources as yet unidentified and by repetition of erroneous text descriptions and illustrations their names have become associated with these layers.

In 1811 Colles described a dense fascial layer in the perineum but he did not state whether it was fatty or membranous in character nor whether it was attached to the posterior border of the urogenital diaphragm as shown in the following quotation from his work:

"Now proceed to dissect the perineum. Raise the skin of the perineum extending the dissection beyond the tubera ischia to the thighs. This exposes to

A study of the available works by Petrus Camper on many phases of his medical research, as well as the *Oeuvres de Pierre Camper* (Paris, H. J. Jensen, 1803, 7-11) and the commemorative paper on the 50th anniversary of his death (*Nederl. Tijds. Geneesk.*, 190, 25, 1893-1917) contain no mention of his name associated with superficial fatty layer of subcutaneous tissue. The Dutch endologists most likely would have given him credit for naming this fascia if he had done so.

See John Struthers (1854) was the earliest source found to use the term Scarpa's fascia and then only for brevity of description rather than from authoritative definition (See: Tobias and Benjamin, 1944, for quotations from this paper).

view a strong fascia, which, on dissection will be found to cover the entire of the perineum and to blend itself with the structure of the scrotum. This fascia, although on a superficial view it appears continuous with the fascia of the muscles of the thigh will yet be found on closer examination to attach itself very firmly to the rami of the ischium and pubis. The texture and connexions of this fascia will serve to explain many of those phenomena attendant on the effusion of urine into the perineum by rupture or ulceration of the posterior part of the canal of the urethra. First, then you will find that this fluid when so effused although it forms a tumour in perineum, rarely terminates by suppuration and ulceration in this spot being here resisted by the dense and unyielding texture of the fascia, diffusion laterally towards the thighs is prevented by the close attachment of this fascia to the rami of the pubis and ischium while its progress forwards is favoured by a quantity of cellular substance, interposed between the surface of the perineal muscles and this fascia. Before you raise this superficial fascia of the perineum, it may be of use to make a transverse incision through it, midway between the tuberosities of the ischia and the arch of the pubis. This incision will enable you to see the muscles of the perineum, lying in their natural situations. Proceeding in the dissection, now remove the superficial fascia of the perineum, and then clear away some cellular substance covering the muscles so as to give a distinct view of them. Next remove these muscles taking care not to cut another fascia which lies under them and which we shall presently examine under the name of the anterior layer of the triangular ligament of the urethra or membranous septum of the perineum.

Therefore except in the case of Colles' fascia original definitions are not given for the extent and connections of these fascial layers, and the fatty or membranous nature of all three fasciae is not established. It is interesting to note that Scarpa's and Colles' fasciae are not mentioned in Gray's *Anatomy* until 1897 while Camper's fascia was not defined until the 1901 edition.

Secondly the indefiniteness as to the existence of the inner membranous layer is further evident from the accounts and illustrations given in the current texts and journals regarding the structure, position and connections of this layer from an anatomic and clinical point of view.

Histologically the subcutaneous tissue, except in certain limited regions of the body devoid of fat like the eyelids or external ear consists of a network of collagenous and elastic fibers surrounding lobules of fat, which extend from the periosteum or deep fascia to

the dermis. It is also now generally agreed that fat is formed within the fibroblast like cells (Clark and Clark, 1940) of the collagenous-elastic network in the subcutaneous tissue and that the proportion of fat to fibers varies with the obesity of the individual and with the area of the body under consideration. Therefore, except in certain regions where the subcutaneous tissue is devoid of fat, a definite membranous layer is not found. Besides, fat cells do not exist individually or in groups without an embedding connective tissue framework (Bremer and Weatherford 1944).

The current descriptions of these fascial layers found in the texts also do not agree with specific studies of the subcutaneous tissue. For example Blechschmidt (1930) in making a study of the subcutaneous tissue from many regions of the body in infants and adults based upon frozen sections stained with methyl blue or van Gieson stains and photographed by transillumination or reconstructed as waxed models observed no subdivision of the subcutaneous tissue into an outer fatty and an inner membranous layer. Only one layer consisting of fat embedded between strands of connective tissue was found between the body wall and the dermis in many areas of the body. Congdon and associates (1946) employing relatively thin sections of the ventral abdominal wall several inches in length cut with a razor blade and stained with a fat stain (Sudan IV) also demonstrated only one layer composed of sheets of connective tissue around deposits of fat in the subcutaneous layer. Any one of the collagenous-elastic sheets within the fat could be called the membranous layer. A similar finding was reported by Forster (1937) studying the cut edges of incisions made into or through the subcutaneous layer of the ventral abdominal wall of cadavers. The fibrous strands or sheets which might be called the membranous layers were embedded within the subcutaneous fatty panniculus with fat on both sides of the membranous sheets or strands. Other specific works dealing with the fascia of the human body such as the one by Singer (1935) also show that membranous layers are embedded within the fat. Some texts even consider the inner membranous layer as the under or deepest surface of the tela subcutanea,

as opposed to the preceding view (Davis 1918 McGregor, 1946). Further confusion is added since it is also stated that the superficial lymph nodes or vessels, vascular channels, and cutaneous nerves run between Camper's and Scarpa's fascia, whereas other texts indicate that they course within Camper's layer. In the perineum the posterior scrotal nerves and vessels are described as running deep to superficial to or within Colles' layer.

Although it is generally stated that extravasates in the perineum do not diffuse further dorsally than the limits of the superficial transverse perineal muscles (posterior part of the urogenital triangle) cases are recorded where extravasates were found along the sides of the anus in the ischioanal fossa (Wolfer 1918). The membranous layer is described as fused with the inguinal ligament or immediately distal to this ligament, with the fascia lata of the thigh. However, extravasates (particularly blood) have been known to pass down on the front of the thigh distal to these connections. The presence of one subcutaneous layer—fatty and membranous components intermingled and not two separate and distinct layers—would help to account for these anatomical and clinical differences.

Except for the microscopic studies mentioned above methods of definitely establishing the presence of these layers have been questionable. Grossly it is not possible in the majority of instances to demonstrate a definite inner membranous layer over the ventral abdominal wall or in the perineum of the normal cadaver or patient without creating such a layer artificially by dexterous use of the scalpel as many anatomists and clinicians are well aware. The collagenous-elastic components of the subcutaneous tissue may be thickened due to the resultant inflammatory process when large amounts of extravasated urine, blood, pus or gases are present in this tissue or these components may also be thickened by stress due to subjacent herniation or abnormal growths. In such instances a definite inflammatory or tensile membranous layer will easily be found—but usually with fat on each side of the layer.

A restudy of the subcutaneous tissue over the ventral abdominal wall, penis, scrotum,

and perineum was made in order to re-evaluate the anatomy and the clinical importance of Camper's, Scarpa's and Colles fasciae in view of (1) the indefiniteness of the structure of the subcutaneous tissue (2) the presence of a membranous layer (or layers) within or at the deep surface of this tissue and (3) the connections of the membranous layer to the deep fascia or periosteum which would limit and direct the spread of extravasates and infections.

MATERIAL AND METHODS

The following methods of approach were utilized to study the subcutaneous tissue of these regions.

1. Microscopic sections were made after fixation in 10 per cent formalin or Zenker acetic solution (a) from blocks of the hypogastric region of the ventral abdominal wall, including all the tissue from the peritoneum through the epidermis from 6 adult male cadavers of varying obesity for the normal adult structure of the subcutaneous tissue (b) from samples of the tissue called Scarpa's fascia," obtained from the abdominal wall of 5 patients at operation for the surgical concept of this layer and (c) from segments of the abdominal wall taken from 3 cases of urinary extravasation (from the penile urethra) to determine the tissue involved in this type of extravasation. In most instances, these tissues were

cut at 10 micra in paraffin and were stained with Heidenhain's modification of the Mallory connective tissue stain. Other samples of the same tissues were also cut in celloidin or with the freezing microtome and stained with hematoxylin and eosin orcein (for elastic fibers) or the Heidenhain's connective tissue stain in addition Sudan IV or Sudan black B were used as fat stains on selected sections.

2. Macroscopic sections were also made since the amount of tissue which can be cut in paraffin and celloidin or with the freezing microtome is so limited and hence the continuity and attachments of the connective tissue layers is interrupted by these methods. These macroscopic sections were made by embalming the larger specimens with, or immersing the smaller ones into 10 per cent formalin and subsequently freezing them with dry ice (solid CO₂). Such specimens consisted of (a) a portion of the body including the lower abdomen, pelvis and thigh from 5 full term male fetuses which were cut on a Vaughan high speed band saw (3 cut in the sagittal and 2 in the coronal plane) as 1/4 inch thick sections (b) comparable regions from 5 adult males similarly prepared and cut (3 in the sagittal and 2 in the coronal plane) as 1/4 inch thick sections (c) segments of the ventral abdominal wall approximately 3 to 5 inches long and 1 to 2 inches wide taken parallel to the mid-rectus incision distal to the umbilicus from 20 bodies at autopsy including all the tissue from the peritoneum through the skin were cut longitudinally as 3/8 inch thick sections (d) similar blocks were taken at a right angle to the mid-rectus incision both above and below the umbilicus

Brief histories of these 3 cases are:

CASE 1. G. E. S. M. H. No. 109, 60 year old, white male was admitted November 30, 1941 with symptoms of urinary extravasation and respiratory infection with cough of 5 days duration prior to admission. His abdomen was redness with subjunct swelling from the symphysis to the umbilicus, more marked on the right than the left side. His penis was gangrenous and tender; the scrotum was swollen, red, and tender. The patient was sent to the operating room immediately. The gangrenous areas of the penis were removed. Multiple incisions were made into the perineum, penis, scrotum, and abdomen, and drained. He died 7 days after admission with clinical diagnosis of lobes pneumonia as the cause of death. The embalmed body was subsequently sent to the Department of Anatomy for embalming and dissection. Samples of tissue were taken from the arione areas involved in the extravasation for microscopic study. This case was also used in previous study (Tobin and Benjamin, 1944).

the scrotum which required secondary closure and prolonged his hospitalization. He was discharged as cured on June 1, 1947.

CASE 2. W. A. R. G. H. No. A 14133 R. 74 year old, white male was admitted December 1, 1947 with pain and soreness in lower abdomen and locomotion for previous 24 hours. His penis was markedly swollen and gangrenous and leaking urine from fistula on the ventral surface. His scrotum and perineum were red and swollen. The patient was taken to the operating room for debridement of the penis and scrotum and for anastomosis of the ureters.

Fig. 1 Drawing to illustrate the method for producing simulated extravasation from the penile urethra. A sagittal section of the pelvis and perineum is shown for clarity. The penile urethra was visualized by means of a McCarthy panendoscope through which a fulgurating electrode was inserted to perforate the ventral wall of the urethra (at approximately 1 inch distal to the external sphincter) the corpus spongiosum urethrae bulbocavernosus muscle and its covering of Buck's fascia. The panendoscope and electrode were withdrawn and a modified Foley catheter with

the "bladder openings" ligated and its lumen perforated to correspond to the level of fulguration was then inserted through the penile urethra and into the bladder. The balloon was inflated and retracted against the bladder neck. The air passage of the catheter was compressed with a bemoostat to keep the balloon inflated. Compressed air followed by a diluted rubber solution (red or yellow liquid latex) was then injected via the catheter into the tissues of perineum to simulate course of extravasation. Arrows indicate pathway of injection mass. 0.75 normal size.

from 2 adult male bodies and were prepared in the same manner as the sections from (c) and (e) 4 samples (1 to 2 inches wide and 3 inches long) of the skin, subcutaneous tissue and underlying muscle or fascia from the lateral surface of the thigh arm and back were similarly prepared to compare the structure of the subcutaneous tissue in these regions with that of the abdominal wall from the bodies used in (d). These macroscopic sections were stained with aniline blue to demonstrate the form relations and connections of the collagenous strands or bands which make up most of the membrane-like layer over relatively large areas of the subcutaneous tissue.⁴

3 Gross dissections of the regions under consideration were also studied in 30 adult male cadavers in the dissecting rooms and photographs taken of the dissected subcuta-

neous tissue in some specimens to verify the conclusions drawn from the stained microscopic or macroscopic sections.

4 Cases of urinary extravasation were also utilized. In addition to the microscopic sections from the 3 real cases of extravasation mentioned before this type of extravasation was simulated in 10 cadavers by perforating the ventral wall of the penile urethra (approximately 1 inch distal to the external sphincter) the corpus spongiosum and its tunica albuginea, the bulbocavernosus muscle and its covering of Buck's fascia by means of a fulgurating electrode introduced through the urethra via a McCarthy panendoscope to visualize and direct the depth of perforation. Following this simulated perforation a Foley (24 or 26 French) catheter was inserted into the penile, membranous and prostatic urethra and for a short distance into the bladder. This catheter had been modified before insertion so that the

⁴See Tobin and Rumery (1948) for a more detailed account of the preparation and staining of such macroscopic sections.

and perineum was made in order to re-evaluate the anatomy and the clinical importance of Camper's Scarpa's and Colles fasciae in view of (1) the indefiniteness of the structure of the subcutaneous tissue (2) the presence of a membranous layer (or layers) within or at the deep surface of this tissue and (3) the connections of the membranous layer to the deep fascia or periosteum which would limit and direct the spread of extravasates and infections.

MATERIAL AND METHODS

The following methods of approach were utilized to study the subcutaneous tissue of these regions.

1. Microscopic sections were made after fixation in 10 per cent formalin or Zenker acetie solution (a) from blocks of the hypogastric region of the ventral abdominal wall including all the tissue from the peritoneum through the epidermis from 6 adult male cadavers of varying obesity for the normal adult structure of the subcutaneous tissue (b) from samples of the tissue, called "Scarpa's fascia," obtained from the abdominal wall of 3 patients at operation, for the surgical concept of this layer and (c) from segments of the abdominal wall taken from 3 cases of urinary extravasation (from the penile urethra) to determine the tissue involved in this type of extravasation.³ In most instances these tissues were

cut at 10 micra in paraffin and were stained with Heidenhain's modification of the Mallory connective tissue stain. Other samples of the same tissues were also cut in celloidin or with the freezing microtome and stained with hematoxylin and eosin orcein (for elastic fibers) or the Heidenhain's connective tissue stain in addition Sudan IV or Sudan black B were used as fat stains on selected sections.

2. Macroscopic sections were also made since the amount of tissue which can be cut in paraffin and celloidin or with the freezing microtome is so limited and hence the continuity and attachments of the connective tissue layers is interrupted by these methods. These macroscopic sections were made by embalming the larger specimens with or immersing the smaller ones into 10 per cent formalin and subsequently freezing them with dry ice (solid CO₂). Such specimens consisted of (a) a portion of the body including the lower abdomen, pelvis and thigh from 5 full term male fetuses which were cut on a Vaughan high speed band saw (3 cut in the sagittal and 2 in the coronal plane) as $\frac{1}{4}$ inch thick sections (b) comparable regions from 5 adult males similarly prepared and cut (3 in the sagittal and 2 in the coronal plane) as $\frac{1}{2}$ inch thick sections (c) segments of the ventral abdominal wall approximately 3 to 5 inches long and 1 to 2 inches wide, taken parallel to the mid rectus incision distal to the umbilicus from 20 bodies at autopsy including all the tissue from the peritoneum through the skin were cut longitudinally as $\frac{1}{2}$ inch thick sections (d) similar blocks were taken at a right angle to the mid rectus incision both above and below the umbilicus

Brief histories of these 3 cases are:

CASE 1. O. K. S. M. H. N. 9906, 60 year old, white male was admitted November 30, 1942 with symptoms of urinary extravasation and respiratory infection with cough of 8 days duration prior to admission. His abdomen was reddened with subacute swelling from the epiphys to the umbilicus, more marked on the right than the left side. His penis was gangrenous and tender; the scrotum was swollen, red, and tender. The patient was shut to the operating room immediately. The gangrenous areas of the penis were removed. Multiple incisions were made into the perineum, penis, scrotum, and abdomen, and drained. He died 7 days after admission with clinical diagnosis of lobar pneumonia as the cause of death. The unclaimed body was subsequently sent to the Department of Anatomy for embalming and dissection. Samples of tissue were taken from the various areas involved in the extravasation for macroscopic study. This case was also used in previous study (Tobin and Pennington, 1944).

CASE 2. E. G. R. M. H. N. 99324, 45 year old, white male was admitted April 30, 1947 with chills and severe pain in the groin, scrotum, and perineum which had been swollen and tender 4 days prior to admission. The next day he became feverish, scrotum, penis, and lower abdominal wall were red and swollen with typical outline of extravasation from the penile urethra, but he had no difficulty urinating. Multiple incisions were made into the scrotum, penis, and lower abdominal wall and drained. A sample of skin and subcutaneous tissue was taken as inch above the fold point of the left inguinal ligament for microscopic study. A diagnosis of urinary extravasation with bacterial infection of these areas was made. There was sloughing of the tissues particularly over

the scrotum which required secondary closure and prolonged hospitalization. He was discharged as cured on June 9, 1947.

CASE 3. W. A. R. G. H. N. 4333 R, 74 year old, white male was admitted December 15, 1947 with pain and soreness in lower abdomen and incontinence for previous 24 hours. His penis was markedly swollen and gangrenous and leaking urine from the urethra on the external surface. His scrotum and perineum were red and distended, with involvement of the abdominal wall from the pubic to the umbilicus and laterally to the iliac crests and for an inch below the inguinal ligaments, as well as to the anterior part of the ischiofemoral fossa, along the sides of the anus. A suprapubic cystostomy was done. Multiple drainage incisions were made into the subcutaneous tissue of the involved areas and drains were placed therein. A sample of the skin and subcutaneous tissue was taken, both distal and lateral to the umbilicus from the right side for microscopic study. There was considerable sloughing of skin and subcutaneous tissue from the involved areas, which required prolonged hospitalization. He had similar extravasation about 10 years previously due to an injury of his perineum. He was discharged February 1948, after unilateral orchiectomy and plastic repair of the penis.

Fig. 1. Drawing to illustrate the method for producing simulated extravasation from the penile urethra. A sagittal section of the pelvis and perineum is shown for clarity. The penile urethra was visualized by means of a McCarthy panendoscope through which a fulgurating electrode was inserted to perforate the ventral wall of the urethra (at approximately 1 inch distal to the external sphincter) the corpus spongiosum urethrae, bulbocavernosus muscle and its covering of Buck's fascia. The panendoscope and electrode were withdrawn and a modified Foley catheter with

the bladder openings" ligated and its lumen perforated to correspond to the level of fulguration. was then inserted through the penile urethra and into the bladder. The balloon was inflated and retracted against the bladder neck. The air passage of the catheter was compressed with a hemostat to keep the balloon inflated. Compressed air followed by a diluted rubber solution (red or yellow liquid latex) was then injected via the catheter into the tissues of perineum to simulate course of extravasation. Fig. 3. Photomicrograph of a paraffin section through the abdominal wall from an emaciated adult male. The subcutaneous tissue consists of strands of collagenous and elastic fibers around deposits of fat (clear areas) between the dermis, *D* and the sheath of the rectus abdominis muscle, *R*. The collagenous fibers in the inner part of the subcutaneous tissue immediately above the rectus sheath might possibly be interpreted as a membranous layer in this section. Compare with Figures 3 and 4. Heidenhain connective tissue stain. $\times 90$.

Fig. 4. Photomicrograph of a paraffin section through the abdominal wall from an obese adult male. Note the increased amount of fat (clear areas) between collagenous and elastic fibers and no suggestion of a definite inner membranous layer in the subcutaneous tissue. St from which section was taken. The stain used, and the labels are the same as for Figure 3. $\times 90$.

Fig. 5.

Fig. 4. Photomicrograph of a paraffin section through the abdominal wall from an obese adult male. The laminated structure of the fat is surrounded by collagenous and elastic fibers in the subcutaneous tissue does not suggest any division of this tissue into an outer fatty and an inner membranous layer. St from which this section was taken, the stain used, and the labels are the same as for Figure 3. $\times 90$.

Fig. 5. Photograph of a macroscopic, frozen section cut in the longitudinal plane through the para-rectus region of the abdominal wall from an obese, adult male. Collagenous tissue was stained with indigo blue. Note that the subcutaneous tissue between the dermis, *D* and the rectus abdominis muscle and sheath, *R*, consists of collagenous fibers around the alveoli of fat. As demonstrated in Figures 3 and 4, there is no subdivision of the subcutaneous tissue into an outer fatty layer and an inner membranous layer. $\times 60$.

Fig. 6 Photograph of macroscopic, frozen sections cut slightly obliquely in the sagittal plane through the pelvic area of a full term male infant. Collagenous fibers in these sections was stained with aniline blue. Note the strands of collagenous fibers around the fat deposits in the subcutaneous tissue in both sections A and B with no separation of this tissue into an outer fatty and an inner membranous layer over the abdominal wall or over the perineum. $\times 0.8$.

bladder openings were ligated and other apertures made into the lumen of the catheter to correspond to the fulgurated perforation. The balloon was then inflated and retracted against the bladder neck with considerable force to prevent the injection mass from entering the bladder. Compressed air followed by an injection mass red or yellow liquid latex was then injected into the catheter so this mass could simulate the course of extravasation (Fig. 1). These cadavers were afterwards embalmed via the femoral artery with 10 per cent formalin. Subsequently 3 of these cadavers were studied by progressive stages of dissection to determine the layers involved in this simulated extravasation whereas the lower abdomen, pelvis and thigh of the other 7 were frozen in dry ice and cut into sections (1 to $1\frac{1}{2}$ inches thick) on a band saw either in the sagittal or coronal plane to avoid interrupting the layers which result when dissection is used as a means of study. These sections were used to observe the course of the simulated extravasation.

OBSERVATIONS

Anatomical. There was no evidence of a subdivision of the subcutaneous tissue over the ventral abdominal wall and the perineum into an outer fatty (Camper's) and an inner membranous (Scarpa's-Colles') layer for this tissue in both microscopic and macroscopic sections of newborn and adult male specimens consisted of a single layer composed of collagenous and elastic fibers¹ in the form of sheets or bands enclosing deposits of fat (Figs. 2 through 11). The subcutaneous tissue over the penis and scrotum consisted of a loose network of collagenous and elastic fibers in which isolated bundles of smooth muscle (dartos) fibers were embedded. The cutaneous nerves, superficial vessels, lymph nodes (Figs. 7 and 9) and vessels were embedded in this one common, continuous layer and not embed-

¹Collagenous fibers made up the greater part of the sheets or bands enclosing the deposits of fat, although elastic and reticular fibers were also present in much smaller amounts. Therefore in the subsequent discussion, the term "fibers" will be used in reference to the collagenous fibers.

bladder openings were ligated and other apertures made into the lumen of the catheter to correspond to the fulgurated perforation. The balloon was then inflated and retracted against the bladder neck with considerable force to prevent the injection mass from entering the bladder. Compressed air followed by an injection mass red or yellow liquid latex was then injected into the catheter so this mass could simulate the course of extravasation (Fig. 1). These cadavers were afterwards embalmed via the femoral artery with 10 per cent formalin. Subsequently 3 of these cadavers were studied by progressive stages of dissection to determine the layers involved in this simulated extravasation whereas the lower abdomen, pelvis and thigh of the other 7 were frozen in dry ice and cut into sections (1 to 1½ inches thick) on a band saw either in the sagittal or coronal plane to avoid interrupting the layers which result when dissection is used as a means of study. These sections were used to observe the course of the simulated extravasation.

OBSERVATIONS

Anatomical. There was no evidence of a subdivision of the subcutaneous tissue over the ventral abdominal wall and the perineum into an outer fatty (Camper's) and an inner membranous (Scarpa's-Colles') layer, for this tissue in both microscopic and macroscopic sections of newborn and adult male specimens consisted of a single layer composed of collagenous and elastic fibers in the form of sheets or bands enclosing deposits of fat (Figs. 2 through 11). The subcutaneous tissue over the penis and scrotum consisted of a loose network of collagenous and elastic fibers in which isolated bundles of smooth muscle (dartos) fibers were embedded. The cutaneous nerves, superficial vessels, lymph nodes (Figs. 7 and 9) and vessels were embedded in this one common continuous layer and not embed-

*Collagenous fibers made up the greater part of the sheets or bands enclosing the deposits of fat, although elastic and reticular fibers were also present in much smaller amounts. Therefore in the subsequent discussion, the term "fibers" will be used in reference to the collagenous fibers.

Fig. 7. Photograph of macroscopic sections from the same specimen shown in Figure 6 and cut and stained by the same methods. I. A, not the continuity of the superficial collagenous fibers in the subcutaneous tissue over the abdomen onto the thigh, here the deeper fibers are attached to the fascia lata, and in B the direction of the collagenous fibers, plat, the ischioanal fossa around the rectum, R. Compare the direction of the latter fibers with those over the perineum shown in Figures 6 A and B. The location of the inguinal lymph nodes, LN, iliofemoral, the subcutaneous layer is shown. $\times 8$.

ded within a fatty layer between a fatty and membranous layer or deep to a definite membranous layer in the lower abdominal, penile, scrotal and perineal regions. In dissections of these regions a cleavage plane could be made along any one of the several sheets or bands of fibers around the fatty alveoli in addition to the artificially created membrane-like layer in the inner part of the subcutaneous tissue (Figs. 12 and 13).

The subcutaneous tissue in these regions was continuous with that in adjacent areas of the body and had the same structure. However the direction, the extent, and the attachment of the collagenous fibers to the deep fascia and periosteum of the body wall were related to the degree of movement possible in the overlying skin. Where considerable movement was possible the course of the fibers was mainly parallel to the skin and in the form of laminae made up of strands or bands several inches in length (Figs. 5, 6 and 9). In such areas only areola like fibers attached the sub-

cutaneous tissue to the subjacent body wall. In the midline distal to the umbilicus the deeper fibers were thickened to form the suspensory ligament of the penis. Cephalad to this ligament there was no evidence of a definite partition formed in the midline by a continuous attachment of fibers to the linea alba which would create two lateral compartments over the ventral abdominal wall to limit the spread of extravasates to either side exclusively. However at the junction of the inferior extremity with the pelvis the fibers were very firmly fused to the deep fascia or periosteum of the body wall. Many of these fibers were attached to the inguinal ligament or to the fascia lata of the thigh. A smaller superficial (subdermal) group of fibers surrounding deposits of fat continued in their course down the thigh (Figs. 7, 9 and 22). In the perineum the fibers were connected laterally to the periosteum of the inferior ramus of the pubis and ischium (Figs. 10 and 22). There was a weak attachment of these fibers to the midline over

Fig 8 Photograph of a macroscopic, frozen section cut in the coronal plane through the perineum of a newborn male infant. Note the arrangement of the collagenous strands stained with aniline blue between the components of the penis, *P* and the skin of the perineum. There is no definite layer which could be designated as a membranous (Colles') layer. $\times 0.9$.

Buck's fascia covering the bulbocavernosus muscle but this attachment was not as firm as that to the rami of the pubis and ischium. At the posterior border of the urogenital triangle the majority of these fibers coursed cephalad into the ischiorectal fossa and were at approximately a right angle to those superficial to the Buck's fascia over the 3 components of the penis in the perineum (Figs 6, 7, 8, 10, 11 and 22). There was no evidence that these fibers attached to the posterior border of the urogenital diaphragm.

Clinical. The finding of one and not two separate (outer fatty and inner membranous) layers of subcutaneous tissue in the anatomic observations was verified from sections of the tissue designated as the membranous (Scarpa's) layer removed from the abdominal wall at operation. Such tissue consisted of strands or sheets of collagenous fibers embedded in or surrounding fat (Fig. 14) and not a distinct membranous layer. Sections of the skin and subcutaneous tissue from the 3 cases of urinary extravasation also showed that the extravasate was within the subcutaneous laminae formed by the sheets or strands of fibers around the lobules or alveoli of fat (Figs 15, 16 and 17) and not limited by an inner membranous layer nor deep to the whole subcutaneous layer—between it and the intrinsic fas-

Fig 9 Photograph of a macroscopic, frozen parasagittal section through the pelvis and thigh of an adult male. Collagenous tissue stained with aniline blue. Note the structure of the collagenous fibers around the deposits of fat in the lower abdominal region and the continuity of the superficial fibers on the thigh, whereas many of the deeper fibers are connected to this ligament *IL*. Superficial nerves, blood vessels, lymph nodes, *LN*, and vessels are embedded within this single layer of fat and collagenous fibers and not between an outer fatty and an inner membranous layer. $\times 0.18$.

ciae covering of the muscles of the body wall. In some instances extravasates may probably be found in such a location, but from these 3 real cases and the 10 simulated cases of extravasation it seems unlikely that this is the usual pathway, for in all the simulated cases the injection mass was within and not deep to the subcutaneous layer (Figs 18, 19, 20 and 21). The extravasate followed the course of the fibrous sheets or bands around the fat deposits and infiltrated the subcutaneous layer from the body wall to the dermis (Figs 15 through 21).

The loose "areola like" layer of collagenous and elastic tissue in the scrotum and penis was infiltrated readily with the injection mass (Figs 18, 19, 20 and 21). This mass was also found in the subcutaneous tissue between the

Fig.

Fig. 13.

Fig. 10. Photograph of macroscopic, frozen section, cut in the coronal plane through the perineum of an adult male. Collagenous fibers are stained (ith aniline blue N) to the base of definite membranous layer between the bulbocavernosus muscle, BCM, around the corpus spongiosum urethrae containing the urethra, U, and the skin of the perineum. Many of these collagenous strands connect the perineum of the inferior ramus of the pubis and ischio. There is loose attachment of the collagenous fibers to Buck's fascia covering the bulbocavernosus muscle. $\times 88$.

Fig. 11. Photograph of macroscopic, frozen section cut slightly obliquely in the coronal plane through the ischio-rectal fossa of the same specimen shown in Figure 10. Note the cephalic direction of the collagenous strands stained (ith aniline blue) around the deposits of fat in the ischio-rectal fossa on each side of sphincter and externus muscle, S. These strands are approximately at right angle to those collagenous strands which lie over the components of the penis in the urogenital triangle. Compare (ith Figures 8 and 9. $\times 44$.

Fig. 12. Photograph of dissection of the subcutaneous tissue over the ventral abdominal wall showing the inner membranous layer (Scarpa's fascia) dissected by the students in gross anatomy. The skin has been reflected and the usual concept of the superficial fatty layer (Camper's fascia) dissected from the inner membranous layer and reflected laterally. Hemostats are elevating the "membranous layer" from the deep fascia over the psoas muscle of the external oblique muscles. The suspensory ligament of the penis is shown in the midline between the reflected flaps of the fatty layer. $\times 0.5$.

Fig. 13. Photograph of the same specimen shown in Figure 12. Hemostats are elevating the dissected "inner membranous" layer but an additional membranous layer superficial to that dissected by the students, is shown over the handles of the forceps in the lower part. Three such membranous layers are found in this specimen of average obesity indicating that dexterity with scalpel can create membranous layers in different depths of subcutaneous tissue. Compare (ith Figures 5 and 9 for collagenous strands which may be utilized as cleavage lines in dissection. $\times 0.25$.

Fig. 14. Photomicrograph of the tissue designated as Scarpa's fascia, removed from the subcutaneous tissue approximately an inch cephalad to the midpoint of the inguinal ligament, during repair for inguinal hernia in an adult male. This sample of Scarpa's fascia consists of layers of collagenous fibers surrounding fat and blood vessels and is not a distinct membranous layer. Heidenhain's connective tissue stain. $\times 9$.

dermis and Buck's fascia along the shaft of the penis and in the subcutaneous layer over the ventral abdominal wall. Except in 1 instance the simulated extravasate did not extend further distally than 1 inch below the inguinal ligament. In several cadavers it did extend into the superficial part of the subcutaneous tissue around the anus but not more than a half inch into the ischioanal fossa (Fig. 18).

It is well known that extravasates through the penile urethra entering the vascular corpus spongiosum urethrae introduce urine, bacteria, and other matter into the vascular system. Subsequent infiltration of the subcutaneous tissue occurs after the extravasate has spread through the coverings of the corpus spongiosum urethrae and Buck's fascia. These studies with simulated extravasation wherein the colored injection mass imitated the course of the urine indicate that the extravasate may follow additional courses which could not readily be visualized in true cases of extravasation except those of several days' duration in which local inflammation of the tissue would delineate the course. For example, as the simulated extravasate courses within the subcutaneous layer it may infiltrate the loose areolar tissue around the walls of cutaneous vessels and nerves and follow retrogradely along their course to enter between the layers of the abdominal wall. The point of attachment of the testes to the lower part of the scrotal sac also consists of loose areolar tissue. The simulated extravasate in 8 of the 10 experi-

Fig. 15. Photomicrograph of a section through the ventral abdominal wall approximately an inch cephalad to the midpoint of the inguinal ligament from the embalmed cadaver of an adult male who had urinary extravasation from the penile urethra (See Case 1 in footnote). This section was cut on the freezing microtome and stained with Sudan black B to show the deposits of fat in the necrotic tissue on each side of the path of extravasation. The extravasate was not deep to a membranous (Scarpa's) layer but within the one common layer of subcutaneous tissue. The gap in the left side of this section is part of the original drainage incision in the subcutaneous tissue. Part of the epidermis was sloughed off. Note its absence over the dermis D in certain areas. The aponeurosis of the external oblique muscle is labelled, E. $\times 65$.

mental extravasations was found to pass through this areolar tissue and to enter within the layers of the spermatic cord. Via this route it coursed retrogradely upward within the spermatic cord (Fig. 20), through the inguinal canal in cases where inguinal hernia had distended the canal (Fig. 21) and infiltrated the retroperitoneal tissue of the abdomen.

In many clinical cases following rupture of the mucous membrane in the penile urethra the vascular erectile tissue of the corpus spongiosum urethrae may be infiltrated with the extravasate before subsequent rupture of the tunica albuginea, bulbocavernosus muscle and its covering of Buck's fascia result in infiltration of the subcutaneous tissue in this area. In other cases the mucous membrane of the penile urethra may form a sinus tract through the erectile tissue and its coverings. The extravasate in such cases would involve the subcutaneous tissues only and by means

Fig. 6, left. Photomicrograph of a paraffin section of the skin and subcutaneous tissue removed from the area immediately above the left inguinal ligament from a patient with urinary extravasation from the penile urethra (See Case 3 in footnote 1) at the time of surgical drainage of the areas of extravasation. Note from the dermis, *D* inward, the extravasated urine, bacteria, and blood cells followed the course of the collagenous fibers surrounding the alveoli of fat as shown by the dark stained material along the fibers. Heidenhain's connective tissue stain. $\times 8$.

Fig. 7. Photomicrograph of a paraffin section of the skin and subcutaneous tissue removed from an area 1 inch lateral and distal to the umbilicus from the right side of a patient at the time of surgical drainage of the areas involved in urinary extravasation from the penile urethra (See Case 3 in footnote 1). Note in Figure 6, the extravasate followed along the collagenous fibers surrounding the deposits of fat and extended to under surface of dermis, *D*. Also note position of cutaneous vessels, *CV* within subcutaneous fat. Heidenhain's connective tissue stain. $\times 8$.

of this tract by pass the erectile tissue. To test whether the method used in the simulated extravasation studies would involve the same tissues as those in the clinical cases with sinus tract formation liquid latex was injected directly into the subcutaneous tissue over the perineal components of the penis in 2 cadavers. This injection mass was found to follow the same pathways as those described above for the simulated extravasations from the perforated penile urethra. In other studies the

injection mass when injected into the subcutaneous tissue above the pubic symphysis likewise filled the same areas in 2 cadavers. Finestone (1941) has made similar studies using a radiopaque injection mass and found the tissue involved to be the same as we have described.

DISCUSSION

Although the subcutaneous tissue in most regions of the body is described as consisting of only one layer that in the region of the low

Fig. 23 Diagrammatic drawing to illustrate the structure of the subcutaneous tissue over the lower abdominal wall, proximal part of the thigh, and the perineum. For simplicity the shaft of the penis and the scrotum are shown only as cross sections through their bases. The skin and the layers which can be dissected in the subcutaneous tissue proximal and distal to the inguinal ligament are shown in the left side of this diagram. A cross section from the same area is shown in insert a. Note, as shown by the arrows in the insert a, and the lines in the dissected area, that the majority of the fibers around the deposits of fat pass from one lamina (of fat and fibers) to the next subjacent layer. The fibers are attached to the inguinal ligament or to the fascia lata distal to this ligament. A smaller finer group of fibers and fat, immediately beneath the skin continue directly from the lower abdominal area onto the thigh. The composition of the subcutaneous tissue in the perineum is shown by a dissection and a cross section (insert b). In the dissection several layers could be created in the subcutaneous tissue and, as indicated by the arrows in the insert b, the majority of the fibers course parallel to the skin and the components of the penis in the urogenital triangle of the perineum. However these fibers are continuous with similar fibers in the ischioanal fossa of the anal triangle, but in the latter location they run at approximately a right angle to those over the urogenital triangle. These fibers did not have a definite attachment to the superficial transverse perineal muscles nor to the posterior border of the urogenital diaphragm, *U.G.D.* There was no evidence of a division of the subcutaneous tissue in the perineum thigh, or lower abdomen into a definite outer fatty and inner membranous layers. Compare with Figures 9, 10 and 11 for the structure of the subcutaneous tissue in these areas as seen in stained sections. X 33

er abdominal wall and in the perineum has been thought to be subdivided anatomically and clinically into an outer fatty and an inner membranous layer. It is interesting to note that approximately 90 years elapsed after Camper Scarpa and Colles published their respective works from which the terms now used for the layers of the subcutaneous tissue in these regions might have been taken before their names were introduced into the anatomic and clinical texts. Before that time most of the texts stated that only one layer was present

and only a few years before these proper names were introduced in the texts were two layers assumed to be in the subcutaneous tissue. It is most likely if these layers were present anatomists and clinicians at that time would have observed them. The evidence presented in this present work indicates that the older idea of one subcutaneous layer in the regions involved in extravasates from the penile urethra should be adopted again in keeping with the same structure of this tissue in the body.

The question may be raised what governs and directs the classical spread of such extravasates if there is only one layer present in the perineum scrotum penis and abdominal wall, which is continuous with the general subcutaneous layer in other parts of the body. The attachments of the collagenous fibers in the subcutaneous tissue to deeper structures at certain areas (such as the inguinal ligament or adjacent fascia lata—Figs. 9 and 22—and the inferior rami of the pubis and ischium—Figs. 10 and 22—together with changes in direction of these fibers in certain areas as in the ischiorectal fossa—Figs. 6 8 10 11 and 22) can account for the limitations. Differences in the structure of this tissue (areolar in the scrotum and around the penis, and fibrous strands surrounding fat in the form of loose laminae parallel to the surface of the skin over the perineum—Figs. 6 8 and 10—and ventral abdominal wall—Figs. 2 3 4 5 6 7 and 9) can account for its ease of spread in the typical directions. In some cases extravasated blood from injury in the perineum has been known to follow not only this typical course but also to extend into the subcutaneous tissue over the thigh and posteriorly along the sides of the rectum in the superficial part of the ischiorectal fossa.

Drainage incisions for extravasates are usually made to a depth which penetrates the whole of the subcutaneous layer. Yet it is known that in many instances the extravasate may be encountered in the superficial part of the subcutaneous tissue once the dermis is incised and such material may be found within the entire thickness of the subcutaneous tissue although in certain early cases the extravasate may be mainly in the deeper part of this tissue before infiltration of the more superficial part has occurred. In the closure of incisions in these areas the entire depth of the subcutaneous tissue does not have to be entered before collagenous and elastic fibers are encountered for they are found even in the superficial part of this so called fatty layer (Figs. 2 3 4 5 16 17 and 22).

As pointed out above unless the case of true extravasation is one of comparatively long standing wherein the inflammation with in this tissue would outline the course of the

extravasate little can be known of its exact or probable extent. The information gained from these simulated extravasation studies suggests that the extravasate may involve other tissues than those usually described in real cases of extravasation. Extravasates may also course retrogradely within the areolar tissue along the sides of the superficial vessels and cutaneous nerves to enter between the layers of the abdominal wall or within the layers of the spermatic cord in addition to passing within the superficial part of the subcutaneous tissue down the front of the thigh or in the ischiorectal fossa.

The concept of one layer of collagenous and elastic fibers around deposits of fat and not two distinct layers (an outer fatty and an inner membranous) in the subcutaneous tissue has been recognized for many years. Langer (1861) Kocher (1907) and Cox (1941) suggested a similar structure for the subcutaneous tissue and showed that the cleavage lines of the skin are related to the direction of the fibers in this tissue as well as their connection to the deep fascia or periosteum in certain areas.

There appears to be no justification for the concept of an outer fatty (Camper's) and an inner membranous (Scarpa's-Colles') fascia in the subcutaneous tissue from historical priority of definition anatomic structure, or the involvement of this tissue in real or simulated cases of urinary extravasation. This erroneous concept was introduced into the medical literature through sources as yet unidentified and has been perpetuated by tradition and inadequate means of study. The authors (Tobin and Benjamin 1944 and 1946) also conformed to the usual concept of the form and attachments of these layers when dissection was used as a means of approaching such problems.

SUMMARY

The present concept of an outer fatty (Camper's) and an inner membranous (Scarpa's-Colles') fascia in the subcutaneous tissue over the ventral abdominal wall and in the perineum and their role in directing and limiting the spread of extravasates are not justified for the following reasons:

1. There are many inconsistencies in the anatomic texts as to the structure and continu-

ity of these layers and their relation to the cutaneous nerves and vessels which may be due to the fact that no priority of definition could be found for these fasciæ since Camper, Scarpa, and Colles did not describe these layers as they are currently defined

2 Studies from microscopic and macroscopic sections from these regions show that the subcutaneous tissue is made up of only one layer—strands or sheets of collagenous and elastic fibers surrounding deposits of fat which is similar to the structure of this tissue in other areas of the body

3 Sections taken from and dissections made of real and simulated cases of extravasation from the penile urethra demonstrate that the extravasates are within the one common layer and not limited by a deep membranous (Scarpa's-Colles') layer. The attachment of the collagenous and elastic fibers to the deep fascia or periosteum of the body wall as well as the change in direction of these fibers and the compactness or looseness of the one subcutaneous layer account for the direction and limitation of the spread of extravasates

GASTRIC RESECTION FOR ESOPHAGITIS AND STRICTURE OF ACID-PEPTIC ORIGIN

OWEN H. WANGENSTEEN M.D., F.A.C.S. and N. LOGAN LEVEN M.D., F.A.C.S.
Minneapolis Minnesota

IN September 1939 a patient was operated upon by one of us, (O.H.W.) at the University of Minnesota Hospitals, for massive hemorrhage from a duodenal ulcer. The patient had an antecedent story of esophagitis for which one of us (N.L.L.) had supervised frequent esophageal dilatations over a period of approximately 4 years. An unexpected windfall from this operation was that dilatation of the esophageal stricture became unnecessary following the procedure of gastric resection for the duodenal ulcer. In the course of the operative procedure undertaken to control the gastric hemorrhage simultaneous extensive gastric resection was performed to thwart further ulcer difficulty. Three years later the same sequence of events was observed in another patient undergoing gastric resection for a gastrojejunal ulcer (following gastrojejunostomy performed for an obstructive duodenal ulcer) this patient also had esophagitis necessitating esophageal dilatation. On the basis of the cessation of necessity for continued esophageal dilatation in the first patient whose esophageal stricture had been dilated more than 100 times one of us (O.H.W.) ventured to predict that successful relief of the ulcer diathesis in this instance too might make further esophageal dilatation unnecessary. Such proved to be the case.

When therefore a third patient presented herself with a picture of a congenitally short esophagus, an esophageal stricture and gastric hemorrhage of unknown etiology it was reasoned that the stricture in this instance too might be occasioned by the regurgitation of hydrochloric acid into the lower reaches of the

esophagus. This latter patient was referred for resection of the esophageal stricture. She was in very poor physical condition presenting all the clinical evidences of hypoproteïnemia from starvation. The patient was easily persuaded, in the light of the success in the other 2 patients to accept the suggestion that an extensive gastric resection be done with the thesis in mind of reducing the capacity of the residual gastric pouch to provide an active acid peptic digestive juice the regurgitation of which into the esophagus, in all likelihood, had been causing the patient's symptoms. A dramatic improvement followed the gastric resection and helped confirm in our minds the impression that esophagitis and esophageal stricture might well be a consequence of the acid peptic digestive mixture in the same manner that duodenal ulcer is. Thereafter 2 additional patients with strictures fairly high in the esophagus were persuaded to accept the same operative procedure with hope of relief from esophageal obstruction. Operation in these latter patients has been done quite recently yet the improvement has been so startling as to warrant, despite this somewhat meager experience the placement of these case histories on record. In the main, they give fairly satisfactory proof that esophagitis is probably a manifestation of ulcer just as much as is an ulcer in the stomach or in the duodenum. Four of the patients listed herein probably had what is ordinarily called esophagitis. Three of the 4 had duodenal ulcer (Cases 1, 2 and 6) and rather severe concomitant complications from the duodenal ulcer the fourth patient had esophagitis only. One of the remaining 2 patients had a congenitally short esophagus with a stricture. She too however had gastric hemorrhage. In this latter instance prior to operation the interpretation put upon the sequence of events was that she 'probably had portal hypertension, a

Bourke M. and Mrs. R. C. Lilly Dr. and Mrs. Harry B. Zimmerman, and the Dr. Bertram Marienty Funds for Surgical Research.

Fig 1 Case 1. a, left, Esophagram showing extent of esophageal stricture, April 1, 1936, there is considerable dilatation of the esophagus above the stricture. b, Normal esophagram, April 3, 1938, almost 9 years after gastric resection, September 2, 1939 for bleeding duodenal ulcer. The patient is symptomatically well and has no demonstrable esophageal narrowing; moreover there is no dilatation of the esophagus above the site of the former stricture.

ruptured esophageal varix which healed with stricture formation"—all of which suggested to the medical service that local excision of the esophageal stricture was perhaps the best therapy. The remaining patient in the group was a young boy who since early years had had trouble in swallowing; the difficulty in swallowing became progressive eventually necessitating frequent dilatation. The case histories of these patients follow.

CASE HISTORIES

CASE 1. Mr L. W. was admitted to the University Hospital on September 3, 1939 and dismissed on September 22, 1939. Patient was 53 years of age at the time of that admission (U. H. No. 643715).

Twenty years ago the patient had had a diagnosis of duodenal ulcer; however it did not give him much trouble until 1935, since which time he has had considerable trouble with periodic obstruction as well as bleeding. The patient was first admitted to the University Hospital in November 1935, with a diagnosis of duodenal ulcer with obstruction; he was hospitalized by the medical service for approximately 1 month and was placed on a Sippy regimen. Following dismissal he began reporting to the out-patient clinic of the department of medicine in January 1936. In February 1936 he complained of difficulty in swallowing and when an esophagram was made a stricture was described in the lower third of the esophagus. On esophagoscopy it was found to be 38

centimeters from the incisor teeth. The stricture was rather long and smooth. In April 1936 dilatations were begun and once or twice each month the esophagus was dilated up until the time of surgery, which was done in September, 1939. In the interval between dilatations the esophageal stricture would usually shrink down to a No. 37 French but could be dilated again without too much difficulty up to a No. 45 French. In February 1936 the patient was hospitalized again for the treatment of his ulcer for a period of about a month. He was discharged with the diagnosis of obstructive duodenal ulcer and esophageal spasm and stricture (Fig. 1 a). In September 1936 he was hospitalized for a period of 3 weeks under medical management with the same diagnosis. In March 1938 he was hospitalized again for a period of 2 weeks.

In August, 1939 the patient was admitted to the medical service for treatment of a bleeding duodenal ulcer. While under medical management the bleeding continued and on September 2, 1939 the hemorrhage was profuse. The hemoglobin, despite transfusions, had fallen from 100 per cent following transfusions down to a level of 20 per cent. Because of this operation was undertaken as an emergency measure—a two-thirds gastric resection being done with open closure of the duodenum. Considerable blood was found in the intestine at the time of the operation. Prior to operation the patient had 38 degrees free hydrochloric acid in a fasting specimen without histamine. Convalescence was satisfactory and patient was dismissed from the hospital 20 days after operation. Several transfusions were given just prior during and after operation.

I November the esophagus was dilated and it was found that it had only contracted down to N. 41 French and dilatation with a No. 45 French bougie was easy. A similar dilatation was done in December and the figures were the same. In February 1940 it was found on examination that a No. 43 French catheter passed easily. The esophagus was dilated up to a No. 45. This was repeated in April and again in June and when the bougie was passed in August, 1940, it was found that a No. 45 went down readily. The patient came in again for examination in March 1941 at which time a No. 45 French sound passed easily. In January 1945 4 years later the patient came in for observation at which time he said he had had no further difficulty in swallowing and was not in need of further esophageal dilatation. It was seen here recently (April 1948) there was no difficulty swallowing an esophagram showed a fairly normal esophagus and a No. 45 French bougie passed without difficulty (Fig. 1 a and b).

Summary A patient of 53 had been hospitalized many times because of the complications of duodenal ulcer. Prior to September 1939 when an emergency gastric resection was done for massive hemorrhage from a duodenal ulcer the patient's esophagus had been dilated approximately 100 times because of esophagitis and stricture. Whereas it had been anticipated that the need for esophageal dilatation would continue it was observed that further esophageal dilatations were unnecessary (Fig. 1 a and b).

CASE 3 M. C. V. D. was aged 83 at the time of admission to University Hospital (U. H. N. 620411).

This patient was first seen at the University Hospital for prostatic obstruction in 1933 at which time he was 75 years of age. In July 1934 he returned because of very large right anterior suprahepatic abscess the patient at this time was very ill. Aspiration with needle was carried out below the right costal margin, the abscess being large and anterior. Subsequently an myoma trocar was inserted and catheter was threaded into the abscess cavity. The patient had a duodenal fistula which closed only slowly. When subsequently during his convalescence barium was given the barium found its way through the duodenal ulcer perforation into a large subphrenic space on the right side.

In 1938 the patient returned because of a bleeding ulcer. He was given several x-ray examinations during 1935 and 1936 and a definite duodenal deformity was observed. In 1936 he was hospitalized by the medical service because of hemorrhage and pain. In 1938 he was hospitalized again because of hemorrhage and at the same time he was treated on the eye service for a conjunctivitis of the left eye. Because of repeated and recurrent attacks of pyloric obstruction the patient was hospitalized in Decem-

ber 1941 and gastrojejunostomy, together with an enteroanastomosis was made. The patient was 83 years of age and it was believed that because of his age gastrojejunostomy was an adequate operation. He improved considerably after the gastrojejunostomy but in January 1942 he complained of a good deal of trouble in swallowing. Because of his generally poor condition he was readmitted for dilatation of the esophagus. Already in December 1941 at which time the patient was admitted for gastrojejunostomy narrowing of the lower end of the esophagus was noted on x-ray examination though at this time the patient did not complain of much difficulty in swallowing. The patient continued to come to the out-patient clinic for periodic dilatation of the esophageal stricture involving the distal 4 centimeters of the esophagus. The patient at this time was subjected to dilatation at 2 week intervals. In August 1942 it was suggested by one of us (O. H. W.) that gastric resection might help the esophageal stricture on the basis that it had helped the esophageal stricture in the instance of Case 1. Mr. L. W. who had undergone gastric resection 3 years previously for massive hemorrhage from a bleeding duodenal ulcer. Because of roentgen-ray evidence suggesting the presence of a jejunal ulcer as well as continued pyloric obstruction gastric resection was undertaken. Because of the difficulty of mobilizing the deformed duodenum, a Finsterer exclusion type of operation called the IV A operation in this clinic was done. The weight of the fragment of stomach removed was 385 grams obviously there was a good deal of pyloric obstruction to produce a stomach of this size. By this time too the technique of gastric resection for ulcer had been well standardized in this clinic, and the conventional short loop posterior anastomosis with a 75 per cent resection was done. The enteroanastomosis was taken down and an end-to-end anastomosis in the jejunum was made there.

Following the gastric resection the patient continued to improve quite definitely. Occasional esophageal dilatation was carried out but it soon became apparent that further dilatation was probably not necessary. On each occasion when dilatation was carried out after June 1943 No. 45 dilator passed through easily. When the patient was last seen in this clinic in February 1945, it was obvious that further esophageal dilatation was unnecessary. A recent letter (May 1948) from the patient physician, Dr. M. D. Mosby of Long Prairie, Minnesota states that the patient had no further difficulty in swallowing after the gastric resection and that the patient died of senility and uremia on July 3, 1947 at 90 years of age.

Summary A patient of 85 years since the age of 75 had been incapacitated because of frequent recurrence of complications of a duodenal ulcer. Gastrojejunostomy carried out for an obstructive duodenal ulcer was followed by a gastrojejunal ulcer accompanied by pro-

gressive symptoms of esophageal stricture. Complete relief of the ulcer diathesis followed gastric resection and esophageal dilatation became unnecessary. The patient died 5 years later of senility at the age of 90 years. He had experienced no difficulty in swallowing after gastric resection.

CASE 3. Mrs. E. K., 58 years of age at the time of admission to the University Hospital (U. H. No. 672670).

This patient has been coming to the University Hospital intermittently since October 1938. She then gave a story of dysphagia of 3 months duration. In January 1936 the patient had a massive hematemesis followed by melena. An abdominal exploration was done elsewhere shortly after an episode of hematemesis at which time a large mass was found in the upper abdomen and a diagnosis of cystic disease of the liver and pancreas was established. Subsequent to the operation two subsequent episodes of hematemesis were experienced by the patient. Large abdominal masses were observed here on physical examination; moreover the patient was found to be anemic, the hemoglobin being only 63 per cent. The white blood cell count was normal with a normal differential. Red blood cells were 2,890,000. Plasma proteins, blood cholesterol and nonprotein blood nitrogen values were normal when the patient was first seen here. Liver function tests were within normal limits.

X-ray examinations demonstrated a stricture in the lower 10 centimeters of the esophagus. The suggestion of a congenitally short esophagus was made. Esophagoscopy revealed a stricture 31 centimeters from the incisor teeth. In the x-ray film the stricture appeared to cover a distance of 3 to 4 centimeters. A pebble like appearance caused by the inflammation of the dilated portion of the esophagus was reported.

Because of the stricture dilatations were instituted beginning with a No. 31 French bougie. The first dilatations were carried up to a No. 39 French. The patient was dismissed from the medical service with a diagnosis of esophageal stricture, probably on the basis of a ruptured esophageal varix with secondary scarification of the esophagus.

Over a period of the next few years the patient was admitted frequently to the medical service of the University Hospital here for dysphagia, hematemesis or other circumstances requiring hospitalization. On one hospital admission a cystocele was repaired; the patient intermittently had swelling of the ankles; there was some hypertension with electrocardiographic evidence of myocardial damage, probably the result of an earlier myocardial infarction. The blood pressure varied between 150 and 185 systolic, with diastolic recordings in the area of 90 to 100. Passive congestion of the lungs and liver was diagnosed. The patient also had emphysema. The plasma proteins were quite consistently under 6 grams

per cent and on one occasion the plasma proteins were as low as 5 grams per cent.

Gastric analysis was made on several occasions and free acid without histamine was 28 degrees with a total acid of 54 degrees; on another occasion with histamine the free acid was 34 degrees with a total of 50 degrees. However the recovery in quantity of acid from the stomach was usually large on each occasion. The patient had occult blood in the stool quite consistently and the hemoglobin varied between 7 and 11 grams.

Despite monthly dilatation the patient's nutrition seemed to worsen, and because of the difficulty in swallowing and the fairly persistent anemia and repeated episodes of bleeding the patient was referred for excision of the stricture in the esophagus in April 1944 (Fig. 1 a). The patient lived in the northern section of the state, almost 400 miles from Minneapolis and had been contemplating moving her home to this area to lessen the difficulty of travel made necessary by the frequent dilatations. The stricture began apparently in the upper portion of the lower third of the esophagus and because of the patient's poor condition operation at that time was not recommended. However the patient was advised that the patient in Case 1 reported here too had undergone approximately 100 esophageal dilatations but that complete freedom from the symptoms of dysphagia had been obtained following gastric resection carried out because of massive hemorrhage from a duodenal ulcer. On August 9, 1944, Mrs. E. K. was admitted for gastric resection; she thought being that regurgitation of acid into the lower reaches of the esophagus was the likely cause of the stricture. This operation was carried out on August 14, 1944.

At operation it was found that the patient had a congenitally short esophagus with a small para-esophageal hernia. She had been under the observation of Dr. N. Logan Leven for some time for esophageal stricture. The question arose as to what to do for this patient. At one juncture, Dr. Leven favored resection of the esophagus with end-to-end anastomosis; moreover the stricture was fairly high up in the esophagus. An alternative procedure would have been to have made a lateral anastomosis between the esophagus and the cardiac end of the stomach through the diaphragm from above. A third procedure which appealed to me (O. H. W.) as being perhaps most rational was to do a gastric resection as one does a gastric resection for duodenal ulcer since it is our opinion that the esophagitis and stricture are consequent to regurgitation of free hydrochloric acid into the lower reaches of the esophagus. It had been difficult to obtain samples of free acid because of the difficulty of passing an ordinary duodenal tube through the stricture. The patient did have free acid however on a fasting sample as well as after the use of histamine. The quantity of acid aspirated from the stomach was large though the acidities were not unusual.

The field of operation was prepared with Novak's solution. Cyclopropane anesthesia was found to be

Fig. 2. Case 3. a, Coiled-wire stricture of lower third of esophagus. Considerable dilatation with food retention above the stricture. A portion of the stomach appears to be above the diaphragm. Situation in April, 1944, few months prior to operation. b, The status of the lower esophagus and residual gastric pouch 4 years after operation.

tion, August 4, 1944. c, Esophagram almost 4 years after gastric resection, May 5, 1948. There is no residual evidence of the former stricture and the coiled-wire like deformity of the esophagus has disappeared. d, Normal esophagram save for persistent appearance of gastric mucosa-like folds in lower esophagus, May 5, 1948.

satisfactory. A left subcostal incision was used. At operation a fairly large cystic liver was found, the left lobe being as large as a normal sized right lobe. There were several large cysts, some of which held more than 3 ounces of fluid. Many adenomas were noted in the liver. A few small cysts were felt along the left kidney and there were many cysts in the pancreas. The right kidney seemed small and it was not certain whether or not it contained any cysts. Adhesions were noted from the omentum down to the left lower quadrant. Many diverticula were felt in the descending and pelvic colon. After discussing our findings with Dr. N. Leven and with the patient both agreed that perhaps gastric resection was the best procedure. It was impossible to pass a duodenal tube through the stricture into the stomach prior to operation. Fluoroscopic examination revealed that the duodenal tube was in the esophagus.

The first step in the operation was to make a gastrostomy opening through which a catheter was passed up through the esophageal stricture. Passage of the catheter was rather difficult; a small No. 22 bougie was finally pushed through. The catheter was caught above and sutured in place and a duodenal tube was pulled down. Then we used a larger bougie. Finally a fairly large bougie went through the stricture. The duodenal tube was left in the stomach, the gastrostomy opening was closed and the resection was carried out. A group III 75 per cent resection was done together with excision of the pylorus and antrum. A Hofmeister retrocolic type of gastrojejunostomy anastomosis was done with two rows of sutures, the anastomosis being made at the ligament of Treitz. The duodenum was closed with two rows of fine interrupted silk sutures over Pets

clips. The catheter in the stomach was pushed into the proximal duodenojejunal loop. The adhesions to the left lower quadrant were all divided. There was also an area in the small intestine, perhaps in the midileum, where the gut was badly knukled by adhesions. These were cut and the bowel was made free. A tear in the surface of the bowel necessitated resuturing with fine interrupted silk. Interrupted silk sutures were used for closure of the abdominal wall. The patient took this rather long operative ordeal quite satisfactorily and left the operating table in good condition. Despite this fact convalescence was rather slow and the patient stayed in the hospital until the first of September at which time she was discharged. On September 1 she appeared in the out-patient clinic and said that she could swallow without difficulty and was eating bread and meat. At this time she returned to her home in International Falls and was not seen in the out-patient clinic again until December 13, 1944. At this time a No. 43 French bougie went down without difficulty. The plasma proteins on December 24, 1944 were 7.1 grams per cent. She appeared to be improving continuously despite the circumstance that her appetite was none too good. On February 21, 1945 a dilator was again passed and it was found that a No. 45 French bougie went down readily. After this there appeared to be no further need for dilations. In February 1946 a sound was passed and was found to go down without difficulty. In August 1946 the patient was hospitalized for a cold and because of asthmatic bronchitis. The presence of arteriosclerotic heart disease and polycystic liver and pancreas was again reaffirmed on physical examination.

Fig 3 Case 4. a, Extent of esophageal stricture November 27, 1946; patient could swallow only fluids. b, Esophagram, March 2, 1948, 8 months after gastric resection (June 27, 1947) shows disappearance of stricture and a normal esophagus. The patient can eat anything. c, Esophagram, May 18, 1948.

There has been no recurrence of hematemesis and no difficulty in swallowing since the time of the operation in August 1944. The patient's hemoglobin has continued between 12.5 to 13 grams per cent since operation. She eats everything and seems to be getting on quite satisfactorily and has gained considerable weight. An x-ray examination of the esophagus made in September 1944, a month after the operation, showed some narrowing of the distal third of the esophagus. An x-ray examination made 2 years later indicated that the esophagus was normal. Both proximal and distal loops of the gastrojejunal stoma fill readily. The present condition of the esophagus is shown in Figure 2 b, c, and d.

Summary This patient had polycystic disease of the liver and pancreas, a congenitally short esophagus and an esophageal stricture of unknown origin. There had been several episodes of hematemesis and it had been reasoned that bleeding was caused by esophageal varices followed by scar formation and esophageal stricture. Esophageal dilatation had been done approximately 100 times over a 6 year interval. Her nutrition was poor and edema and hypoproteinemia were present. Resection of the esophageal stricture had been urged but gastric resection was carried out on the thesis that the esophageal stricture was probably a manifestation of ulcer disease. The result justified the means (Fig 2 a, b, c, and d).

CASE 4 Mr C. G. aged 17 years first came here in November 1946 with a story of difficulty in swallowing (U. H. No. 772864).

The difficulty in swallowing dated back over many years but had been getting worse and worse until the patient could no longer swallow solid foods of any kind. The hemoglobin was 16 grams per cent, the free hydrochloric acid fasting was 18 degrees with 60 degrees of free hydrochloric acid after histamine. The volume of secretion was large, being 100 cubic centimeters fasting and 88, 70 and 50 cubic centimeters respectively after three successive doses of 0.5 milligram of histamine given at 30 minute intervals. Considerable difficulty was had in dilating the patient's esophageal stricture. A No. 37 French dilator causing a good deal of bleeding. An esophagram disclosed stricture of the distal third of the esophagus with considerable narrowing and some dilatation of the proximal two-thirds of the esophagus (Fig 3 a).

Esophagoscopy was done on November 20 and disclosed stricture of the lower end of the esophagus. Biopsy specimen was taken and the histologic diagnosis was chronic inflammation. The biopsy tissue was taken 20 centimeters from the teeth. Another fragment of tissue was taken at 32 centimeters from the teeth. All these areas showed evidence of chronic inflammation (esophagitis).

Following dilatation the patient's condition improved and he continued to return for further dilatation at 2 week intervals. On June 27, 1947, because of the continued necessity of dilatation, a gastric resection was done (75 per cent). Inasmuch as an attempt was being made here to evaluate com-

Fig. Case 3. Cork-screw stricture of lower third of esophagus. Considerable dilatation with food retention above the stricture. A portion of the stomach appears to lie above the diaphragm. The presence of arteriosclerotic heart disease and polycystic liver and pancreas was again reaffirmed on physical examination.

Fig 3 Case 4. a Extent of esophageal stricture November 27, 1946 patient could swallow only fluids b Esophagram, March 2, 1948, 8 months after gastric resection (June 27 1947) shows disappearance of stricture and a normal esophagus The patient can eat anything c, Esophagram, May 18, 1948.

There has been no recurrence of hematemesis and no difficulty in swallowing since the time of the operation in August 1944. The patient's hemoglobin has continued between 12.5 to 13 grams per cent since operation. She eats everything and seems to be getting on quite satisfactorily and has gained considerable weight. An x ray examination of the esophagus made in September 1944 a month after the operation showed some narrowing of the distal third of the esophagus. An x ray examination made 2 years later indicated that the esophagus was normal. Both proximal and distal loops of the gastrojejunal stoma fill readily. The present condition of the esophagus is shown in Figure 2 b c, and d.

Summary This patient had polycystic disease of the liver and pancreas a congenitally short esophagus and an esophageal stricture of unknown origin. There had been several episodes of hematemesis and it had been reasoned that bleeding was caused by esophageal varices followed by scar formation and esophageal stricture. Esophageal dilatation had been done approximately 100 times over a 6 year interval. Her nutrition was poor and edema and hypoproteinemia were present. Resection of the esophageal stricture had been urged but gastric resection was carried out on the thesis that the esophageal stricture was probably a manifestation of ulcer disease. The result justified the means (Fig 2 a b c, and d).

CASE 4. Mr C G aged 17 years first came here in November 1946 with a story of difficulty in swallowing (U. H. No 772864).

The difficulty in swallowing dated back over many years but had been getting worse and worse until the patient could no longer swallow solid foods of any kind. The hemoglobin was 16 grams per cent the free hydrochloric acid fasting was 18 degrees with 60 degrees of free hydrochloric acid after histamine. The volume of secretion was large being 100 cubic centimeters fasting and 88.70 and 50 cubic centimeters respectively after three successive doses of 0.5 milligram of histamine given at 30 minute intervals. Considerable difficulty was had in dilating the patient's esophageal stricture a No. 37 French dilator causing a good deal of bleeding. An esophagram disclosed stricture of the distal third of the esophagus with considerable narrowing and some dilatation of the proximal two-thirds of the esophagus (Fig 3 a).

Esophagoscopy was done on November 20 and disclosed stricture of the lower end of the esophagus. Biopsy specimen was taken and the histologic diagnosis was chronic inflammation. The biopsy tissue was taken 29 centimeters from the teeth. Another fragment of tissue was taken at 32 centimeters from the teeth. All these areas showed evidence of chronic inflammation (esophagitis).

Following dilatation the patient's condition improved and he continued to return for further dilatation at 2 week intervals. On June 27 1947 because of the continued necessity of dilatation a gastric resection was done (75 per cent). Inasmuch as an attempt was being made here to evaluate com-

plete extrinsic deviation of the stomach a vagotomy and bilateral celiac ganglionectomy were carried out simultaneously. Convalescence was satisfactory and patient was discharged from the hospital on July 3. On July 5 he returned with the picture of a psychosomatic was hospitalized for a period of 13 days in the psychiatric service.

There has been considerable and continued improvement since the gastric resection in the patient's ability to swallow; moreover when he has returned from dilatation the tendency of the stricture to narrow down and resist stretch has not been observed previously. In February 1948 a 45 French sou flew through his throat with difficulty and there seemed to be minimal evidence of any constriction. At the present time (May, 1948) the patient eats solid foods such as bread and meat without difficulty. Moreover the esophagus shows considerable improvement from the preoperative situation (Fig. 3, l and c). The boy appears to have made a very satisfactory functional adjustment too and is getting on very well in school.

Summary. A boy of 17 years with a stricture of the lower half of the esophagus of unknown origin. Esophagoscopy indicated the presence of esophagitis. No ulcer could be demonstrated but the gastric acids were high. During the year prior to operation esophageal dilatation was done usually every 2 weeks to help maintain a flagging nutritional status. Gastric resection was followed by complete relief of the difficulty in swallowing (Fig. 3, a and b).

CASE 5. Mrs. A. C. aged 36 years (U. H. N. 66758).

Patient began coming to University Hospitals in 1938 because of painful running ears. She was then 46 years of age. Tympanocentesis was done and on later admissions mastoid operations were performed. In 1939 patient underwent tracheostomy in the gynecological department of the hospital for a tertiary syphilis and salpingitis. In 1942 it was noted that the patient had trouble in swallowing solid food. When esophagram was made in July 1942 esophageal strictures together with a peribulbar gastric ulcer were reported. These findings were confirmed by re-examination of the esophagus in June 1943. Gastric analysis in July 1942 showed a large volume of gastric secretion with 66 degrees of free hydrochloric acid and a histamine. Frequently during 1943 and 1944 when the stool was studied for occult blood (guaiac) blood was almost always found. At that time diagnosis of likely esophageal tract re had been made in July 1944 on the basis of the symptoms. The patient was put on a Sippy diet and powders because of the complaint of gastric pain and difficulty in swallowing. Food seemed to stick in the esophagus and there was dull pain behind the sternum

on swallowing. The patient meanwhile was observed in the psychiatric clinic and was treated for emotional instability. By August 1945 the patient was confined on the basis of her own symptoms that she had a peptic ulcer. The patient continued to be observed in the psychiatric clinic but by July 1944 the physicians in the department of internal medicine in the outpatient clinic were convinced that the patient had an ulcer together with esophageal stricture and esophageal varices.

A diagnosis of esophageal stricture and esophageal varices was established by esophagoscopy examination in September 1947. The patient continued to complain of postprandial pain on eating and persistent difficulty in swallowing. She can swallow only soft food and meat and vegetables such as celery and carrots cannot be swallowed. A gastric analysis done with histamine on February 3, 1948 demonstrated large quantities of acid in each specimen. The highest amount of free hydrochloric acid was 100 degrees following the second half milligram of histamine. The patient had had no dilatation of her esophagus prior to operation but there was a history of difficulty in swallowing for approximately 6 years.

On March 15, 1948 a conventional 80 per cent gastric resection (Group III) operation was done on the basis that the patient had digestive difficulties were probably essentially manifestation of ulcer disease that would give to the hyperchlorhydria he probably has periodic eruptions or ulcers in the stomach and a persistent esophagitis. The portal venous pressure was measured at the time of operation, and was found to be only 8 centimeters of saline solution. It is unlikely therefore that the patient has portal hypertension or so called esophageal varices. The spleen was found to be small but because of the conjectured presence of esophageal varices and portal hypertension prior to operation, it was thought wise to excise the spleen and to perform a biopsy upon the liver. The liver itself looked normal and proved to be so histologically. Convalescence was satisfactory and was for some temporary diarrhea, patient got on very well. Almost from the beginning following the operation, he swallowed considerably better. When an esophagram was made on May 4 the stream of barium went down more readily than on previous examinations.

Summary. A patient with unusual complaints who had diagnosed her own condition 5 years previously as being due to ulcer. Dysphagia also had been present over a 5 year interval. A recent gastric resection was done with relief of abdominal pain and difficulty in swallowing.

CASE 6. Mr. H. B. aged 47 years (U. H. N. 780565).

This patient had a history of peptic ulcer since 1911. In 1940 he had duodenal ulcer perforation which closed surgically. Six weeks later the

Fig. 4. Case 6. a. When this film was made, June 4, 1947 the patient had carried a gastrostomy for several years, he could not swallow his saliva. The duodenum is deformed and there is a crater in the pyloric outlet. b. Nature and extent of stricture, March 3, 1948. A satisfactory esophagram was not obtained after esophageal dilatation. c. Esophagram made May 18, 1948 3 months after gastric resection on March 19, 1948 the esophagram has improved as has the patient. The patient is eating solid food and is swallowing satisfactorily. The esophagus will have to be dilated periodically until it will take a No. 45 French dilator. It remains to be seen whether a normal appearing esophagus can be re-established in this patient.

obstruction of the esophagus had progressed to the extent that he could not swallow his saliva and a gastrostomy was done to permit feeding him. This was done at the Wisconsin General Hospital. Since performance of his gastrostomy he has been able to swallow liquids only periodically usually having to expectorate saliva as well. In the summer of 1947 his physician Dr. William Focke of Poyette, Wisconsin was in the clinic when the preceding case that of C. G. was being discussed in the out patient clinic. He had just returned a few weeks after gastric resection and reported himself as already improved. Dr. Focke said he had a patient who in many respects was very much like the case of C. G. and volunteered that he would like to send his patient here. The patient arrived in July 1947 and an effort was made to examine the esophagus with barium but so little barium went through, that the examination was unsatisfactory (Fig. 4 a). An attempt was made to use the esophagoscope and this also was unsatisfactory. Finally a No. 5 ureteral catheter was passed down the esophagus into the stomach and was fished out through the gastrostomy opening. A silk thread was then brought back and anchored to the cheek. After dilatation re-examination was done with barium and it was found that a stricture extended down from the midsegment of the thoracic esophagus to the stomach (Fig. 4 b). With many dilatations it became possible to dilate the esophagus up to about a No. 20 French. At that juncture the

patient felt much better so he left and was not seen for several months.

Meanwhile January 1948 another perforation of a duodenal ulcer occurred. This time the patient was treated conservatively by suction applied to the gastrostomy tube and he appeared to get on satisfactorily. When he reported here for observation again in April 1948 the esophagus again appeared completely occluded. The esophagus was gradually stretched up to a No. 20 French again. The patient's hemoglobin at this time was 14.3 grams, leucocytes numbered 10,500. There was a large volume of acid in every sample aspirated. Volumes of 45 to 50 cubic centimeters were present in each specimen including the fasting specimen. The free hydrochloric acid fasting was 42 degrees and after histamine rose to 74 degrees. When the patient came here he was thin, very weak and it was difficult for him to stand.

At the time of operation on March 19, a granuloma containing purulent material was found in the retro-gastric space suggesting that the perforation in January had occurred into the lesser sac. There was a hard thick fibrous plastic area plastered up against the transverse colon which lent the impression in the preoperative x ray film of a stricture there. The stomach was large. It became necessary to make an open closure of the duodenum. This was made with a single row of interrupted silk sutures. The duodenojejunal ligament was dissected down with some difficulty and 80 per cent of the stomach was re-

sected. The removed gastric segment devoid of omentum, weighed 227 grams. A single row gastrojejunal anastomosis was made and the lying duodenal tube was placed in the proximal duodenojejunal loop. Because of the presence of the subclinical retrogastric abscess encountered (absence of fever and leucocytosis) air vent suction drains were put into the subhepatic area on the right and behind the spleen on the left side. The patient convalesced satisfactorily but was kept in the hospital for weeks after operation to encourage better feeding. About the time the patient left the hospital it was found that a No. 20 French bougie was inserted without any difficulty. Two weeks later he returned and dilatation was accomplished up to a No. 33 French without any difficulty. A few days later it was found that a No. 35 French bougie could be passed without much difficulty at this juncture the patient returned home. He returned for observation again May 5, approximately 6 weeks after the operation, and said that he was eating well and had no difficulty in swallowing. At this time the esophagus was dilated to a No. 37 French with little difficulty. May 8 the patient returned at our request and it was found that a No. 37 French bougie went through without great difficulty. The patient is having very little difficulty in swallowing. Moreover the x-ray film made at this time showed considerable improvement in the lower reaches of the stricture but still showed some evidence of spasm or narrowing at the upper end of the esophageal stricture (Fig. 4, c). The patient is eating well however and feels considerably improved. He eats meat, hard rolls, celery and carrots without difficulty. Prior to the operation, it is to be remembered the patient had difficulty in swallowing his saliva.

Summary A patient of 47 years with a history of periodic severe difficulty from a duodenal ulcer since the age of 10. Eight years prior to admission here surgical closure of a duodenal perforation was done followed a few months later by gastrostomy for feeding because of the patient's inability to swallow his own saliva occasioned by the stricture of the lower half of the esophagus. Considerable improvement following a recent gastric resection (Fig. 4, a, b and c).

ETIOLOGICAL CONSIDERATIONS

Whereas this group of cases is small and in the instance of the last 2 patients cited, the

In the patient dilatation is still being done at gradually lengthening intervals. He eats everything and puts on very little weight. Some of the other patients reported herein require dilatation. One additional patient, M. B. N. aged 70, University Hospital No. 78466, with esophageal stricture associated dilatation has been subjected to gastric resection since this paper was written. He underwent operation on July 11, 1935. His subsequent gain in weight and security for continued dilatation has disappeared.

time interval has been brief nevertheless, it is difficult to escape the conclusion that esophagitis is a manifestation of ulcer disease.

Much has been written about the etiology of esophagitis. Vinson (1940) suggests that nonspecific inflammation is the most common lesion of the esophagus and that the majority of benign strictures are of uncertain etiology. Vinson states that approximately 10 per cent of esophageal strictures occur as a sequel to the nausea and vomiting of pregnancy. Butt and Vinson (1936) observed that postmortem evidences of esophagitis occur in 7 per cent of individuals. Twenty per cent of that number had a history of peptic ulcer. Olsen (1948) stresses the association of abdominal disease especially illness giving rise to vomiting as antecedents of esophagitis.

The proventriculus of the rat's stomach has the same type of epithelial covering as has the esophagus moreover it is well known that ulcer when observed in the rat's stomach is found almost invariably in the proventriculus (2, 3) similarly the histamine ulcer is provoked readily in the rat's proventriculus (1, 2, 3). The pig's stomach has a fairly wide ring of esophageal epithelium around the esophagogastric juncture. It is just in that area that the histamine provoked ulcer is elicited regularly (6). In other words the squamous epithelium of the esophagus is more vulnerable to injury by the acid-peptic digestive juice than is the glandular epithelium of the stomach.

Ulcer is observed most frequently in the duodenum. And the reason probably is that it is the sole exit through which the entire output of gastric juice escapes from the stomach. Regurgitation of the acid digestive juice into the lower reaches of the esophagus is not an uncommon circumstance as manifested by acid eructations or a sensation of substernal burning. This occurrence also has been substantiated in the fluoroscopic observations of Robins and Jankelson (1926). They observed return of the barium mixture into the lower esophagus after being swallowed in 46 per cent of persons examined in the prone position. If all the gastric juice left the stomach via the esophagus esophagitis would in all probability be the most frequent of all clinical types of ulcer.

There is a growing conviction among clinicians dealing with the upper alimentary canal that hiatus hernia interferes with effective closure of the esophagogastric juncture, thus inviting periodic regurgitation of gastric juice into the lower reaches of the esophagus. Moreover Dey and his associates (1946) appear to have shown that the artificial creation of hiatus hernia in the dog leads to reflex shortening of the esophagus. They observed too that manipulation of the upper abdominal viscera led to contraction of the longitudinal muscle fibers of the esophagus with resultant reflex shortening. The fibrosis and contraction theory of the origin of so called thoracic stomach appears to account satisfactorily for many cases of congenitally short esophagus. In an able and critical review Smithers (1945) states that not infrequently patients in whom a diagnosis of congenitally short esophagus has been made by means of x ray examination are found later at surgery or on postmortem examination to have the entire stomach in the abdomen. In other words hiatus hernia may abet the ulcer diathesis not alone as it relates to the rather frequent association of gastric ulcer with the hernia but it appears also to be a forerunner of ulcer disease in the esophagus.

As one learns the natural history of a disease he interrogates more intelligently patients having some manifestation of that disease. We feel that in this experience we have been learning something of the natural history and a rather unexpected though probably not bizarre behavior of so called acid peptic ulcer. Esophagitis may be the only manifestation of ulcer. Every patient with a duodenal or gastric ulcer should be interrogated carefully with reference to the following: periodic sensation of burning in the esophagus; acid eructations and the tasting of food long after its ingestion; substernal pain difficulty in or pain on swallowing. And if in the roentgen-ray examination of every ulcer suspect great care is observed to note any abnormal behavior of the lower esophagus with reference to evidence of spasm, persistent narrowing or halting of the forward progress of the barium column into the stomach, the esophagitis form of ulcer disease would be recognized and diagnosed more frequently than it is.

The gastric mucosa is the most resistant to digestion of the natural membranes with the acid peptic digestive mixture come in contact. Investigators are still trying to answer the question posed by John Hunter more than a century ago: Why doesn't the stomach digest itself? When clinicians and roentgenologists pool their information garnered in the light of the suggestion that esophagitis is a manifestation of ulcer disease, it may be that next to duodenal ulcer, esophagitis is the next most frequent variety of ulcer excruciating gastric ulcer in frequency. Certainly, patients with obstructive duodenal ulcer and vomiting esophagitis must be common in case it is in the experimental animal a condition which will be amplified in a subsequent publication.

RATIONALE OF GASTRIC RESECTION FOR RELIEF OF ESOPHAGITIS AND ESOPHAGEAL STRICTURE

An effective gastric resection has two features which commend it as a suitable therapeutic agency for the relief of esophageal obstruction arising as a manifestation of ulcer disease. (1) It reduces the acidity and the digestive capacity of the juice secreted by the residual gastric pouch, a circumstance owing in part to the regurgitation of bile pancreatic juice and succus entericus from the short proximal duodenojejunal loop into the remaining gastric pouch. (2) Gastric resection quickens the gastric emptying time. Both these features are essential. In Case 2 reported herein, it was noted that whereas the pyloric obstruction disappeared following performance of gastrojejunostomy the functional manifestation of the esophagitis and esophageal stricture only came into evidence following that operation. In other words reduction of gastric emptying time alone is not effective therapy for esophagitis or esophageal stricture due to acid peptic ulcer of the esophagus; effective simultaneous reduction of gastric acidity is also necessary. A gastric resection which fails to reduce gastric acidity effectually cannot overcome the ulcer diathesis and will prove

¹Since this paper was written, good experimental evidence in the dog and rat has been obtained, indicating a far greater susceptibility of the esophageal over gastric mucosa to injury by the acid-peptic digestive juice.

no more effective in the relief of esophagitis and esophageal stricture of acid peptic origin than gastrojejunostomy.

The criteria of a satisfactory gastric resection for ulcer have been described elsewhere (7,8,14,15). Suffice it here to say that a three-quarter gastric resection carried out on the Billroth II plan of operation with a Hofmeister end-to-side gastrojejunal anastomosis, with a short afferent duodenojejunal loop together with complete excision of the antral mucosa—these serve to constitute a satisfactory and effective gastric resection for ulcer (14).

Following gastric resection the pool of digestive juices accumulating periodically in the residual gastric pouch loses its capacity to irritate the lower reaches of the esophagus and with periodic dilatation of the esophagus for a few months after operation until the normal diameter is re-established (No. 45 French) the need for continual dilatation of the esophagus disappears. Whether a normal sized esophageal lumen will return in the patient described in the protocol of Case 6 who carried a gastrostomy for 8 years during which time he could not swallow his saliva remains to be seen. Certain it is that the less the penetration of the effects of the esophagitis into the deeper layers of the esophageal wall the more likely is restitution of a normal esophageal lumen to be achieved.

Some speculation as to whether cardiospasm and strictures of the lower end of the esophagus owing to the swallowing of lye might be helped by gastric resection seems warranted. In any case one of us (O. H. W.) feels that this thesis should be explored.

SUMMARY AND CONCLUSIONS

The case histories of 6 patients presenting clinical evidences of esophagitis, esophageal

stricture or both are cited in which relief of the esophageal obstruction followed gastric resection. Three of these patients (Cases 1, 2 and 6) had an associated duodenal ulcer one had a gastric ulcer (Case 5) one had a congenitally short esophagus and repeated hematemesis of unknown origin (Case 3). In Case 4 a boy of 17 there was a stricture of long length of the lower portion of the esophagus of unknown origin. Relief of the ulcer diathesis by a satisfactory gastric resection appears to be satisfactory treatment for esophagitis and esophageal stricture resulting therefrom as a corollary of this experience, it is suggested that these observations constitute strong evidence suggesting that esophagitis is a manifestation of ulcer disease.

SURGICAL TREATMENT OF PATENT DUCTUS ARTERIOSUS

WILLIS J POTTS M.D., F.A.C.S., Chicago, Illinois

IT is only ten years since the first patent ductus arteriosus was ligated successfully by Gross (3). During this decade much has been learned about the surgical management of these cases. Although in general the operative procedure is fairly well standardized there still is considerable difference of opinion as to the best and safest method of closing the patent ductus. The medical world was greatly elated by Gross's success in getting a single ligature tied around the first ductus. Although no one wishes to shade the glory of the first success it is known today from the trial and error method that a single ligature tied snugly around a patent ductus is not sufficient to maintain occlusion in a considerable percentage of the cases. Gross (2) himself was the first to recognize this fact. He used double ligatures, tried injecting sclerosing solution between the ligatures, then added cellophane wrapping around the ligatures to stimulate snug closure by fibrosis. After treating 47 patients by these various methods and finding incomplete closure or recurrence of the fistula in 20 per cent, he abandoned methods of ligation and now routinely clamps, divides and sutures all patent ductus.

Although this attitude is not shared by all surgeons it appears to be making headway. Jones (4) in a series of 53 ductus ligations reports aortopulmonary fistula in 2 cases, 5 early recurrences of the murmur due to incomplete occlusion and 5 late recurrences of the fistula due to the tapes partially cutting through the wall of the ductus. Jones (5) now divides and sutures all ductus and in similar series has been highly pleased with his results.

Wangenstein has concluded that the ductus should be cut and sutured. He reports division of the ductus in 33 consecutive patients without mortality or recurrence.

Blalock, on the contrary, believes that double ligation, one suture placed well on the pul-

monary end, the other on the aortic end of the ductus, plus a transfixion suture between these ligatures, assures adequate closure. If there is any uncertainty about complete closure he adds a ligature of umbilical tape.

Shapiro in an analysis of 643 patients operated upon by 46 surgeons reports a mortality rate of 4.9 per cent and a recanalization rate of 8.7 per cent. He concluded from a study of 172 cases with uninfected ductus severed and sutured without mortality or recanalization that ligation of the patent ductus is now obsolete.

My attitude toward the surgical treatment of patent ductus arteriosus is colored by my own experience. To divide and suture a ductus is not a simple operation and should not be undertaken until one has familiarized himself on animals with the handling and suturing of large vessels. For trained surgeons to whom the opportunity of doing practice vascular surgery on animals has not been available I believe that proper ligation of a patent ductus is a safer procedure. Furthermore, any surgeon is wise to begin his operative work in this field on children because the operation is much easier in a child than in an adult.

At the Children's Memorial Hospital in Chicago the management of patent ductus has gone through two phases of surgical approach and surgical management.

In the first 12 cases an anterior submammary incision was made (Fig. 1). The chest was opened through the left third interspace and sufficient exposure was obtained by cutting the second and third ribs at the sternal margin. In children the ribs are pliable and the upper flap of ribs and attached muscle can easily be held aside with a claw retractor. A rib spreader may well be used but unless one is constantly on guard the lower flange is apt to rest against the heart and influence its rhythm unfavorably. In the next 28 cases a posterolateral approach has been used (Fig. 2).

From the Children's Memorial Hospital, Chicago, Illinois.

Fig. 3. Anterolateral approach to patent ductus arteriosus.

and the chest entered through the fourth left interspace. This incision is easier to make, gives better exposure, is easier to close and leaves a less conspicuous scar.

The first 22 consecutive patent ductus were ligated as illustrated in Figure 3. There was no mortality and to our knowledge there has been no recanalization. In spite of the latter fact which may well be coincidental and judged by the experience of others will undoubtedly change, and because of the fact that it is not the best surgery to bury large amounts of nonabsorbable foreign material on

large vessels and against a bronchus, investigation was undertaken for the development of a ductus clamp which would be effective, non-traumatic, and safe. It appears that such a clamp has been developed (Fig. 4). The basic feature of this clamp previously described (6) is embodied in a row of very fine teeth in the apposing jaws. The principle of the Indian fakir who walks on spikes has been applied to a clamp. He walks on spikes without injury to his feet only because he steps on many points at one time. Likewise a clamp with fine teeth can be applied to a vessel without

injury only because the many teeth distribute the pressure widely. The serrated portion of the jaws of the clamp 21 millimeters long and 1 millimeter wide is hollow ground so that at the base of the teeth it is about 0.5 millimeter wide. There are 40 teeth to the inch (16 to 1 cm). Each tooth is about 1 millimeter long. The hub of the clamp is so constructed that the jaws can be closed to a point of complete apposition but not interdigitation of the teeth. When closed the teeth embed themselves in the adventitia and will not slip. Experimental studies on dogs indicate that any of the large vessels may be adequately occluded without tissue injury. It is important that these clamps be made of good well tempered stainless steel.

OPERATION

The operative technique as used on 18 consecutive patients is as follows (Fig 5). In tracheal anesthesia is used. A cannula or large needle is placed in the right saphenous vein at the ankle for the administration of fluids or blood if necessary. We routinely have in the operating room 500 cubic centimeters of blood. The child is laid on its right side and a curved incision is made beneath the left scapula. The chest is opened through the left fourth interspace. In children below 12 years rib resection is rarely necessary.

The lung is collapsed covered with a moist pad and held out of the way with a two-bladed retractor made of flexible monel metal. At this point it is important for the anesthetist to stop spontaneous respiration by breaking the Herring Brauer reflex and breathing for the patient by intermittent pressure on the anesthetic bag. By so doing the surgeon is greatly aided because movement of the diaphragm is stopped and with it the up-and-down motion of structures in the chest.

The phrenic nerve is easily identified and about 1 centimeter posterior to and parallel with it the mediastinum is opened. The ductus is readily located by palpating the point of maximum thrill. The vagus nerve and its recurrent laryngeal branch coursing around the ductus is next identified. A number of lymph nodes usually lying about the ductus are wisely dissected out and removed because they interfere with clear visualization.

Fig 2. Posterolateral incision and surgical approach to patent ductus arteriosus.

Careful painstaking unhurried and adequate dissection of the ductus from its surrounding structures is the important step in this operation. A lappet of pericardial sac usually overlies the ductus and must be completely separated from it. The proper line of cleavage for this dissection is through the adventitial layer. (In one patient I failed to dissect the pericardium completely from the pulmonary end of the ductus. When the clamp was applied the teeth held in the pericardium but one side of the cut ductus tended to retract and made suturing difficult.) The posterior portion of the ductus must be dissected from the bronchus blindly. Again if

Fig. 3. Exposure of ductus and method of obliteration by multiple ligatures.

the line of cleavage through the adventitia is followed this step will be simplified.

After a curved cystic duct forceps has found its way beneath the ductus a strip of umbilical tape is drawn through to elevate it while the dissection is completed, first on the aortic side and then on the pulmonary side. The tape is then removed and while the ductus is elevated with a curved forceps the angled clamp is applied to the aortic end of the ductus. If the ductus is short the clamp is crowded as far as possible toward the aorta. While slight traction is being made on this clamp to elevate the ductus, the second clamp is applied on the pulmonary end.

With a long straight scissors designed by Dr. Sidney Smith, a small cut is made in the ductus. If no bleeding occurs (none has) it is completely severed midway between the clamps. The stumps distal to each clamp are usually 2 to 3 millimeters long.

The aortic stump is sutured first. No 5-0 Deknatel silk swaged on a curved No 9 atraumatic needle has been found very satisfactory. Until recently each stump was closed with a double row of a continuous over

and-over suture. Because occasionally there was some bleeding between the stitches we now use a continuous mattress suture all the way across the end of the ductus, then return with the same suture in an over-and-over manner at a slightly different level and tie the ends at the point where the sewing was begun. The clamp is partially released. If there is any bleeding the clamp is closed and an extra stitch or two is put in where necessary. A strip of gelfoam is then laid over the suture line and the aorta is retracted gently with a malleable retractor while the pulmonary end of the ductus is sutured in a similar manner.

The mediastinal pleura is closed with a few interrupted silk stitches. Just before the last stitch is drawn up penicillin 100,000 units in 1 cubic centimeter of water is sprayed over the ends of the sutured ductus. The lung is completely re-expanded by the anesthetist. A No 16 or No 18 F de Pezzer catheter with all but the flange removed is inserted from the inside out through a small puncture wound in the sixth interspace. The ribs are apposed with two catgut sutures about adjoining ribs. To avoid pressure on the intercostal nerve the

Fig. 4. a and b, the straight clamp used on the pulmonary end of the ductus; c and d, the angled clamp for the aortic end of the ductus; e, a much enlarged drawing of the teeth of the clamp.

suture about the lower rib is put in subperiosteally. The muscles are closed with a running catgut suture and the skin is closed with silk.

While the anesthetist makes pressure on the anesthetic bag to force all the air from the chest the drainage catheter is clamped. After the patient is returned to bed the catheter is attached to a water seal. On the second or third postoperative day the catheter is removed. Penicillin, 30,000 units every 3 hours is given intramuscularly for 5 to 7 days after operation routinely.

The results in the second group of 18 patients in whom the ductus was severed and sutured have been completely satisfactory. There were no deaths and no postoperative complications.

DISCUSSION

Mortality and morbidity statistics will all ways be lower in children because cardiac

reserve has not been depleted and because in children the ductus is longer, more elastic, and more easily freed from surrounding structures.

The diagnosis of patent ductus in this series of cases was made by Dr Stanley Gibson and confirmed at operation in every case.

The ages of these patients varied from 2 to 13 years. The most suitable age for operation is between the third and seventh year.

Postoperative complications although not troublesome occurred in the first group of patients. One child aged 4 had a severe postoperative tracheobronchitis and a collapse of the left lung. Both cleared spontaneously. Temporary paralysis of the recurrent laryngeal nerve occurred in two patients—the second and fourth child operated upon. Both of the injuries occurred because during dissection the proper line of cleavage was not followed and the ductus was accidentally

Fig. 5. Technique of division and suture of patent ductus arteriosus.

opened. In the rather panicky application of clamps the nerves were pinched.

We have had no reason to regret drainage of chest after operation no case of empyema or infection around the tube has developed.

The outside diameter of the ductus was usually about 6 to 8 millimeters some were as small as 4 millimeters others as large as 12 millimeters. One child aged 13 weighing 52 pounds, with a much enlarged heart on the verge of failure had a ductus which actually measured 18 millimeters in diameter. During the first two months after operation she gained 22 pounds.

CONCLUSIONS

1. Surgical obliteration of a patent ductus arteriosus has become an accepted procedure.
2. Whether the ductus should be ligated or divided is discussed.

3. Although 22 patent ductus have been successfully ligated it is believed that the preferable operation is division and suture.

4. Employing ductus clamps which utilize a new principle of safety 18 consecutive ductus have been divided and sutured.

5. There has been no mortality in either group.

ANATOMIC VARIATIONS OF THE EXTRAHEPATIC BILIARY SYSTEM AS SEEN BY CHOLANGIOGRAPHIC STUDIES

N FREDERICK HICKEN M.D. F.A.C.S.,

Q B CORAY M.D. and BRUCE FRANZ, M.D., Salt Lake City Utah

CONTRARY to accepted opinions the gall bladder and the bile ducts present many variations in configuration and anatomical positions. Text books on anatomy fail to describe these anatomical aberrations thereby creating the impression that the extrahepatic biliary system follows an immutable structural pattern. Such inferences are not correct.

The fact that the gall bladder may be imbedded in, adherent to or suspended from the ventral surface of the liver invites many positional variations. For example in short stocky people the liver may be small and situated high under the costal margin thereby making the gall bladder a resident of the upper abdominal cavity. On the other hand in the tall ptotic individual the lower surface of the liver may extend below the crest of the ilium thus placing the gall bladder in the recesses of the lower abdomen. The bile ducts which pass down along the free edge of the hepatoduodenal ligament are not rigidly anchored and therefore have no constant position.

Our studies indicate that the bizarre structural pattern of the extrahepatic biliary system occurs with such regularity as to present a most annoying problem. How can the surgeon avoid injuring the misplaced ducts, perform plastic and reconstructive operations or even locate the elusive intraductal stones unless he is conversant with these variables? Likewise the radiologist is unable to interpret contrast cholangiograms correctly unless he is familiar with these mutations.

The material herein presented represents roentgenographic visualizations of the extra-

hepatic biliary system obtained during and after operations on the biliary tract. These contrast cholangiograms were obtained by injecting radiopaque solutions such as diodrast, into the gall bladder and bile ducts and then exposing an x ray film. The resulting cholangiogram gave an excellent roentgenographic pattern of the entire extrahepatic biliary system. Exact anatomical patterns of size, shape, and position of each segment of the biliary system were obtained.

A uniform technique was employed in all operative cholangiograms in order to minimize roentgenographic distortions. The Lys-holm grid was placed directly under the back of the patient in such a manner that it included the entire upper abdominal cavity. The x ray tube stood 25 inches above the cassette and was centered on a point one inch above and one inch to the right of the umbilicus. The rays were directed perpendicularly to the cassette. All films were taken during a period of sustained apnea in order to minimize distortions resulting from motion of the thoracic cage. As all anesthetics were administered by endotracheal intubation it was possible to distend the lungs by positive pressure and thus suspend respiration until the cholangiogram was taken.

OBSERVATIONS

A study of the cholangiograms reveal an amazing variation in size, shape, configuration and position of all components of the extrahepatic biliary system. Representative cases are presented.

Gall bladder The visualized gall bladders represented in Figures 1 to 8 indicate that this organ may occupy any position in the right side of the abdominal cavity. It may rest against the lateral abdominal wall (Fig 1),

Fig. 6.

Fig. 4. Operative cholangiogram. The small ovoid gall bladder hangs suspended from the ventral surface of the liver but it does not possess a pouch of Hartmann. The cystic duct passes upward, arches medially and then passes horizontally to unite with common hepatic duct, directly over the body of the second lumbar vertebra. The slender common duct passes diagonally downward and to the left as it descends over the bodies of the third and fourth lumbar vertebrae. Note that the papilla of Vater is practically in the midline, while in the former cholangiograms it lies lateral to the vertebral column.

Fig. 5. Operative cholangiogram. This vertically placed gall bladder represents the "ptotic type," with its fundus reaching below the crest of the ilium. Note how the long, sacculated cystic duct passes directly upward to join the

common hepatic duct. The dilated choledochus is vertically placed but occupies a lateral position which is in striking contrast to the medially placed ducts in Figure 4. Note the calculus obstructing the ampulla of Vater which accounts for the dilatation of the choledochus.

Fig. 6. Operative cholangiogram. This pear-shaped gall bladder is nestled against the bodies of the second and third lumbar vertebrae and is practically contiguous with the proximal segment of the common bile duct. Note how the cystic duct passes in a horizontal direction toward the right lateral abdominal wall, then turns on itself and passes medially to meet the transverse common hepatic duct over the body of the second lumbar vertebra. The choledochus is pushed over to the midline so it lies over the midportion of the lumbar vertebra, a distinct variable from Figure 5

medialward and then passes downward thus forming a semicircle (Fig. 4). At times the cystic duct lies contiguous to the common hepatic duct as the two descend downward between the leaves of the hepatoduodenal ligament for a distance of 3 inches before the two ducts unite (Fig. 3). At other times the entire cystic duct courses upward in a perpendicular direction (Fig. 5). In Figure 8 the cystic duct encircles the gall bladder, the

latter being mesial and ventral to its evacuating duct.

The manner in which the cystic duct forms its junction with the common hepatic duct is very interesting. As a rule the cystic duct empties into the right lateral wall of the common hepatic bile duct (Fig. 1). It may, however, open into the anterior surface of the common hepatic duct (Fig. 2) or even more rarely into the left mesial wall of the

Fig. 1. Postoperative cholangiogram obtained by injecting persisting external biliary fistula of 3 years' duration with diodrast. The stone-laden gall bladder occupies transverse position lying up under the tenth rib. Apparently the gall stones produced an intermittent obstruction of the cystic duct, thereby forcing bile and mucus out through external orifice of the fistula. The long, sacculated cystic duct passes medially in transverse plane to unite with the horizontally placed common hepatic duct. The choledochus first passes medially and then curves laterally so as to course down and to the right, thus forming a partial arc. Note that the papilla of Vater is placed lateral to the lower border of the body of the second lumbar vertebra.

Fig. 2. Operative cholangiogram. The distended gall bladder occupies true transverse position. The tortuous, sacculated cystic duct courses medially in transverse plane

1 unit with the horizontally situated common hepatic duct. The cystic duct forms a junction with the anterior surface of the common hepatic duct rather than assuming the usual lateral position. Again the common bile duct assumes a half crescent shape as it passes down and to the right of the bodies of the first, second, and third lumbar vertebrae.

Fig. 3. Operative cholangiogram. This gall bladder assumes a vertical position as it is suspended from the ventral surface of the liver. Note the presence of Hartmann's pouch, which is not seen in Figures 1 and 2. The cystic duct descends along the lateral margin of the common hepatic duct for considerable distance before effecting its union. The choledochus assumes a but is considered a normal position, passing downward and slightly medially. The papilla of Vater is lateral to lower border of second lumbar vertebra.

or it may be superimposed over the body of the third lumbar vertebra (Fig. 8). Occasionally it assumes a horizontal position (Fig. 2) or it may hang downward so its fundus extends into the upper pelvic cavity as in Figure 5. Again the gall bladder can have an "S" shaped configuration (Fig. 7) or resemble a small ovoid light globe (Fig. 4). It may present a smooth pear-shaped outline (Fig. 6) or exhibit an irregular sacculated effect as in Figure 3. Rockwood encountered a gall bladder lying external to the muscles of the abdominal wall with a cystic duct which

insinuated its way between the fibers of the muscles and traversed the fascial planes and peritoneum until it reached the common hepatic bile duct. This evidence proves that the gall bladder does present many variations as to size, location, and shape.

Cystic duct. The positions of the cystic duct quite naturally varies with those of the gall bladder which it drains. The cystic duct may appear as a direct continuation of the gall bladder (Fig. 1) or it may appear as a sacculated tube lying in a horizontal plane (Fig. 2). Occasionally it courses upward, turns

or it may be superimposed over the body of the third lumbar vertebra (Fig. 8). Occasionally it assumes a horizontal position (Fig. 2) or it may hang downward so its fundus extends into the upper pelvic cavity as in Figure 5. Again the gall bladder can have an S shaped configuration (Fig. 7) or resemble a small ovoid light globe (Fig. 4). It may present a smooth pearshaped outline (Fig. 6) or exhibit an irregular sacculated effect as in Figure 3. Rockwood encountered a gall bladder lying external to the muscles of the abdominal wall with a cystic duct which

innervated its way between the fibers of the muscles, and traversed the fascial planes and peritoneum until it reached the common hepatic bile duct. This evidence proves that the gall bladder does present many variations as to size, location, and shape.

Cystic duct. The positions of the cystic duct quite naturally varies with those of the gall bladder which it drains. The cystic duct may appear as a direct continuation of the gall bladder (Fig. 1) or it may appear as a sacculated tube lying in a horizontal plane (Fig. 2). Occasionally it courses upward, turns

Fig 10.

Fig 11

Fig 12.

Fig 10. Operative cholangiogram. The dilated common duct assumes a "half crescent shape" rather than descending in a vertical plane. The proximal segment is in a horizontal position while the distal portion passes downward and to the right. This produces an acute angulation. The shadow in the ampullary area represents an impacted stone.

Fig 11. Operative cholangiogram. The common hepatic bile duct and the choledochus traverse a vertical plane as they pass downward over the midportion of the second, third, and fourth lumbar vertebrae. The papilla of Vater

does not pass to the right of the vertebral column before penetrating the duodenal wall. The entire extrahepatic biliary system thus occupies a midline position.

Fig 12. Operative cholangiogram. The common hepatic duct assumes a transverse position as it passes medially to unite with the cystic duct over the midportion of the second lumbar vertebra. The proximal segment of the choledochus is in a horizontal plane. It then angulates and passes downward to the right. Angulation of the choledochus is of common occurrence.

Choledochus The common bile duct has no constant pattern or position. The textbook description is depicted by Figure 5 wherein the choledochus descends along the lateral margin of the hepatoduodenal ligament lying lateral to the right margins of the bodies of the second and third lumbar vertebra. As the retroduodenal segment of the choledochus penetrates the duodenal wall it curves laterally so the papilla of Vater is more laterally placed than any other portion of the duct (Figs. 1 3 7 10 12). However the choledochus may pass downward in a vertical plane (Figs. 6 11) or it may travel in a left oblique direction (Fig 4) or it can transcribe a zig zag pattern as in Figure 13. In many instances the common bile duct lies directly

over the bodies of the second and third lumbar vertebra, rather than being lateral to them. Again the choledochus may form a definite semicircle (Figs. 2 10 13) or it may lie in a horizontal plane (Fig 15). One is amazed at the inconstant anatomical patterns presented by the common bile duct and this may account for some of the difficulties which the surgeon encounters when he attempts to extirpate intraductal stones.

GENERAL CONSIDERATIONS

It is apparent that the surgeon must be conversant with the anatomical variants of the extrahepatic biliary system if surgical treatment is to be effective. True the gall bladder can usually be found by exposing the

Fig 7

Fig 8

Fig 9

Fig. 7. Operative cholangiogram. The "3" shaped gall bladder is transversely placed so it lies under the eleventh rib. The long, tortuous, dilated cystic duct assumes an unusual pattern. Note how it first passes upward, then arches medially so it lies anterior to the common hepatic bile duct. It then passes downward along the medial margin of the common hepatic duct so the two are contiguous. The choledochus has normal position with the papilla of Vater being lateral to the lower border of the second lumbar vertebra.

Fig. 8. Operative cholangiogram. The fundus of the contracted gall bladder lies in the midline directly over the body of the third lumbar vertebra, while the cystic duct passes first to the right, then upward, and finally to the left to join the common hepatic duct over the midportion of second lumbar vertebra. The first portion of the dilated choledochus passes transversely across the body of the

second lumbar vertebra, angulates and descends over the left side of the third lumbar vertebra. The ampulla of Vater was not localized because it contained several stones which had displaced the contrast media.

Fig. 9. This postoperative cholangiogram depicts the normal position of the bile ducts. The common hepatic bile duct descends in a vertical direction just lateral to the bodies of the first and second lumbar vertebrae. The choledochus which is formed by junction of the cystic and common hepatic ducts at the level of the lower margin of the second lumbar vertebra, and from here it descends in vertical plane. The ampulla of Vater was not visualized because it contained several stones which had been overlooked at the primary operation, but despite this obstruction much of the duodenum had escaped into the duodenum. Note the long, dilated stump of the cystic duct resulting from the hydrostatic pressure incident to the ampullary obstruction.

common hepatic duct as the two form the choledochus (Fig 7)

Common hepatic bile duct The common hepatic duct is usually formed by a union of the right and left hepatic ducts at the level of twelfth thoracic vertebra. It is generally believed that the newly formed common he-

patic duct descends along the free edge of the hepatoduodenal ligament in a vertical plane (Fig 3) but it was interesting to observe the frequency with which it assumes a horizontal position (Figs 1 2 3 8 12 15). This horizontal pattern must be kept in mind when exploring this duct for floating calculi

Fig. 10

Fig. 11

Fig. 12.

Fig. 10. Operative cholangiogram. The dilated common duct assumes a "half crescent shape" rather than descending in a vertical place. The proximal segment is in a horizontal position, while the distal portion passes downward and to the right. This produces an acute angulation. The shadow in the ampullary area represents an impacted stone.

Fig. 11. Operative cholangiogram. The common hepatic bile duct and the choledochus traverse a vertical plane as they pass downward over the midportion of the second, third, and fourth lumbar vertebrae. The papilla of Vater

does not pass to the right of the vertebral column before penetrating the duodenal wall. The entire extrahepatic biliary system thus occupies a midline position.

Fig. 12. Operative cholangiogram. The common hepatic duct assumes a transverse position as it passes medially to unite with the cystic duct over the midportion of the second lumbar vertebra. The proximal segment of the choledochus is in a horizontal plane. It then angulates and passes downward to the right. Angulation of the choledochus is of common occurrence.

Choledochus The common bile duct has no constant pattern or position. The textbook description is depicted by Figure 5 wherein the choledochus descends along the lateral margin of the hepatoduodenal ligament lying lateral to the right margins of the bodies of the second and third lumbar vertebra. As the retroduodenal segment of the choledochus penetrates the duodenal wall it curves laterally so the papilla of Vater is more laterally placed than any other portion of the duct (Figs. 1, 3, 7, 10, 12). However the choledochus may pass downward in a vertical plane (Figs. 6, 11) or it may travel in a left oblique direction (Fig. 4) or it can transcribe a zig zag pattern as in Figure 13. In many instances the common bile duct lies directly

over the bodies of the second and third lumbar vertebra rather than being lateral to them. Again the choledochus may form a definite semicircle (Figs. 2, 10, 13) or it may lie in a horizontal plane (Fig. 15). One is amazed at the inconstant anatomical patterns presented by the common bile duct and this may account for some of the difficulties which the surgeon encounters when he attempts to extirpate intraductal stones.

GENERAL CONSIDERATIONS

It is apparent that the surgeon must be conversant with the anatomical variants of the extrahepatic biliary system if surgical treatment is to be effective. True the gall bladder can usually be found by exposing the

Fig. 3.

Fig. 4.

Fig. 5.

Fig. 3. Operative cholangiogram. The common hepatic duct lies lateral to the body of the first lumbar vertebra. Here it unites with the cystic duct. The proximal portion of the choledochus is horizontally placed. It then forms right angle turn and passes downward in the midline. The common hepatic and choledochus thus produce "stair step" pattern.

Fig. 4. Postoperative cholangiogram. The common hepatic duct lies high in the abdominal cavity lateral to the right margin of the twelfth thoracic vertebra. The choledochus forms a semicircle as it arches medially and then passes

downward and to the lateral border of the third lumbar vertebra.

Fig. 5. Operative cholangiogram. This patient had a large carcinoma of the head of the pancreas which was obstructing the ampulla of Vater. Not the dilated common hepatic duct which lies in horizontal plane. The cystic duct unites with the posterior surface of the common hepatic duct. The dilated common bile duct has been pushed upward and medially so it traverses direct horizontal plane. The ampulla of Vater is displaced to the left of the third lumbar vertebra. Appreciation of these transverse positions is essential for correct surgical approach.

ventral surface of the right lobe of the liver but in Figures 5 and 8 the gall bladders have no contact with the liver except by means of the common hepatic duct and its two hepatic tributaries. In one instance we found an elusive gall bladder in the lesser omental cavity. Indeed it was so well hidden that the surgical notes of the two earlier operations stated that the gall bladder was missing. When dealing with an acute suppurative cholecystitis the problem of locating the gall bladder is much more complicated. If the inflammatory process has spread to the stomach, duodenum, pancreas, colon, and omentum one

may experience great difficulty in isolating the enmeshed but distended gall bladder. For example, if the gall bladder seen in Figure 8 should become acutely inflamed it might readily be mistaken for a pancreatic, mesenteric or duodenal cyst because of its unusual location.

In a recent publication we have emphasized the manner in which the cystic duct can and does complicate surgery of the biliary system. When the cystic duct is short and effects an immediate fusion with the common hepatic duct both of these structures may be included by the cystic duct ligature. When the cystic

duct descends along the side of the common hepatic duct the surgeon may leave a long residual stump which eventually becomes dilated and produces the reformed gall bladders of Beye (Fig 9) Should the cystic duct cross over the common hepatic duct and unite with its medial wall then the laterally placed common hepatic duct could be mistaken for the cystic duct, ligated and thus produce an obstructive jaundice (Fig 7) These errors of commission can best be minimized by obtaining cholangiographic visualizations of the biliary system prior to clamping or ligating any of the ducts.

The choledochus has always been a surgical puzzle. Even when the surgeon locates the duct he is never certain that all of the offending calculi have been removed. The large number of patients requiring secondary operations on the biliary tract provides adequate proof that such a problem exists. The angulations, unusual configurations and the anatomical displacements of the common bile duct merely increases the inefficiency of intraductal explorations. One has but to study Figures 6, 8, 13, 14, 15 to appreciate some of the problems which confront the surgeons during these intraductal explorations.

When the common bile duct presents any unusual configuration or position it is an easy matter to force an exploring probe through the duct wall thus forming an internal biliary fistula. In observing numerous operators probing the common bile duct they all attempt to pass the probe downward in a vertical plane believing this to be the normal position of the choledochus. When rigid instruments are forced along the lumen of the angulated choledochus traumatic perforations may ensue. Such errors can be completely eliminated by first determining the exact configuration of the bile ducts by means of cholangiographic studies.

During the past 13 years it has been our practice to obtain a visualizing cholangiogram as soon as the abdomen is opened before any portion of the extrahepatic biliary tract has been disturbed. This can be accomplished by introducing a solution of diodrast into the gall bladder or the bile ducts and then taking an x ray film. Within a period of 10

minutes the radiologist presents the surgeon with an accurate roentgenographic pattern of all components of the biliary system. These visual patterns have been very helpful in determining the type of corrective operation to be employed.

SUMMARY

1. Roentgenographic studies of the extrahepatic biliary systems of patients during and after operations have been made. This was accomplished by injecting a solution of diodrast into the gall bladder or bile ducts and then taking an x ray film. These cholangiographic studies present accurate roentgenographic outlines denoting the size, shape, configuration and anatomical position of each segment of the extrahepatic biliary system.

2. The gall bladder was found to occupy almost every position in the right side of the abdominal cavity. It was seen to lie under the eleventh rib to be contiguous to the right lateral abdominal parietes to be pushed so far medially as to superimpose the body of the third lumbar vertebra and even to hang down into the recesses of the pelvic cavity.

3. The cystic duct was seen to pass medially in a horizontal plane to descend vertically downward toward the lateral border of the third lumbar vertebra to ascend perpendicularly from a gall bladder situated in the pelvic cavity or to describe a tortuous course as it passes mesially to unite with the common hepatic bile duct. It was noted that the cystic duct united with the right lateral wall, the anterior surface or even the left mesial wall of the common hepatic bile duct. There seemed to be little uniformity in pattern.

4. The common hepatic duct was usually noted as passing downward and medially to unite with the cystic duct. At times however it occupied a horizontal position.

5. The choledochus presented no uniform pattern. In some instances it descended in a vertical plane again it was found to lie in a transverse position. Sometimes it appeared as a vertical tube then again it would present a 'zig zag' outline or even be so distorted as resemble the letter S. Occasionally it presented a tortuous contour even transcribing semicircular forms. At times the cho-

A RATIONALE FOR THE SURGICAL TREATMENT OF DUODENAL ULCER

R. ARNOLD GRISWOLD M.D., F.A.C.S., Louisville, Kentucky

THE most rational explanation for the maintenance of chronic peptic ulcer in the human is the inability of the mucosa to withstand the proteolytic activity of the gastric contents. This may be due to (a) lowered resistance of the mucosa, including alteration of its protective mucous secretion (b) increased proteolytic activity of the secretion including reduction of the dilut ing and neutralizing influence of saliva and upper intestinal contents or (c) a combination of these factors.

While acute peptic ulcer may be initiated in the experimental animal by numerous etiologi cal factors, chronic ulcer is maintained only by a persistent reduction of the mucosal resistance-proteolytic activity ratio (4 21). The formation of a chronic jejunal ulcer following the Mann-Williamson operation depends upon shunting of the strongly alkaline biliary pancreatic and other upper intestinal juices away from the gastric outlet so that undiluted unneu tralized gastric contents impinge on the jejunal mucosa (19 20). The production of pep tic ulcer by histamine or caffeine implantation depends upon increasing the proteolytic di gestion (5 16 24 27, 37). Lysozyme by de grading the mucosa of its protective mucous coating may predispose to ulceration (22 23). Vascular or other nutritional factors may re duce mucosal resistance (4 30).

The chief mechanisms for the stimulation of gastric secretion are the humoral and vagal phases (Fig 1). The humoral phase is normally initiated by the action of food on the pyloric part of the stomach or in the intestine (6 14 33 34). It may also be brought about by al co hol caffeine or histamine (8, 24 26, 27 28). The vagal (cephalic) phase depends upon the transmission down the vagus nerve of im pulses that originate in the higher centers be cause of normal (thought smell or taste of

food) or abnormal (emotional) psychic phe nomena (3 9 36). The vagal phase may also be increased by organic brain lesions or hypo glycemic stimulation of the nerve center (7, 15). An important factor in gastric secretion is the fact that the gastric juice secreted by the humoral route is high in acid but low in pepsin while the secretion initiated by vagal stimula tion is not only high in acid but also high in pepsin (3, 13).

Clinically, it has been convenient to use the acidity of the gastric contents in quantity and concentration as a measure of the proteolytic activity of the gastric secretion and most ef forts at the treatment of peptic ulcer have been aimed at reduction or neutralization of the acidity of the gastric juice. It is generally forgotten that it is the pepsin activated by the acid which is the true measure of proteolytic activity and that the concentration and amount of acid present in the gastric secretion is not necessarily a true parallel of the proteo lytic activity of that secretion (17 18).

Most methods of treatment have been aimed at modifying or reducing gastric secretion without reference to the cause of the excess secretion in that particular case. Among the medical treatments diet and antacids have been used to neutralize excess acidity. Secre tory depressants have proved useful. Rest (both emotional and physical) is widely recog nized as beneficial—probably by reducing emotional stimulation of the vagus. Gastro jejunostomy, subtotal gastrectomy and vagot omy have been most popular surgical proce dures. Gastrojejunostomy is effective in many cases by relieving pyloric obstruction, and what is probably more important by allowing a reflux of alkaline jejunal contents to neu tralize gastric acidity. Subtotal gastric resec tion has aimed at suppressing the humoral secretion, and in addition unless a Billroth I type of anastomosis is performed takes ad vantage of the neutralizing action of gastro

Fig. Mechanisms for stimulation of gastric secretion. V Origin of vagal impulses from the central nervous system. G Site of formation of gastrin. This is limited to the pyloric part of the stomach. Nervous (vagal) phase of gastric secretion stimulated by (1) emotional factors, (2) hypoglycemia, (3) taste, thought, or smell of food, (4) intracranial lesions. Humoral phase of gastric secretion stimulated by (1) food in pyloric part of stomach, (2) mechanical irritation of pyloric part of stomach, (3) products of protein digestion after absorption by intestinal mucosa, (4) histamine, caffeine, or alcohol in blood or stomach.

jejunostomy (2 39) It also removes a variable amount of gastric mucosa. In the last few years vagotomy has been popularized to abolish the vagal secretion.

The work of Dragstedt and others on sections of the vagus nerve has awakened a renewed interest in the physiological background of peptic ulcer and has stimulated a search for better methods of surgical treatment (25 29 35) There have now been enough vagus sections reported to indicate that neither vagotomy nor gastric resection alone is the final answer to all cases of peptic ulcer (1 10 38) From the recent literature it would appear that the recurrence rate of ulcer following either gastric resection or vagotomy is about equal. The undesirable side-effects of the two operations are comparable. The mortality rate following vagotomy is probably considerably less than that following gastric resection. Gastrojejunostomy is still a useful operation either alone or in conjunction with subtotal gastric resection or vagotomy although when used alone it does not give as high a percentage of cures as do either resection or vagotomy and is frequently followed by gastrojejunal ulcer.

With the foregoing facts in mind and the probability that there are two factors (vagal

and humoral) concerned with the maintenance of peptic ulcer it occurred to us that it would be useful to determine which secretory mechanism is predominant in a given case before carrying out any operative procedure in an attempt to abolish the abnormal mechanism. Actually the question is, should the humoral phase of gastric secretion be modified by subtotal gastric resection, or should the cephalic phase be abolished by vagotomy?

Our present concept of ulcer maintenance may be illustrated as in Figure 2. The line, ulcer threshold, is a level of mucosal resistance including such factors as the amount of mucous and other protective mechanisms. This level probably varies in different patients and from time to time in the same patient. Gastric secretion, in amount and concentration exceeding this threshold, would cause maintenance of an ulcer. Spontaneous or seasonal remissions and exacerbations of peptic ulcer show that the ratio of proteolytic activity to mucosal resistance may vary from time to time. From the fact that the majority of ulcers may be healed by abolishing either the humoral or vagal phase (subtotal resection or vagotomy) it would appear that in most of them the situation would be somewhat as shown in column 1 where the suppression of either the humoral or vagal secretion would bring proteolytic activity below the threshold line. However in column 2 in which the vagal secretion exceeds the threshold, it would appear that vagotomy would heal the ulcer while gastric resection would result in recurrence or gastrojejunal ulcer. Likewise, in column 3 vagotomy would be ineffective in controlling the ulcer while gastric resection would bring the column below the threshold line.

Working according to this hypothesis we have attempted to differentiate between the humoral and vagal factors in ulcer patients by performing preoperative studies of the comparative response to humoral and to vagal stimulation. The functions¹ tested are secretory rate, emptying rate (a function of gastric motility), peptic power and least important

¹The gastric function studies reported in this work were developed and carried out by Dr. Arthur M. Schoen of the Department of Medicine and Pharmacology of the University of Louisville School of Medicine under grant from the National Institute of Health.

of all, acidity. The secretory rates and emptying rates are calculated according to the methods of Schoen (31, 32). Peptic power is measured by a modification of the method of Mett (12), and the hydrogen ion concentration is measured electrometrically.

We have been able to differentiate in the few cases thus far studied between one group which seems to respond predominately to vagal stimulation and another group which seems to respond predominately to humoral stimulation as measured by secretory rate, emptying rate, and output of pepsin and hydrochloric acid. A third and probably the largest group seems to respond almost equally well to either stimulus. The following case reports represent an example from each group.

CASE 1. Predominate response to vagal stimulation (Fig 3 and Table I). Patient L. S., 63 year old white male with symptoms of peptic ulcer disease for 30 years had melena in November, 1947. He had 3 episodes of marked gastric retention between December 1947 and April 1948. There was fluoroscopic and x ray evidence of crater in duodenal bulb, marked duodenal deformity and 40 per cent retention of barium at 5 hours on November 24, 1947. Celiotomy performed on April 29, 1948 revealed marked duodenal deformity with induration and scarring. Symptoms of gastric retention and pain were subsiding at the time of the gastric function studies on April 22, 1948. The average values of basal function during the three control periods were: peptic power 4,000 units per cubic centimeter free acidity 34 clinical degrees (milliequivalents per liter) secretory rate, 0.77 cubic centimeter per minute emptying rate, 1.21 cubic centimeters per minute. The average rate of secretion of free hydrochloric acid (hydrogen ions) was 0.0262 milliequivalent per minute and the average rate of secretion of pepsin was 3,100 units per minute (not shown in Fig 3).

The high peptic power of the control (basal) secretion is strongly suggestive of a high concentration of vagally stimulated gastric juice. The accompanying low rate of basal secretion of essentially normal acidity indicates a low output of hydrochloric acid and mucus during the control periods. The differences in emptying rates between the three control periods are within the range of a normal healthy individual.

Histamine had the usual influence on the rate of secretion of hydrochloric acid. The output of free hydrochloric acid was increased

Fig 2. Concept of peptic ulcer maintenance. When column exceeds the threshold, the ulcer is maintained. Patients represented by column 1 should benefit from either vagotomy or subtotal resection. Those represented by column 2 should benefit from vagotomy but not from subtotal resection. Those of column 3 should benefit from subtotal resection but not from vagotomy.

from 0.0262 to 0.563 milliequivalent per minute (not shown in Fig 3). The acidity of the gastric juice was increased from 34 to 125 clinical degrees (milliequivalents per liter). While the peptic power of the gastric juice was diminished following the injection of histamine, the actual output of pepsin from the mucosa was increased during the first period after the histamine injection (18½ minutes) from 3,100 to 8,000 units per minute (not shown in Fig 3). This increased output of pepsin by the gastric mucosa following the injection of histamine has been attributed to the "washing-out" by the increased secretion of the parietal cells of the gastric crypts and alveoli which contained a normal accumulation of secretion from the acid and pepsin secreting cells. The rate of pepsin output at the time the maximum rate of histamine stimulated gastric secretion occurred was only 1,580 units per minute. The increase in the rate of gastric emptying was due partly to the increased volume of gastric contents as a result of the increased secretory rate. There was an initial depression of the emptying rate following the injection of histamine.

Insulin hypoglycemia produced a much higher rate of gastric secretion and emptying than did histamine. The increase of gastric function was preceded by a depression of all components. This latter phenomenon has occurred consistently in all people after the injection of insulin. The maximum rate of pepsin output during insulin hypoglycemia was

Fig. 3. Gastric function of one whose predominate response was to vagal stimulation. P, Peptic power of residual gastric juice, 1 end of test period adjusted to per .68. FA, Free acidity of residual gastric juice at end of test period. S, Average secretory rate during test period. E, Average emptying rate during test period. Albumin tubes were digested completely minimum peptic power 5,200 units per cubic centimeter.

60,400 units per minute which is far in excess of either the basal rate (3,100 units per minute) or the maximum rate following the injection of histamine (8,000 units). This maximum rate of pepsin output occurred during the period when secretory rate was also a maximum.

Although the maximum concentration of free hydrochloric acid in the histamine stimulated gastric juice was essentially the same as the maximum attained during hypoglycemia (125 and 124 clinical degrees) the maximum rate of secretion of free acid following histamine was 0.563 milliequivalent per minute as compared with 1.380 milliequivalents per minute during insulin hypoglycemia (not shown in Fig. 3).

TABLE I.—SUMMARY OF THE RESPONSES OF GASTRIC FUNCTION TO HISTAMINE AND INSULIN HYPOGLYCEMIA

¹ Unit per cc.—same as Malt unit except that expressed of 5 was used for calculating peptic power.

² Peptic output—peptic power X secretory rate.
³ Free acid output—free acidity X secretory rate.

Fig. 4. Gastric function of one whose predominate response was to humoral stimulation.

Fig. 5. Gastric function of one whose response was about equal to vagal and humoral stimulation.

CASE 2 Predominate response to humoral stimulation (Fig 4 and Table I). Patient E. W. 62 year old white male with recurrent symptoms of peptic ulcer for more than 6 years showed evidence of complete obstruction in February 1948. A ray examination on March 15, 1948 showed 00 per cent retention of barium at the end of 5 hours. Celiotomy performed on March 26, 1948 revealed evidence of duodenal ulcer and marked scarring of the first part of the duodenum. The pyloric obstruction was subsiding at the time of the gastric function studies on March 22, 1948. The average values of basal gastric function during the three control periods were: pepsin power 0 units per cubic centimeter, free acidity 0 clinical degrees (milliequivalents per liter) secretory rate, 1.15 cubic centimeters per minute emptying rate 1.90 cubic centimeters per minute.

The absence of active pepsin and hydrochloric acid (pH of the basal secretion was 7.0) in the gastric juice of the control periods suggests that the nervous phase of gastric secretion was acting not at all or very little. With no food in the stomach or intestines the humoral phase also would not be acting hence

the absence of acid and pepsin in the basal secretion. A small amount of acid or pepsin could have been neutralized by mucous secretion.

Histamine increased the secretory rate and stimulated the production of hydrochloric acid. The response to histamine in this patient was less in every respect than the response in patient L.S. (Fig 3). The presence of pepsin in the histamine stimulated gastric juice, again could be due to the 'washing-out' process mentioned under Case 1. This would imply however that some pepsin had been present in the gastric alveoli previous to the injection of histamine. Whether it had been produced during the basal periods by either the nervous or humoral phases cannot be determined. Histamine again caused an initial depression of the emptying rate which was followed immediately by an increased rate of emptying.

During the 10 minute period immediately following the injection of insulin there was a marked decrease in all components of gastric function. This phenomenon occurs whenever insulin is injected. The increase of gastric function which usually follows the initial period of inhibition did not occur in this person (Fig 3). Instead there was a persistence of the state of diminished gastric activity. The initial increase of the peptic power following the injection of insulin resulted from the decreased secretory rate and does not represent an increase in the output of pepsin. Actually, the output of pepsin dropped from 570 units per minute to 460 units per minute during the 10 minute period following the injection of insulin and it continued to drop to zero (not shown in Fig 4).

CASE 3 Equal response to vagal and humoral stimulation (Fig 5 and Table I). Patient A. M. 47 year old white male with history of peptic ulcer for 10 years had a massive hemorrhage in April, 1943. X-ray examination and fluoroscopy showed crater in duodenum and clover leaf deformity of the pyloric cap on June 22, 1943. Typical symptoms of peptic ulcer were subsiding at the time of the gastric function studies on June 23, 1943. The average values of basal gastric function during the three control periods were: peptic power 1,600 units per cubic centimeter free acidity 29 clinical degrees (milliequivalents per liter) secretory rate 1.04 cubic centimeters per minute emptying rate 2.24 cubic centimeters per minute. The average rate of secretion of free hydrochloric acid (hydrogen ions) was 0.0302 milliequivalent per minute, and the average rate of secretion of pepsin was 660 units per minute (not shown in Fig 5).

The lower concentration of pepsin in the basal secretion of this person as compared with the pepsin concentration in the basal secretion of patient L.S. (Fig 3) suggests a lower concentration of vagally stimulated gastric juice. The pepsin output of this patient under basal conditions was 1,660 units per minute which is less than one-half of the pepsin output of patient L.S. under similar conditions. A comparison of the acidities and secretory rates of the basal secretions of this person with patient L.S. suggests that in this person there was relatively a higher rate of secretion of nonacid and nonpepsin constituents (mucous secretion).

Comparisons of the maximum responses to histamine and insulin show that histamine

stimulated the secretion of hydrochloric acid slightly more than did insulin hypoglycemia (0.340 milliequivalent per minute for histamine, and 0.224 milliequivalent per minute for insulin hypoglycemia). Secretory rate also was stimulated somewhat more by histamine (4.0 c.c. per minute for histamine, and 3.10 c.c. per minute for insulin). However peptic power output of pepsin and emptying rate were all stimulated more by insulin (Table I).

We are now basing our operative therapy on the differentiation of duodenal ulcer patients into the groups as shown by these tests, doing subtotal resections on those patients who respond predominately to humoral stimulation and vagotomy on those responding predominantly to vagal stimulation. In the third group in which it would seem that equally good results would follow either procedure, the choice of operation may depend upon factors other than the gastric function studies. The gastric resections performed are the standard high resections with care to remove all antral tissue. Continuity is usually re-established by anterior Polya gastrojejunostomy. Vagotomy is carried out transthoracically unless there is a special indication for abdominal exploration or unless gastrojejunostomy is to be added to the vagotomy. No gastric ulcers are included in this study since we believe that the incidence of unsuspected carcinoma in gastric ulcer is so high that any procedure which does not involve resection of the ulcer is dangerous. It is also believed that gastric ulcer results from a different condition than duodenal or jejunal ulcer not having the same age incidence, sex incidence, or necessarily the same physiological characteristics. Gastrojejunostomy is performed in addition to vagotomy on all patients whose stomachs are not empty at the end of 2 hours following the ingestion of barium. While it is realized that a normal stomach may retain barium as long as 5 hours, it is felt that in the hypertonic, hypermotile stomach with ulcer any retention beyond 2 hours indicates relative pyloric obstruction and that symptoms of retention may occur unless a drainage operation is combined with the vagotomy. It has been argued that the addition of gastrojejunostomy prevents a thorough evaluation of vagotomy. On

the other hand, gastric resection of the Polya Hofmeister or similar types also takes advantage of gastrojejunostomy by bringing the alkaline jejunal contents to the most vulnerable spot, which is the area of the anastomosis.

It is evident that it will require many cases handled according to this method followed over a period of years to test the validity of our hypothesis. This work is presented in its present early stage in the hope that others who are interested in the problem of peptic ulcer may work along similar lines to prove or disprove this hypothesis in a shorter time than we would be able to do alone and to develop practical tests of gastric function which will give more adequate information in planning a rationale of treatment than have the tests which are in general use.

During the 10 minute period immediately following the injection of insulin there was a marked decrease in all components of gastric function. This phenomenon occurs whenever insulin is injected. The increase of gastric function which usually follows the initial period of inhibition did not occur in this person (Fig. 3). Instead there was a persistence of the state of diminished gastric activity. The initial increase of the peptic power following the injection of insulin resulted from the decreased secretory rate and does not represent an increase in the output of pepsin. Actually the output of pepsin dropped from 570 units per minute to 460 units per minute during the 10 minute period following the injection of insulin and it continued to drop to zero (not shown in Fig. 4).

CASE 3. Equal response to vagal and humoral stimulation (Fig. 5 and Table I). Patient A. M. 47 year old white male with history of peptic ulcer for 6 years had a massive hemorrhage in April, 1948. X ray examination and fluoroscopy showed crater in duodenum, and clover leaf deformity of the pyloric cap on June 22, 1948. Typical symptoms of peptic ulcer were subsiding at the time of the gastric function studies on June 3, 1948. The average values of basal gastric function during the three control periods were: peptic power, 1,600 units per cubic centimeter free acid, 17.29 clinical degrees (milliequivalents per liter); secretory rate, .04 cubic centimeters per minute; emptying rate, 2.24 cubic centimeters per minute. The average rate of secretion of free hydrochloric acid (hydrogen ions) was 0.0303 milliequivalent per minute and the average rate of secretion of pepsin was 1.660 unit per minute (not shown in Fig. 5).

The lower concentration of pepsin in the basal secretion of this person as compared with the pepsin concentration in the basal secretion of patient L.S. (Fig. 3) suggests a lower concentration of vagally stimulated gastric juice. The pepsin output of this patient under basal conditions was 1,660 units per minute which is less than one-half of the pepsin output of patient L.S. under similar conditions. A comparison of the acidities and secretory rates of the basal secretions of this person with patient L.S. suggests that in this person there was relatively a higher rate of secretion of nonacid and nonpepsin constituents (mucous secretion).

Comparisons of the maximum responses to histamine and insulin show that histamine

stimulated the secretion of hydrochloric acid slightly more than did insulin hypoglycemia (0.340 milliequivalent per minute for histamine and 0.224 milliequivalent per minute for insulin hypoglycemia). Secretory rate also was stimulated somewhat more by histamine (4.0 c.c. per minute for histamine and 3.10 c.c. per minute for insulin). However peptic power output of pepsin and emptying rate were all stimulated more by insulin (Table I).

We are now basing our operative therapy on the differentiation of duodenal ulcer patients into the groups as shown by these tests, doing subtotal resections on those patients who respond predominately to humoral stimulation and vagotomy on those responding predominately to vagal stimulation. In the third group in which it would seem that equally good results would follow either procedure the choice of operation may depend upon factors other than the gastric function studies. The gastric resections performed are the standard high resections with care to remove all antral tissue. Continuity is usually re-established by anterior Polya gastrojejunostomy. Vagotomy is carried out transthoracically unless there is a special indication for abdominal exploration or unless gastrojejunostomy is to be added to the vagotomy. No gastric ulcers are included in this study since we believe that the incidence of unsuspected carcinoma in gastric ulcer is so high that any procedure which does not involve resection of the ulcer is dangerous. It is also believed that gastric ulcer results from a different condition than duodenal or jejunal ulcer not having the same age incidence, sex incidence or necessarily the same physiological characteristics. Gastrojejunostomy is performed in addition to vagotomy on all patients whose stomachs are not empty at the end of 2 hours following the ingestion of barium. While it is realized that a normal stomach may retain barium as long as 5 hours, it is felt that in the hypertonic, hypermotile stomach with ulcer any retention beyond 2 hours indicates relative pyloric obstruction and that symptoms of retention may occur unless a drainage operation is combined with the vagotomy. It has been argued that the addition of gastrojejunostomy prevents a thorough evaluation of vagotomy. On

Figs 1 and 2 S B 42-132. Elastica, Fig 1 left $\times 16$ Fig 2 $\times 88$. Origin traumatic. Operation revealed a ruptured disc at the fourth lumbar vertebra. Pathologically, the lamellae of the annulus fibrosus are partly preserved, partly destroyed. The inner lamellae are increasingly necrotic (IL, Fig 1). The disc proper shows dense hyaline cartilage with gradual thinning into fibrous cartilage and reticular dissolution around numerous large cartilage cells (Fig 2). No part of the nucleus pulposus was found. Result good in the beginning 5 years after operation, patient complained of moderate sciatic pain in the left buttocks and was dissatisfied with the result.

GROUP I

The poorest results were found in the 15 patients of our first group namely in discs which the surgeon described as *bulging*. This term is meant to indicate that the posterior part of the annulus fibrosus protruded upward without any visible lesion of the annulus or the cartilage. This form seems to correspond with what has been called *hidden disc*. It was assumed that this anomaly was the cause of the clinical symptoms and signs. Hence the annulus was incised and the allegedly diseased disc material removed.

Histopathological examination of the biopsy material fails to show any abnormality. It contains normal lamellae of fibrous cartilage sometimes with adherent gelatinous tissue.

Results Not more than one third of the persons in this group experienced reasonable benefits from operation. The inference is that in those not improved the bulging annulus had not been the cause of the complaints. Gurdjian¹ states that in his experience persons with bulging disc and good operative results had shown invariably the typical defect in the myelogram and had suffered traumatic lesions.

Personal communications.

of the disc lamellae without a visible rent in the annulus. Mixter¹ takes exception to the last part of this opinion. He believes that a small rent of the annulus may be easily overlooked unless the patient's spine is over stretched during operation.

A bulging disc results from a paunchy posterior annulus fibrosus without rent in the annulus and without detachment of the disc from the bone. It should not be incised unless there is definite evidence of its encroachment upon a posterior root.

GROUP II

In our second group a rent in the annulus fibrosus was found during operation through which disc material was *herniating* into the spinal canal. A spinal root was found hooked up over it.

Histological examination of the biopsy material reveals cartilaginous lamellae of the disc in varying degrees of necrosis and liquefaction (Fig 1). The inner lamellae of the disc are often necrotic. Dense hyaline cartilage is seen gradually thinning out into fibrous cartilage with reticular dissolution of the tissue around large cartilage cells (Fig 2). Oc

THE MECHANISM OF THE INTERVERTEBRAL DISC PROTRUSION

F. H. LEWEY, M.D. Philadelphia, Pennsylvania

THE concept of sciatica has changed so radically and rapidly in the 15 years since Muxter and Barr's basic contribution to its diagnosis and surgical treatment that pathological anatomy and physiology have been unable to keep up with the clinical development.

Both sciatica and low back pain—the scourge of neurologists and orthopedic surgeons for scores of years—seem to have become a problem for the neurosurgeon. However, growing experience has shown that operative treatment does not benefit, in the long run, more than one-half to two-thirds of the patients in this group. Indeed, the fact that the neurosurgeons have changed their operative approach and technique repeatedly would suggest that they were not wholly satisfied with their results. It is quite confusing to see not only that the success of the same operative method varies widely in the hands of different surgeons but also that a method is sometimes dismissed by the same surgeon who had praised it previously because he found it ineffective in some patients.

It has been suggested that valid statistics of the final results of an operative method will be obtained only if it is performed by the same surgeon with controls for comparison in a sufficient number of patients taken at random. However, this method of sampling will give the expected results only if the basic pathology is uniform and that is exactly what is under scrutiny. If the presumption is made that the mechanism of disc protrusion is not the same in all patients, then it is obvious that one type of treatment will not fit all patients.

Most conjectures concerning the mechanism of the intervertebral disc protrusion are not based on objective experience with the pathological process. A great amount of de-

tailed knowledge has been collected as to the clinical x-ray and operative findings in the disc syndrome but very little is known about the pathological anatomy of the process. A few operative and many diagrammatic sketches have been published indicating what was seen at operation and what the surgeon inferred as to the mechanism of the intervertebral disc disorder. Very few of these concepts were based on histologic-pathological findings. Not even a uniform nomenclature has been generally accepted. The terms hidden or bulging disc, ruptured, herniating protruded, and slipped disc are sometimes used as if interchangeable. In reality they denote entirely different conditions.

Statistics concerning 40 cases of disc removal for sciatica from patients whose clinical, x-ray, operative, and pathological data were complete and who could be followed-up for a sufficient number of years form the basis of Table I. These cases represent part of a group of 169 in which removal was carried out by F. C. Grant and R. A. Groff in the Hospital of the University of Pennsylvania and the Graduate Hospital in Philadelphia respectively between the years 1939 and 1943.

TABLE I.—TYPES OF DISCS OPERATIVELY REMOVED

Types	No.	Per cent	Good or better results		Average result of the whole group
			No.	Per cent	
Bulging	18	45	2	11	Fair to poor
Herniating	17	43	9	53	Excellent to good
Slipped	14	35	8	57	Good to fair
Total	49				

Histopathological examination of the 169 discs removed at operation and of 20 controls seems to suggest that the pathological findings may be grouped into three almost equal classes with widely different results.

From the Neuropathological Laboratory of the Neurosurgical Service of the University Hospital and the Department of Neuroanatomy of the Graduate School of Medicine, University of Pennsylvania.

Figs. 4 and 5. A, 50 years, 42-146 Fig. 4 phosphotungstic acid hematoxylin, $\times 88$ Fig. 5, van Gieson, $\times 88$ Origin no trauma remembered. Clinically typical sciatica of 20 years duration. Operation revealed a large disc over which the nerve was hooked up and freed. Pathologically the piece removed represents a section of the intervertebral disc (Fig. 4). The surface of its bony attachment is only 6 centimeter long but its extension toward the center of the disc is more than 1 centimeter long. It shows clearly from above downward the ragged bony attachment of hyaline cartilage (H) followed by fibrous material but no pulp. The detail (Fig. 5) shows patches of brown atrophy (B) and a few strands of connective tissue fibers at its inner margin. Result good.

result suggests that the surgical technique may be improved

In slightly more than one-third of our cases of disc removal injury led to rupture of the lamellae extending into the epiphyseal plate and to fracture of the rim of the vertebra. This lesion frees the disc from its anchorage and permits it to slip backward. In doing so it encroaches upon a root and extends it. The sharp bony margins may secondarily sever the slipped portion of the disc partially or completely.

DISCUSSION

Various questions pertaining to the disc syndrome have been raised. The most puzzling of all is what happened to the victims of sciatica who were not operated upon prior to the last 15 years? True the neurologist saw patients with chronic sciatica. But with our present experience one would expect large numbers of them eventually to enter institutions for the chronically sick. This was definitely not the

Fig. 3 H, 4+ Elastica, $\times 85$ Origin traumatic. Clinically typical spondylitis. X ray spondylolisthesis. Operation revealed small disc consisting of a small rim of eticular hyaline cartilage surrounding the nucleus pulposus. The nerve was found bony and freed. Pathologically an advanced granular reticular necrosis (N) of the feathery gelatinous substance surrounding the pulp was found. An unusually large portion of the nucleus pulposus as adherent to the disc. The picture shows the typical tuft-like structures (T) lined by cartilage cells, some of them in gelatinous degeneration. Result good.

asionally an amorphous mass is found which may represent liquefied cartilage or may constitute part of the nucleus pulposus (Fig. 3). However there is no evidence that the hernia usually consists of nucleus pulposus. In other instances the rent does not go straight inward but obliquely upward severing the attachment of one or more lamellae to the epiphyseal plate (Fig. 4). Pieces of brown atrophy lined by connective tissue are sometimes visible and may indicate the long duration of the process (Fig. 5).

Result. Removal of the herniated tissue and freeing of the involved posterior root gave excellent or good results in 83 per cent of those operated upon in this group.

A herniating disc results from traumatic necrosis of the disc lamellae and their protrusion

through a rent in the annulus fibrosus. Liquefied cartilage or viscous material of the nucleus pulposus may be extruded. The protruded mass has to be excised and the content of the disc eventrated sufficiently to free the overextended posterior root. The good operative results indicate that the surgical procedure was adequate in this group.

GROUP III

In our third group of patients it was found that an eccentric posterior portion of the disc had actually slipped backward from its attachments to the bony surface of the vertebral bodies. In other words, this type represents a true focal protrusion of the intervertebral disc. It is not easy to explain satisfactorily from the operative appearance of the disc or from gross examination of the specimens the mechanism of slipping. The apparent reason for this is that the surgeon has to cut into the protruding material in order to remove it. The direction of the incision is dictated by the narrow space of exposure rather than the anatomical situation. Only when the slipped portion of the disc was broken off and removed in its entirety was a revealing specimen made available.

Pathological examination shows a picture entirely different from that of the previous group. We find parts of the epiphyseal plate and sometimes of the bone itself (Fig. 6). A group of loosely arranged bone septa is present, sometimes filled with red bone marrow fragments of the posterior longitudinal ligament and cartilaginous lamellae of the disc. The continuity of bone, epiphyseal plate, hyaline, and fibrous cartilage is evident. The tissue may be in degeneration as is to be expected after being separated for quite a while from its normal environment. The fact that this often gives the inner part of the disc a gelatinous appearance but that no tufts or cartilage cells are visible suggests that the tear has been confined to the posterior one-fourth or one-third of the disc.

A similar though less complete pathological picture is found if the protruded disc has not been fractured and the annulus has had to be incised to remove the injured lamellae. Again we find a large portion of the disc with its at

Fig. 4.

Fig. 5

Figs. 4 and 5. A., 50 years 42-146. Fig. 4, phosphotungstic acid hematoxylin, $\times 85$. Fig. 5, van Gieson, $\times 8$. Origin, no trauma remembered. Clinically, typical sciatica of 20 years duration. Operation revealed a large disc over which the nerve was hooked up and freed. Pathologically, the piece removed represents a section of the intervertebral disc (Fig. 4). The surface of its bony attachment is only 6 centimeter long, but its extension toward the center of the disc is more than 1 centimeter long. It shows clearly from above downward the ragged bony attachment of hyaline cartilage (*H*) followed by fibrous material but no pulp. The detail (Fig. 5) shows patches of brown atrophy (*B*) and a few strands of connective tissue fibers at its inner margin. Result good.

tachment. The line of cleavage as a rule runs smoothly through the hyaline cartilage (Fig. 7) or particles of bone may be found in a ragged line of separation (Fig. 8). In either instance the disc is characterized by its horse-shoe shape which results from the elasticity of its stiff fibers after their separation from the bone. The cartilaginous lamellae are cross-sectioned so that one layer after the other is visible from the rest of the annulus fibrosus on the left to the more central portions of the disc on the right (Fig. 7). Areas of partial necrosis and softening and others of granular degeneration are visible in the fibrous part of the disc. Only occasionally remnants of cartilage cells or other parts of the nucleus pulposus are found. In other words the histological sections show a radial slice of a disc transecting the lamellae in a vertical sector and running parallel with the cartilage fibers.

Results. The fact that only 57 per cent of those operated upon in this group had a good

result suggests that the surgical technique may be improved.

In slightly more than one third of our cases of disc removal injury led to rupture of the lamellae extending into the epiphyseal plate and to fracture of the rim of the vertebra. This lesion frees the disc from its anchorage and permits it to slip backward. In doing so it encroaches upon a root and extends it. The sharp bony margins may secondarily sever the slipped portion of the disc partially or completely.

Fig. 6. Sister R. 42-4. Elastica, $\times 8$. Origin traumatic. Clinically typical sciatica. X-ray upper posterior angle of the fifth lumbar vertebra broken off. Operation revealed ruptured disc. The root as hooked up, not freed. Pathologically the picture shows the posterior lower angle of the fifth lumbar vertebra broken down a bone lamellae (B). The posterior longitudinal ligament (PLL) is adherent to the bone (C) its posterior (right) margin, the hyaline and fibrocartilaginous tissue of the intervertebral disc (D) its inferior surface. Only few ring-shaped lamellae of the disc are preserved as dark lines. Most of the tissue shows a hyaline degeneration which becomes slightly gelatinous toward the center of the disc. Result: excellent for 3 years until she began tremendous physical work resulting in instability of her back. She was working without complaints while wearing her brace but fusion, as recommended by orthopedists. Went to India for missionary work. Without fusion. Satisfied 7 years later.

case. There is good reason to believe that parts of the protruded disc become separated and resorbed in the course of time. One also wonders how it happens that in a considerable number of husky persons trivial trauma leads to infraction not only of the epiphyseal cartilage but also of the bone. If however this mechanism is operative why is it found in only about one-third of the patients with disc syndrome?

The majority of both neurologists and neurosurgeons agree today that not all cases of

sciatica are caused by a protruding disc or lend themselves equally well to operative treatment. Consideration of the anatomical and pathological findings indicates clearly that sciatic pain—in contrast to the pure low back pain—cannot be blamed on an abnormal disc unless a posterior root is compressed by it. Decompression of the involved root is therefore the first requisite of a successful operation for sciatica. This explains clearly why a simple bulging disc should be left alone.¹ The validity of this statement may be strengthened by the fact that bulging discs were found in necropsy in 28 per cent of 75 persons who at no time had complained of sciatica (Horwitz).

In considering the postoperative results the patients of this, more than the other two groups, complained of backache rather than true sciatica. Our material is too small for a conclusive estimate but if our impressions were correct the wisdom of removing parts of a normal disc would be further challenged because an already unsatisfactory stability of the spine would be disturbed to a still greater extent. A more rational procedure in this group of patients might be fusion of the spine so highly recommended by orthopedic surgeons, yet not found to be superior to simple disc removal by neurosurgeons.

There can be no doubt that disc material herniating through a rent in the annulus fibrosus needs thorough removal to free the involved posterior root. But again the question arises: What is the rationale from the pathological point of view of scraping out from within the disc all available material or of attempting evacuation of the nucleus pulposus? Finally, why does the annulus fibrosus, surrounding the disc rupture just at its posterior circumference?

These questions cannot be answered without a true three dimensional concept of the configuration of the normal intervertebral disc together with its attachment to its adjacent vertebrae.

It has been said that the intervertebral disc functions as a water cushion between two vertebrae. This is obviously no more than an

¹ Nordin and Grantham have recently stressed these points.

Fig. 9. Diagram of the structure of the disc lamellae.

als of the notochord. Some technical operative recommendations seem to stem from this erroneous concept.

Actually the disc is composed of numerous cylindroid-shaped lamellae arranged around one another in near concentric fashion (Fig. 9). The greater part of these lamellae consists of fibrous cartilage. The lamellae fuse together at their upper and lower ends in a homogeneous plate of hyaline cartilage (Fig. 12). These plates represent simultaneously the upper and lower surfaces of the disc and the epiphyseal plates by means of which the disc is attached to the adjacent vertebrae. The external layers of the lamellae which form the circular wrappings of the disc—the annulus fibrosus—are strongly fibrous and stiff. They do not fuse into the epiphyseal plate but

Fig. 10. L. 43 years, colored, 42-35. Elastica, $\times 65$. Origin traumatic. Clinically typical sciatica. X-ray sclerosed aorta. Operation: herniating disc. Pathologically severe reticular trophic of fibrous cartilage with large fibrocartilage cells. This is a progressed state of degeneration, possibly of vasculonutritional origin, characterized by absence of viable cells within the boxes. Some boxes are filled with connective tissue, others are empty. Result seemed good in the beginning but was unsatisfactory 5 years later, probably because of the insufficient blood supply from the sclerosed aorta.

are directly inserted into the bone surface of the vertebrae (Sharpey's fibers).

The central portion of the disc consists of a biconvex lentil-shaped mass—the nucleus pulposus—which is gelatinous in youth and becomes more fibrous in adult life. Peterson describes the nucleus pulposus as true fibrocartilage in an almost fluid interfibrillary substance and Schaffer as chondro-mucoid jelly. Soft fibrous cartilage lining the nucleus pulposus protrudes tuft or feather like into its ragged cavity. Notochord cells are found in its center at birth but disappear after the third year of life. Fick, Saunders, Dockerty and Love have described and illustrated vesicular cells in the pulp of adults which they identify with notochord cells. However most anatomists and pathologists agree that no notochord cells survive in adults unless in a true chordoma. The cells seen in the gelatinous part of the disc are surrounded by a halo and arranged in groups of 2 or 4 within a mother capsule (Koclikier). They represent cartilage cells.

Small foci of softening and cavity formation in the fibrous cartilage seem to occur normally. Conversely wear and tear in consequence of strain and age seem to change the disc in the opposite direction. The nucleus pulposus loses its viscous appearance and becomes more fibrous, tendinous, chondroid and eventually calcified (Uebermuth). Rathcke found gross calcification of the nucleus pulposus in 4.1 per cent of spines in patients between the ages of 30 and 50 and 8.7 per cent in the older age group. A powder-like calcium deposit is often seen on the tufts of the nucleus pulposus of older persons. The disc lamellae shrink and seem to be more brittle. Signs of brown atrophy are found. However no indication of disease was observed in our disc biopsies with the three following exceptions. Marked necrosis was present in the discs of 3 middle aged colored men with x-ray evidence of progressive sclerosis of the descending aorta (Fig. 10). They were considered as of vasculonutritional origin. Infection, inflammation and cartilaginous metaplasia as described by Saunders and Inman were absent in our material. Schmorl believes that they are very rare in adults.

Fig. 11. Cross section of normal disc with separate nuclei pulposi, extending backward to dorsal aspect (D) and adjacent vertebrae. Modified after Boernig.

All authors agree that necroses with liquefaction of cartilage are common in biopsy material (Smith Saunders and Inman) and fairly frequent in necropsy material (Schmorl and Junghans). However there is difference of opinion as to cause and effect. Some believe that the disc ruptures because its lamellae have become necrotic in consequence of disease others see in the necrotic tissue the effect of trauma. Hence the first group is in favor of thorough surgical dismemberment of the disc to prevent further expulsion of diseased lamellae. Some are of the opinion that the extruded liquefied tissue is necessarily part of the nucleus pulposus. They speak of protrusion of the nucleus pulposus and go so far as to attempt scooping out of the entire central part of the disc. In our own biopsy material of herniating discs tufts capsule cells or other characteristics of the nucleus pulposus were usually absent in the removed amorphous viscous material.

The position of the nucleus pulposus within the normal disc plays a major role in the theories of the protruding disc. Luschka described as a normal variant of the nucleus pulposus a posterior recessus which would bring the gelatinous mass close to the annulus fibrosus. However Schmorl saw Luschka's posterior recessus in only 15 per cent of 400 normal spines although segmentation of the pulp and even 2 or 3 independent gelatinous masses occurred in 75 per cent of 95 normal discs (Fig. 11 Boernig). Horwitz found unilateral posterior dislocation of the nucleus pulposus in 5.25 per cent of 75 normal discs.

Fig. 12. Diagrammatic picture of anchorage of disc lamellae in epiphyseal plate. Bone dotted cartilage horizontally dashed. The left picture is of a juvenile individual in whom the expanded rim of the vertebrae is still cartilaginous and contains the ring shaped bone nucleus. The Sharpey fibers of the annulus fibrosus are inserted deeply in the cartilaginous rim. The right picture shows the situation in the adult. The expanded rim of the vertebrae is ossified. Sharpey's fibers persist in the bone whereas the disc lamellae remain anchored to the small, permanently cartilaginous epiphyseal plates. Modified after Schmorl.

Schmorl whose opinion is based on the investigation of 8 000 spines summed up his experience in 1930. As I become more familiar with the discs and their pathological changes I am more and more convinced that their tissue is most delicate and vulnerable. It is frequently damaged by strain almost within the range of normal movements or by minor external force. Anatomical studies indicate furthermore that the annulus fibrosus is less dense posteriorly than anteriorly and laterally and finally that the disc itself is less firmly fixed in the bone at the posterior circumference of the

Fig. 13. Sagittal section of normal intervertebral disc showing the adjacent vertebrae with the incomplete ossification of their rims. a Longitudinal ligament b fibrous cartilage c hyaline cartilage d bone lamellae (after Petersen).

Fig 14 left H K 3045. Clinically pain in the right back radiating down the right leg for 5 months. Poner back. Lastgore on right, bilateral absence of Achilles reflex; traumatic origin. X-ray. Spondylolisthesis of fifth lumbar. Myelogram filling defect between the fourth and fifth lumbar vertebrae on the right. Operation a loose cartilage, as found and removed. Pathologically this appeared to be ruptured fibrocartilaginous disc consisting of part of the annulus fibrosus with torn layers of straight and loose lamellae. Result, excellent.

Fig 5 R 605, 58 years. Clinically traumatic origin. Incomplete sciatica. X-ray narrowing of the fourth lumbar interspace. Chip outside. Collapse of upper posterior angle of the fifth lumbar. Fifth epiphyseal fracture. Wedging of the fifth lumbar to the degree that the posterior half of the fifth lumbar is only about three-fourths as thick as its anterior half. Fifth lumbar to 7 millimeters. Calcification of orta. Operation showed herniating disc. The annulus fibrosus was incised and the disc curetted out. The nerves were freed. Histologically this is well preserved disc with complete layers of hyaline and fibrous cartilage, the latter minor reticular rarefactions. Result good. Check-up 5 years after operation. X subjectively complaisant. Patient is satisfied.

vertebra. If we combine these considerations with the normal architecture of the disc lamellae it is easily understood that mild torque of the spine may lead to rupture of lamellae of the disc with subsequent necrosis and possible liquefaction. The debris may be pressed through a dehiscence of the annulus fibrosus. This mechanism explains why portions of the annulus are comparatively rarely found in the biopsy material and that the torn annulus often tends to fall back in place as soon as the nuclear part of the protrusion is removed (Bradford and Spurling). One may wonder under these conditions whether excision of more of the annulus and disc lamellae than is traumatized and necrotic anyway will be of help to the patient. Certainly not much can be expected in this instance from packing the cavity with bone chips since there is no free

bone surface to which they may become attached. Finally, no good reason for fusion of the spine can be seen in the group of the herniating disc since the results of its simple removal are very satisfactory.

One third of our patients with disc syndrome had sustained a fracture of the epiphyseal plate with or without a chip fracture of the adjacent vertebral body. This is an extraordinary experience in a group of healthy individuals undergoing sometimes so mild an injury that it is difficult to remember it. The explanation may be seen in the normal development of the surface of the vertebral body. In the early years of life the upper and lower expansions of the vertebrae are not ossified. A cap of cartilage is glued over them. Its inner surface represents the permanent epiphyseal plate while its sides cover the still re-

cessed rim in a circular fashion (Fig 12) A ring shaped bone nucleus embedded within the cartilage builds eventually the bony expansions of the vertebral surfaces However this process may remain incomplete in otherwise normal persons Large and small cavities are extant between flimsy bony septa (Fig 13) Hence this part of the vertebra is most endangered by brusque changes in position of the spine It is true the disc is protected by the longitudinal ligaments but the posterior ligament is not attached to the vertebra proper and only loosely to the annulus fibrosus Thus in addition to the universal greater vulnerability of the posterior aspect of the disc an individual constitutional factor has to be considered namely the insufficient ossification of the vertebral rim

Were the protrusion of the disc symmetrical its attachments had to be broken off both at the superior and inferior epiphyseal plates all around the posterior circumference and at least in part at the lateral surfaces. I have not seen a histological specimen containing the two opposite epiphyseal plates and I have not heard that a surgeon has described the protrusion of a disc all around the posterior circumference The histological picture speaks in favor of a vertical or oblique infraction of the epiphyseal plate and the posterior angle of the bony rim with loosening of a comparatively small sector rather than a horizontal fracture with expulsion of a large posterior semilunar section of the disc Such an eccentric detachment and protrusion of the disc easily overtares the elasticity of the fibrous cartilage. Its fibers rupture or become useless for the stability of the disc

The annulus fibrosus appears to be often intact primarily and to be torn secondarily by the impact of the sharp margins of the fractured bone. Hence the situation seems to be the reverse of what happens in the herniated disc Here lamellae and annulus are torn primarily and disc material becomes extruded there the disc material becomes necrotic after fracture of the epiphyseal plate and subsequent overextension of disc fibers This may or may not be followed by rupture of annulus fibrosus

These pathological findings suggest the usefulness of a more radical surgical procedure

It may be advisable to remove not only the broken-off fragments of bone and cartilage but to smooth down the remaining sharp bone spicules and to scrape out semidetached particles from the intervertebral space This is the only condition in which filling of the cavity with bone chips seems reasonable since here is a freshened bone surface to which it may become attached

If the disc has slipped without rupture of the annulus fibrosus in other words, if the surgeon has to incise the annulus in order to remove the fragments it may be difficult to decide during operation which type of injury is present The collapse of the upper or lower posterior angle of the vertebral body or fracture of the epiphyseal plate may be evident in the x ray picture so that the surgeon is prepared for what to expect in operation Lateral various oblique views and stereoscopic pictures may be necessary to visualize the damage in some instances (Fig 14) Wedging of the whole vertebra reducing the posterior part of the fifth lumbar to only three-quarters of its anterior half (17 mm to 21 mm) is apparent in others (Fig 15)

I have confined myself in this paper to a description of the pathological changes of the intervertebral disc and its bony attachment in the sciatic syndrome. However it may be expected that the elastic ligaments which contribute to the stabilization of the spine would become involved by a trauma or in disease independently of the disc which condition would lead to temporary or permanent impingement upon a posterior root Elsberg Spurling Mayfield and Rogers Craig and Walsh Dockerty and Love have pointed to this possibility This material will be discussed separately since its surgical implications differ from those here described

SUMMARY

1 Anatomical and pathological investigations of 169 discs removed in operation and 20 controls indicate that the mechanism of the intervertebral disc protrusion is not uniform

2 Three conditions are described which differ widely in their mechanism and their surgical prognosis They are

a. The bulging disc without a rent in the annulus fibrosus and without detachment of

vertebra. If we combine these considerations with the normal architecture of the disc lamellae it is easily understood that mild torque of the spine may lead to rupture of lamellae of the disc with subsequent necrosis and possible liquefaction. The debris may be pressed through a dehiscence of the annulus fibrosus. This mechanism explains why portions of the annulus are comparatively rarely found in the biopsy material and that the torn annulus often tends to fall back in place as soon as the nuclear part of the protrusion is removed (Bradford and Spurling). One may wonder under these conditions whether excision of more of the annulus and disc lamellae than is traumatized and necrotic anyway will be of help to the patient. Certainly not much can be expected in this instance from packing the cavity with bone chips since there is no free

bone surface to which they may become attached. Finally no good reason for fusion of the spine can be seen in the group of the herniating disc since the results of its simple removal are very satisfactory.

One third of our patients with disc syndrome had sustained a fracture of the epiphyseal plate with or without a chip fracture of the adjacent vertebral body. This is an extraordinary experience in a group of healthy individuals undergoing sometimes so mild an injury that it is difficult to remember it. The explanation may be seen in the normal development of the surface of the vertebral body. In the early years of life the upper and lower expansions of the vertebrae are not ossified. A cap of cartilage is glued over them. Its inner surface represents the permanent epiphyseal plate while its sides cover the still re-

cessed rim in a circular fashion (Fig 12) A ring shaped bone nucleus embedded within the cartilage builds eventually the bony expansions of the vertebral surfaces. However this process may remain incomplete in otherwise normal persons. Large and small cavities are extant between flimsy bony septa (Fig 13) Hence this part of the vertebra is most endangered by brusque changes in position of the spine. It is true the disc is protected by the longitudinal ligaments but the posterior ligament is not attached to the vertebra proper and only loosely to the annulus fibrosus. Thus in addition to the universal greater vulnerability of the posterior aspect of the disc, an individual constitutional factor has to be considered namely the insufficient ossification of the vertebral rim

Were the protrusion of the disc symmetrical its attachments had to be broken off both at the superior and inferior epiphyseal plates all around the posterior circumference and at least in part at the lateral surfaces. I have not seen a histological specimen containing the two opposite epiphyseal plates and I have not heard that a surgeon has described the protrusion of a disc all around the posterior circumference. The histological picture speaks in favor of a vertical or oblique infraction of the epiphyseal plate and the posterior angle of the bony rim with loosening of a comparatively small sector rather than a horizontal fracture with expulsion of a large posterior semilunar section of the disc. Such an eccentric detachment and protrusion of the disc easily overtaxes the elasticity of the fibrous cartilage. Its fibers rupture or become useless for the stability of the disc.

The annulus fibrosus appears to be often intact primarily and to be torn secondarily by the impact of the sharp margins of the fractured bone. Hence the situation seems to be the reverse of what happens in the herniated disc. Here lamellae and annulus are torn primarily and disc material becomes extruded; there the disc material becomes necrotic after fracture of the epiphyseal plate and subsequent overextension of disc fibers. This may or may not be followed by rupture of annulus fibrosus.

These pathological findings suggest the usefulness of a more radical surgical procedure

It may be advisable to remove not only the broken-off fragments of bone and cartilage but to smooth down the remaining sharp bone spicules and to scrape out semidetached particles from the intervertebral space. This is the only condition in which filling of the cavity with bone chips seems reasonable since here is a freshened bone surface to which it may become attached.

If the disc has slipped without rupture of the annulus fibrosus in other words if the surgeon has to incise the annulus in order to remove the fragments it may be difficult to decide during operation which type of injury is present. The collapse of the upper or lower posterior angle of the vertebral body or fracture of the epiphyseal plate may be evident in the x ray picture so that the surgeon is prepared for what to expect in operation. Lateral various oblique views and stereoscopic pictures may be necessary to visualize the damage in some instances (Fig 14). Wedging of the whole vertebra reducing the posterior part of the fifth lumbar to only three-quarters of its anterior half (17 mm to 21 mm) is apparent in others (Fig 15).

I have confined myself in this paper to a description of the pathological changes of the intervertebral disc and its bony attachment in the sciatic syndrome. However it may be expected that the elastic ligaments which contribute to the stabilization of the spine would become involved by a trauma or in disease independently of the disc which condition would lead to temporary or permanent impingement upon a posterior root. Flisberg Spurling Mayfield and Rogers Craig and Walsh Dockerty and Love have pointed to this possibility. This material will be discussed separately since its surgical implications differ from those here described.

SUMMARY

1 Anatomical and pathological investigations of 169 discs removed in operation and 20 controls indicate that the mechanism of the intervertebral disc protrusion is not uniform.

2 Three conditions are described which differ widely in their mechanism and their surgical prognosis. They are

a The bulging disc without a rent in the annulus fibrosus and without detachment of

the disc from the bone. Material removed by incision of the disc revealed normal cartilage lamellae.

b The herniated disc. Traumatized disc lamellae necrotic or liquefied are protruded through a rent of the annulus fibrosis into the spinal cavity where they may encroach upon and overextend a posterior root. Herniation of the nucleus pulposus is the exception rather than the rule.

c The slipped disc in which the trauma involves the cartilaginous epiphyseal plate and which is sometimes accompanied by a chip fracture of the vertebral rim. This frees the disc from its anchorage and permits an eccentric portion of its posterior circumference to slip backward. A posterior root may become hooked up over the protrusion. The sharp bony edges of the fracture may secondarily rupture the slipped disc. It is explained that an individual constitutional disposition may be responsible for this type of lesion. This condition is visible in the x ray picture.

3 No indication of primary disease of the disc could be detected. Trauma appears to be the only cause of herniation or slipping of the disc.

4 The results of incision and dismemberment of a bulging disc are so poor as to suggest that in the 66 per cent of these patients not benefited by operation the bulging disc was not the cause of the sciatic syndrome. The inference is that the bulging disc should not be removed unless it clearly involves a root.

5 The results of simple removal of the herniated disc are so satisfactory that there seems to be no need for further improvement of the operative technique.

6 Operation on the slipped disc gives good to fair results in about one-half of the persons

operated upon which fact suggests that there is still room for improvement.

7 The question is discussed under which conditions thorough evagination of the disc may be indicated and when filling of the intervertebral space with bone chips or spinal fusion may be useful.

REPAIR OF INGUINAL HERNIA WITH EXTERNAL OBLIQUE FASCIA

Critical Evaluation of Results

CHARLES W MAYO M.D., F.A.C.S., and JAMES K KEELEY M.D. Rochester Minnesota

INGUINAL hernia and measures for the correction of this anatomic abnormality have long attracted the interest of surgeons of all countries as evidenced by the voluminous literature on this subject and the many methods of treatment that have been used. It has been widely accepted that an indirect inguinal hernia can be repaired accurately and that a satisfactory result will be obtained. The cardinal features of such repair are high ligation of the hernial sac and reinforcement of both the external and internal inguinal rings. The importance of several other factors has been stressed repeatedly. These factors include intelligent preoperative preparation of the patient as a whole and of the skin of the groin in particular, safe and satisfactory anesthesia, adequate exposure of the structures of the inguinal canal, meticulously complete hemostasis, careful aseptic technique and accurate apposition of fascia to fascia without tension. It might be thought that attention to these details would lead to permanent correction of the hernia in every case.

RECURRENCE OF HERNIA AFTER HERNIORRHAPHY

On consideration of the incidence of recurrence of hernia after herniorrhaphy as reported in the literature, one is forced to conclude that there is no perfect surgeon and no perfect surgical procedure. Although many surgeons have gained wide experience in the surgical repair of hernias, when the results of treatment have been carefully tabulated and analyzed in the various medical journals, the recurrence rates remain too high. Attention has long been directed to measures which might improve these results.

A review of the literature indicates that many causes for surgical failure have been advanced. Although Marcy Halsted, McArthur and others who wrote a half century ago when herniorrhaphy was first established anatomically as a satisfactory procedure, found that wound infection was the most important etiologic factor in the recurrence of a hernia, sepsis has rarely been incriminated as a major factor in recent years. Bloodgood estimated that 5 per cent of men have a weak or obliterated conjoint tendon, which can be detected by physical examination. He found that the hernias occurred after herniorrhaphy in 50 per cent of cases in which the conjoint tendon was of this type. This anatomic aspect of the problem has been clarified by Anson and McVay (1, 10) who found that in 97 per cent of cases there is a red muscle border at the lateral free margin of the internal oblique muscle which is unsuited for fascia-to-fascia suture to pelvic ligaments and that the tendon of the transversus abdominis muscle (usually tendinous in its lower lateral portion) is inserted into Cooper's ligament on the superior pubic ramus. They further pointed out that reuniting the transversalis fascia, that is the fascia or tendon of the transversus abdominis muscle to Cooper's ligament also can be used to repair a femoral hernia or to prevent the development of such a hernia. Burton has reviewed the clinical application of these anatomic findings.

Many surgeons have found that the incidence of recurrent hernia is likely to be high if the original hernia has been present for a long time and if the patient has poor anatomic structures that is, weak or deficient fascial layers. This is particularly true if the hernial sac is large or if the hernia has extended into the scrotum. In cases in which a truss has

From the Division of Surgery, Mayo Clinic, and the Division of Surgery, Mayo Foundation.

the disc from the bone. Material removed by incision of the disc revealed normal cartilage lamellae.

b The herniated disc. Traumatized disc lamellae necrotic or liquefied are protruded through a rent of the annulus fibrosus into the spinal cavity where they may encroach upon and overextend a posterior root. Herniation of the nucleus pulposus is the exception rather than the rule.

c The slipped disc in which the trauma involves the cartilaginous epiphyseal plate and which is sometimes accompanied by a chip fracture of the vertebral rim. This frees the disc from its anchorage and permits an eccentric portion of its posterior circumference to slip backward. A posterior root may become hooked up over the protrusion. The sharp bony edges of the fracture may secondarily rupture the slipped disc. It is explained that an individual constitutional disposition may be responsible for this type of lesion. This condition is visible in the x ray picture.

3 No indication of primary disease of the disc could be detected. Trauma appears to be the only cause of herniation or slipping of the disc.

4 The results of incision and dismemberment of a bulging disc are so poor as to suggest that in the 66 per cent of these patients not benefited by operation the bulging disc was not the cause of the sciatic syndrome. The inference is that the bulging disc should not be removed unless it clearly involves a root.

5 The results of simple removal of the herniated disc are so satisfactory that there seems to be no need for further improvement of the operative technique.

6 Operation on the slipped disc gives good to fair results in about one half of the persons

operated upon which fact suggests that there is still room for improvement.

The question is discussed under which conditions thorough eventration of the disc may be indicated and when filling of the intervertebral space with bone chips or spinal fusion may be useful.

least 5 years have elapsed since the operation. A review of the literature has failed to reveal any report of a large series of cases of hernia in which the patients have been observed this long after herniorrhaphy has been performed.

THE MCARTHUR OPERATION

In 1901 McArthur described a technique for the surgical repair of inguinal hernia by utilizing strips of external oblique fascia as suture material. He pointed out that the permanence of such a repair does not depend on foreign suture material and on apposition of scar tissue but on a lacing of the structures of the inguinal canal with living fascial sutures. A strip of fascia about 4 to 6 inches (10 to 15 cm) long and about $\frac{1}{8}$ to $\frac{1}{4}$ inch (0.5 cm) wide is obtained from the medial border of the external oblique fascia. This strip of fascia should not be separated from its attachment to the pubic tubercle. It is used to fasten the conjoint tendon to the inguinal ligament (Poupart's ligament) in order to obliterate the inguinal canal. In cases in which there is considerable relaxation of the tissues a similar strip of fascia obtained from the lateral border of the external oblique muscle may be used.

By means of animal investigation McArthur demonstrated that living fascial sutures that is fascial sutures that are left attached to the pubic tubercle as previously described will survive for months or years. This observation was confirmed by postmortem examination of human beings who had undergone herniorrhaphy in which living fascial sutures had been employed.

At present there is no operation that can be used satisfactorily in all cases of inguinal hernia. An ideal operation would be one that would be followed by a smooth convalescence, satisfactory healing of the incision and a low incidence of recurrence. The McArthur type of herniorrhaphy appears to meet these requirements as well as does any other type of operation.

MATERIAL

In a period of 12½ years from July 1, 1931 to December 31, 1942 inclusive one of us (C.W.M.) operated on 332 patients for inguinal hernia. In the early part of this period

TABLE I — TYPE OF UNILATERAL HERNIA FOUND AT OPERATION IN 168 CASES

Side of involvement	Type of hernia			Total
	I direct	Direct	Double sac	
Left	44	8	0	52
Right	86	4	7	97
Total	130	12	7	149

ox fascia and catgut were used as suture material in 102 cases. Nylon sutures were used in 8 cases. A modification of McArthur's herniorrhaphy was used in the 222 remaining cases which form the basis of this report. The ages of the patients ranged from 11 to 73 years and the average age was 47 years. Five of the patients were women and the remainder were males. The occupation of the patients varied widely.

The hernia was classified as a recurrent hernia in 5 of the 222 cases. In 1 of the 5 cases a hernia had recurred in each groin. The primary hernias were unilateral in 168 cases and bilateral in 49 cases. Table I shows the side of involvement and the type of unilateral hernia encountered in the 168 cases. Bilateral herniorrhaphy was performed in 38 of the 49 cases in which a primary hernia was present in each groin.

SURGICAL TREATMENT

In all of the 222 cases the patients were anesthetized with nitrous oxide-oxygen and ether. As previously stated a modification of McArthur's herniorrhaphy was performed in all of these cases. This operative procedure has been used for many years by different surgeons. The technique is briefly as follows.

An incision about 4 inches (10 cm) long is made nearly parallel to and about $\frac{1}{2}$ inch (1 cm) above the inguinal ligament (Poupart's ligament). The fascia of the external oblique muscle is divided in the direction of its fibers. The skin is retracted superolaterally to the upper limit of the tendinous portion of the external oblique muscle. A pedicled suture is obtained from the medial border of the external oblique muscle just as it is in the McArthur operation. The fascial suture which still is attached to the pelvic tubercle

been worn for a long time the pressure exerted by the truss has been said to have caused thinning and devitalization of the inguinal tissues (8). The increasing incidence of recurrent hernia among persons of advanced age has been noted by many surgeons.

The choice of suture material has been a matter of considerable controversy. Kangaroo tendon and ox fascia have largely been replaced by catgut in herniorrhaphy. In a study of a series of cases in which the patients were followed for from 1 to 10 years after herniorrhaphy was performed Parsons found that the hernia recurred in 3.5 per cent of the cases in which silk was used as the suture material and in 12.7 per cent of the cases in which catgut was used. In other words, in the cases in which catgut was used the incidence of recurrent hernia was approximately four times as great as it was in the cases in which silk was used. Cotton, silver and steel wire have their advocates. Many surgeons have strongly urged the use of the types of fascial sutures employed by McArthur and Gallie respectively. It has been suggested that if fascial sutures are an added safeguard in cases of large hernias hernias that are difficult to repair or recurrent hernias, they should be employed in all cases of hernia in order to reinforce the repaired anatomic structures.

Fallis, Zimmerman and other authors have concluded that the choice of the operative procedure in a given case is of minor importance as compared with the selection of the surgeon. Patrick in an investigation of the causes of recurrence of hernia in the British Army found that in 63 per cent of the cases of recurrent hernia the hernial sac had not been treated adequately at the time of operation. Fallis has stated that all hernias can be repaired and that all recurrences, therefore, are the result of technical error. It is the surgeon's responsibility not only to avoid errors in technique but also to fit the surgical procedure to the individual patient.

The site of recurrence is a matter on which there is not general agreement. Whether all herniations developing after an attempt at repair of a hernia previously present in the same area should be considered to be recurrent hernias rather than primary hernias is a moot

question. Most statistical studies indicate that 75 per cent of primary inguinal hernias in males are indirect and that the remaining 25 per cent are direct in type. The great majority (about 90 per cent) of hernias which occur after repair of indirect or direct inguinal hernias are direct in type and occur low in the operative scar. A recurrence in the vicinity of the internal ring is probably to be interpreted as a technical failure at high ligation and fascial approximation about the cord at the upper end of the inguinal canal. Of special significance in this connection is the report by Grace and Johnson of a follow up study in 1,032 cases in which operation for hernia had been performed on patients who were more than 50 years of age. In at least 50 per cent of the cases in which the hernia recurred after the operation the patients were unaware of the recurrence. This finding should be considered in comparing the results reported by different surgeons. For statistical purposes, any hernia which appears in the same groin at any time after a herniorrhaphy must be classified as a recurrent hernia.

The time that may elapse between a herniorrhaphy and the recurrence of a hernia has not been determined definitely. In many of the cases reported in the literature, the patients have been followed for only 1 or 2 years. Statistics based on cases in which the patients have been followed for this period of time suggest that 70 to 80 per cent of recurrent hernias appear in the first year after the operation. Bloch reviewed the results obtained in a large series of cases in which operations had been performed in German clinics. He estimated that 34.8 per cent of recurrent hernias do not appear until 2 years after the operation. Burdick, Gillespie and Higginbotham found that 113 or approximately 40 per cent of 284 recurrent hernias did not become evident until more than 2 years after herniorrhaphy.

Obviously an analysis based on the observation of patients for 1 or 2 years after herniorrhaphy has been performed will fail to indicate the incidence of recurrent hernia. It is our opinion that in cases of hernia, as in cases of malignant lesions, the results of surgical treatment cannot be evaluated until at

least 5 years have elapsed since the operation. A review of the literature has failed to reveal any report of a large series of cases of hernia in which the patients have been observed this long after herniorrhaphy has been performed.

THE MCARTHUR OPERATION

In 1901 McArthur described a technique for the surgical repair of inguinal hernia by utilizing strips of external oblique fascia as suture material. The hernia was classified as a recurrent hernia in 5 of the 222 cases. In 1 of the 5 cases a hernia had recurred in each groin. The primary hernias were unilateral in 168 cases and bilateral in 49 cases. Table I shows the side of involvement and the type of unilateral hernia encountered in the 168 cases. Bilateral herniorrhaphy was performed in 38 of the 49 cases in which a primary hernia was present in each groin.

SURGICAL TREATMENT

In all of the 222 cases the patients were anesthetized with nitrous oxide-oxygen and ether. As previously stated a modification of McArthur's herniorrhaphy was performed in all of these cases. This operative procedure has been used for many years by different surgeons. The technique is briefly as follows.

An incision about 4 inches (10 cm) long is made nearly parallel to and about $\frac{1}{2}$ inch (1 cm) above the inguinal ligament (Poupart's ligament). The fascia of the external oblique muscle is divided in the direction of its fibers. The skin is retracted superolaterally to the upper limit of the tendinous portion of the external oblique muscle. A pedicled suture is obtained from the medial border of the external oblique muscle just as it is in the McArthur operation. The fascial suture, which still is attached to the pelvic tubercle,

Fig. 1. Technique of herniorrhaphy (modified from McArthur).

is protected with a sponge that has been moistened with a warm isotonic solution of sodium chloride.

The hernial sac then is ligated as high as possible. If the hernia is of the direct type, the hernial sac need not be excised. Instead it can be infolded satisfactorily with pursestring sutures. The free end of the fascial suture is threaded through a Gallie needle and is used to fasten the conjoint tendon to the shelving edge of the inguinal ligament so as to obliterate the inguinal canal. Although the inferior portion of the free margin of the internal oblique muscle frequently is composed of red muscle fibers, a considerable amount of fascia usually can be found superiorly. This fascia is approximated to the inguinal ligament by rolling the border of the muscle posteriorly. The first stitch that is taken with the fascial suture should penetrate the periosteum of the

pubis (Fig. 1) in order to prevent bulging in the lower end of the incision. The external oblique fascia is closed beneath the spermatic cord with interrupted cotton sutures so as to make a new subcutaneous inguinal ring (external abdominal ring) superficial to the abdominal inguinal ring (internal abdominal ring). The skin is closed over the structures of the spermatic cord.

If the patient is a male a suspensory bandage is applied before he leaves the operating room. The patients routinely are permitted to get out of bed in from 2 to 4 days after the operation and they generally are dismissed from the hospital before the twelfth postoperative day. At the time of their dismissal the patients are warned that the hernia is likely to recur if they do any excessive straining within 6 months. They also are advised to do everything possible to prevent the development of

Fig. 2. Incidence and time of appearance of recurrent inguinal hernias.

infection of the respiratory tract and the attendant coughing and sneezing

RESULTS

Follow up data were obtained in 208 (94 per cent) of the 222 cases. Since a large proportion of the patients lived a considerable distance from the clinic the follow up data were obtained by sending a questionnaire to all the patients who survived the operation. In 2 of the 168 cases in which the hernias were unilateral the patients died in the hospital within 2 weeks after the operation. In these 2 cases the patients were men who were 52 and 64 years of age respectively. In each case necropsy revealed that death was due to pulmonary embolism. Follow up data were obtained in 155 of the 166 remaining cases.

The incidence of recurrent hernia in this group of 155 cases is shown in Table II. The incidence of recurrence and the time that elapsed between the herniorrhaphy and the appearance of the recurrent hernia are shown graphically in Figure 2. The graph refutes the widely held opinion that recurrent hernias usually appear within the first year or two after herniorrhaphy has been performed. It will be noted that the rate of recurrence was

3.9 per cent in the first year after operation was performed. It is our opinion that the true rate of recurrence cannot be determined until 5 years have elapsed. In this series of cases, the correct rate of recurrence was not 3.9 per cent but 11.9 per cent (Table II).

In 32 cases in which follow up data failed to reveal any evidence of recurrence of hernia within the first 5 years after operation similar data also were obtained after 10 or more years had elapsed. In this subsequent period of 5 or more years a recurrent hernia appeared in only 1 of the 32 cases. In this case, the patient was a man who was 54 years of age when the herniorrhaphy was performed. Although

TABLE II — INCIDENCE OF RECURRENCE OF UNILATERAL INGUINAL HERNIA

Years after operation	Cases	Recurrences	
		Number	Per cent
0-1	31	6	3.9
0-2	18	0	0
0-3	4	0	0
0-4	35	8	22.9
0-5	5	4	80

Temporary as of January, 1917. Table includes only cases in which patients were traced for the specified period.

the result appeared to be satisfactory when the patient was examined 9 months after the operation bulging appeared in the inguinal region 10 years later. The information obtained by this follow up study of 32 patients for an additional period of 5 years indicates that 5 years may be considered an adequate period of observation.

Bilateral inguinal hernias were present in 49 of the 222 cases. In 38 of the 49 cases herniorrhaphy was performed on both sides simultaneously. One of the patients, a man aged 58 years, died of pulmonary embolism on the sixth postoperative day. Follow up data were obtained in 34 of the 37 remaining cases. In these 34 cases the recurrence rate was 13 per cent in 5 years. This figure includes every recurrence in this group regardless of whether the recurrence was unilateral or bilateral. Statistically this result appears to have been better than might have been expected in view of the recurrence rate of 11.9 per cent in the cases of unilateral hernia. In 11 of the 49 cases in which bilateral hernias were present herniorrhaphy was performed on one side only.

Operation was performed for a recurrent inguinal hernia in 4 of the 222 cases. In these cases the results were recorded as satisfactory 9 months, 5 years, 8 years and 11 years, respectively after the operations were performed. Previous herniorrhaphy seldom distorts the tissues sufficiently to make the subsequent performance of a McArthur type of herniorrhaphy inadvisable.

In the cases in which the patients had worn a truss before the operation was performed the rate of recurrence was three or four times as great as it was in the cases in which a truss had not been worn. This finding confirms the widely held opinion that special consideration should be given to adequate reinforcement of the inguinal ring in cases in which a truss has been worn. We also found that there was a general correlation between the rate of recurrence and the length of time that a truss had been worn.

Our study did not reveal any significant difference between the results obtained in

cases in which the hernia had extended into the scrotum and the results in cases in which the hernia did not extend into the scrotum.

SUMMARY

A review of the literature indicates that widespread confusion exists regarding the cause site time of appearance and frequency of recurrent inguinal hernias. This paper is based primarily on an analysis of the results obtained in 222 cases of inguinal hernia in which a modification of McArthur's operation was performed by one of us (C.W.M.). In 155 cases of unilateral hernia the recurrence rate was 11.9 per cent in 5 years. In 34 cases of bilateral hernia in which herniorrhaphy was performed simultaneously on both sides the recurrence rate was 13 per cent in 5 years. The last figure includes all recurrent hernias, whether unilateral or bilateral.

We believe that the end results of herniorrhaphy cannot be evaluated accurately until 5 years have elapsed since the operation. It is our opinion that the reporting of end results observed within a shorter period is an inaccurate and misleading practice which should be abandoned.

Although one surgical procedure should not be used routinely in the repair of inguinal hernia, we have found that the use of external oblique fascia by a modification of McArthur's technique is superior to any other method that we have used.

SURGICAL TREATMENT OF RADIATION BURNS

JAMES BARRETT BROWN, M.D., F.A.C.S., FRANK McDOWELL, M.D., F.A.C.S. and
MINOT P. FRYER, M.D., St. Louis, Missouri

EXCESSIVE exposure to x rays produces changes in the skin and other tissues that sometimes require excision and repair. Radium and other radioactive substances also may cause severe changes. Atomic warfare may produce lesions similar to those seen in local areas at present. The skins of some individuals may be unusually sensitive to the x ray and exposure may produce acute episodes that may clear up in time. Permanent chronic changes however develop in practically all skins which have been exposed to heavy or repeated excessive or incorrect dosages of x rays.

These comments have no relation to the usefulness or indications for x ray therapy, nor are they meant to suggest any directional approach to the problems in the use of radiation therapy.

SOURCES

Burned hands of physicians are the most frequently seen at the present time (Fig. 2). Many of these burns occur while difficult fractures are being reduced under the fluoroscope. The physician's anxiety for the welfare of his patient may have dulled his regard for his own personal safety. Nevertheless such burns are preventable and every physician using an x ray machine should be aware of the effects of a single large dose and of the irreversible cumulative effect of repeated small doses over many years.

The list of early workers in radiation who have been burned is long and contains many names well known to the profession. Dr. Walter Cannon, late professor of physiology at Harvard, suffered burns of his hands that required excision and grafting. His burns resulted from exposure while doing pioneer work in his x ray studies of the gastrointestinal system before the late effects on the skin were known.

Dentist's fingers are sometimes burned (Fig. 3) especially if they hold films in the mouths of patients during exposure.

Prolonged fluoroscopic examinations have produced some most unfortunate burns as a result of miscalculations in distance time or filters (Figs. 1, 5, 15, 16, 20, 21). Examinations of empyema fluid levels, fractured metatarsals and fractured vertebrae have produced especially bad burns. As these burns are of such great trouble both to the patient and to the one responsible for them, it seems advisable to give warning of this source.

Ichne eczema, *port wine stains*, *plantar warts*, *epidermophytosis* and *pruritus ani* are all troublesome diseases but are as nothing compared to the possible effects of excessive radiation therapy (Figs. 4, 8, 9, 11, 13, 14).

Sailor's skin or *'farmer's skin'*—the dry, atrophic, telangiectatic skin resulting from decades of heavy exposure to sunlight—is especially intolerant of x radiation. The pathological changes in this type of skin are similar to those in a mild x ray burn and it is probably advisable to treat by other means keratoses, skin cancers and even lip cancers in such patients.

Commercial epilation of superfluous hair by x ray has caused some of the most dramatic extensive and useless burns (Figs. 5, 17, 18). Patients have been seen with burns of the entire lower legs, the outside of the thighs, the axillae, outside of upper arms, entire forearms, hands, back of neck, entire face and entire front of neck. The prolonged morbidity, suffering and loss of economic and social status endured by these patients cannot be condoned in the face of the slightness of their original complaint of superfluous hair. This commercial procedure cannot be too severely condemned.

Hemangioma and plantar warts. As more time elapses the distant effects of radiation treatment will become more apparent and perhaps in some instances changes in therapy

the result appeared to be satisfactory when the patient was examined 9 months after the operation bulging appeared in the inguinal region 10 years later. The information obtained by this follow-up study of 32 patients for an additional period of 5 years indicates that 5 years may be considered an adequate period of observation.

Bilateral inguinal hernias were present in 49 of the 222 cases. In 38 of the 49 cases herniorrhaphy was performed on both sides simultaneously. One of the patients, a man aged 38 years died of pulmonary embolism on the sixth postoperative day. Follow-up data were obtained in 34 of the 37 remaining cases. In these 34 cases the recurrence rate was 13 per cent in 5 years. This figure includes every recurrence in this group regardless of whether the recurrence was unilateral or bilateral. Statistically this result appears to have been better than might have been expected in view of the recurrence rate of 11.9 per cent in the cases of unilateral hernia. In 11 of the 49 cases in which bilateral hernias were present herniorrhaphy was performed on one side only.

Operation was performed for a recurrent inguinal hernia in 4 of the 22 cases. In these cases, the results were recorded as satisfactory 9 months, 5 years, 8 years and 11 years, respectively after the operations were performed. Previous herniorrhaphy seldom distorts the tissues sufficiently to make the subsequent performance of a McArthur type of herniorrhaphy inadvisable.

In the cases in which the patients had worn a truss before the operation was performed the rate of recurrence was three or four times as great as it was in the cases in which a truss had not been worn. This finding confirms the widely held opinion that special consideration should be given to adequate reinforcement of the inguinal ring in cases in which a truss has been worn. We also found that there was a general correlation between the rate of recurrence and the length of time that a truss had been worn.

Our study did not reveal any significant difference between the results obtained in

cases in which the hernia had extended into the scrotum and the results in cases in which the hernia did not extend into the scrotum.

SUMMARY

A review of the literature indicates that widespread confusion exists regarding the cause site time of appearance and frequency of recurrent inguinal hernias. This paper is based primarily on an analysis of the results obtained in 222 cases of inguinal hernia in which a modification of McArthur's operation was performed by one of us (C.W.M.). This commercial procedure cannot be too severely condemned.

Hemangioma and plantar warts. As more time elapses the distant effects of radiation treatment will become more apparent and perhaps in some instances changes in therapy

Fig. 6. Sole of foot burn extending so deep that cross leg flap had to be used, rather than free graft. Two operations.

differentiated is sailor's or farmer's skin which is similar but is caused by the cumulative effect of decades of overexposure to sun light in persons who do not form sufficient melanin to protect themselves (in other words, they do not tan). Differentiation can be made by the history and by the fact that sailor's skin symmetrically affects both forearms, both hands, and the entire face and neck in most patients. Telangiectasis is often predominant in x-ray burns, whereas atrophy and keratosis predominate in sailor's skin.

Coal spots rarely occur except in association with x-ray burns. Carcinoma may develop in either.

The progress of a severe chronic x-ray burn through the stages of atrophy telangiectasis,

coal spots, keratosis, and carcinoma is irreversible and inevitable if the patient lives long enough. This course is not affected by the use of any drugs or other means of treatment known at present except the surgical excision and repair of the area. The stages may overlap and the speed of the progress varies greatly so that it is often a major problem to decide when and if to undertake excision. Fast progress in any patient and even slow progress in a young individual are indications for treatment. A paradox of treatment

Fig. 17. Commercial x-ray treatment for removal resulting in almost total burns of lower legs.

SURGICAL TREATMENT OF RADIATION BURNS

JAMES BARRETT BROWN, M.D., F.A.C.S., FRANK McDOWELL, M.D., F.A.C.S. and
MINOT I. FRYER, M.D. St. Louis, Missouri

EXTENSIVE exposure to x rays produces changes in the skin and other tissues that sometimes require excision and repair. Radium and other radioactive substances also may cause severe changes. Atomic warfare may produce lesions similar to those seen in local areas at present. The skins of some individuals may be unusually sensitive to the x ray and exposure may produce acute episodes that may clear up in time. Permanent chronic changes, however, develop in practically all skins which have been exposed to heavy or repeated excessive or incorrect dosages of x rays.

These comments have no relation to the usefulness or indications for x ray therapy, nor are they meant to suggest any directional approach to the problems in the use of radiation therapy.

SOURCES

Burned hands of physicians are the most frequently seen at the present time (Fig. 1). Many of these burns occur while difficult fractures are being reduced under the fluoroscope; the physician's anxiety for the welfare of his patient may have dulled his regard for his own personal safety. Nevertheless, such burns are preventable and every physician using an x ray machine should be aware of the effects of a single large dose and of the irreversible cumulative effect of repeated small doses over many years.

The list of early workers in radiation who have been burned is long and contains many names well known to the profession. Dr. Walter Cannon, late professor of physiology at Harvard, suffered burns of his hands that required excision and grafting. His burns resulted from exposure while doing pioneer work in his x ray studies of the gastrointestinal system before the late effects on the skin were known.

Dentist's fingers are sometimes burned (Fig. 3), especially if they hold films in the mouths of patient during exposure.

Prolonged fluoroscopic examinations have produced some most unfortunate burns as a result of miscalculations in distance, time, or filters (Fig. 1, 16, 20, 21). Examinations of empyema fluid level, fractured metatarsals and fractured vertebrae have produced especially bad burns. As these burns are of such great trouble both to the patient and to the one responsible for them, it seems advisable to give warning of this source.

Itch, eczema, port, melasma, plantar warts, epidermophytosis, and pruritus ani are all troublesome diseases, but are as nothing compared to the possible effects of excessive radiation therapy (Figs. 4, 8, 9, 11, 13, 14).

Sailor's skin or farmer's skin—the dry, atrophic telangiectatic skin resulting from decades of heavy exposure to sunlight—is especially intolerant of x radiation. The pathological changes in this type of skin are similar to those in a mild x ray burn, and it is probably advisable to treat by other means keratosis, skin cancer, and even lip cancers in such patients.

Commercial epilation of superfluous hair by x ray has caused some of the most dramatic extensive and useless burns (Fig. 5, 17, 18). Patients have been seen with burns of the entire lower leg, the outside of the thigh, the axillae, back of upper arm, entire forearm, hands, back of neck, entire face, and entire front of neck. The prolonged morbidity, suffering, and loss of economic and social status endured by these patients cannot be condoned in the face of the lightness of their original complaint of superfluous hair. The commercial procedure cannot be too severely condemned.

Hemangioma and further warts. As more time elapses the distant effect of radiation treatment will become more apparent and perhaps in some instances change in therapy

the result appeared to be satisfactory when the patient was examined 9 months after the operation bulging appeared in the inguinal region 10 years later. The information obtained by this follow-up study of 32 patients for an additional period of 5 years indicates that 5 years may be considered an adequate period of observation.

Bilateral inguinal hernias were present in 49 of the 222 cases. In 38 of the 49 cases, herniorrhaphy was performed on both sides simultaneously. One of the patients a man aged 58 years, died of pulmonary embolism on the sixth postoperative day. Follow up data were obtained in 34 of the 37 remaining cases. In these 34 cases the recurrence rate was 13 per cent in 5 years. This figure includes every recurrence in this group regardless of whether the recurrence was unilateral or bilateral. Statistically this result appears to have been better than might have been expected in view of the recurrence rate of 11.9 per cent in the cases of unilateral hernia. In 11 of the 49 cases in which bilateral hernias were present herniorrhaphy was performed on one side only.

Operation was performed for a recurrent inguinal hernia in 4 of the 222 cases. In these cases, the results were recorded as satisfactory 9 months, 5 years, 8 years and 11 years, respectively after the operations were performed. Previous herniorrhaphy seldom distorts the tissues sufficiently to make the subsequent performance of a McArthur type of herniorrhaphy inadvisable.

In the cases in which the patients had worn a truss before the operation was performed the rate of recurrence was three or four times as great as it was in the cases in which a truss had not been worn. This finding confirms the widely held opinion that special consideration should be given to adequate reinforcement of the inguinal ring in cases in which a truss has been worn. We also found that there was a general correlation between the rate of recurrence and the length of time that a truss had been worn.

Our study did not reveal any significant difference between the results obtained in

cases in which the hernia had extended into the scrotum and the results in cases in which the hernia did not extend into the scrotum.

SUMMARY

A review of the literature indicates that widespread confusion exists regarding the cause site time of appearance and frequency of recurrent inguinal hernias. This paper is based primarily on an analysis of the results obtained in 222 cases of inguinal hernia in which a modification of McArthur's operation was performed by one of us (C W M). In 155 cases of unilateral hernia the recurrence rate was 11.9 per cent in 5 years. In 34 cases of bilateral hernia in which herniorrhaphy was performed simultaneously on both sides, the recurrence rate was 13 per cent in 5 years. The last figure includes all recurrent hernias whether unilateral or bilateral.

We believe that the end results of herniorrhaphy cannot be evaluated accurately until 5 years have elapsed since the operation. It is our opinion that the reporting of end results observed within a shorter period is an inaccurate and misleading practice which should be abandoned.

Although one surgical procedure should not be used routinely in the repair of inguinal hernia, we have found that the use of external oblique fascia by a modification of McArthur's technique is superior to any other method that we have used.

These comments have no relation to the usefulness of or indications for x ray therapy nor are they meant to suggest any directional approach to the problems in the use of radiation therapy.

SOURCES

Burned hands of physicians are the most frequently seen at the present time (Fig. 2). Many of these burns occur while difficult fractures are being reduced under the fluoroscope. The physician's anxiety for the welfare of his patient may have dulled his regard for his own personal safety. Nevertheless such burns are preventable and every physician using an x ray machine should be aware of the effects of a single large dose and of the irreversible cumulative effect of repeated small doses over many years.

The list of early workers in radiation who have been burned is long and contains many names well known to the profession. Dr. Walter Cannon, late professor of physiology at Harvard, suffered burns of his hands that required excision and grafting. His burns resulted from exposure while doing pioneer work in his x ray studies of the gastrointestinal system before the late effects on the skin were known.

From the Department of Surgery, Washington University School of Medicine.

Dentist's fingers are sometimes burned (Fig. 3) especially if they hold films in the mouths of patients during exposure.

Prolonged fluoroscopic examinations have produced some most unfortunate burns as a result of miscalculations in distance, time or filters (Figs. 1, 15, 16, 20, 21). Examinations of empyema fluid levels, fractured metatarsals and fractured vertebrae have produced especially bad burns. As these burns are of such great trouble both to the patient and to the one responsible for them, it seems advisable to give warning of this source.

Acne, eczema, port wine stains, planar warts, epidermophytosis and pruritus ani are all troublesome diseases but are as nothing compared to the possible effects of excessive radiation therapy (Figs. 4, 8, 9, 11, 13, 14).

Sailor's skin or farmer's skin—the dry, atrophic, telangiectatic skin resulting from decades of heavy exposure to sunlight—is especially intolerant of x radiation. The pathological changes in this type of skin are similar to those in a mild x ray burn and it is probably advisable to treat by other means keratoses, skin cancers and even lip cancers in such patients.

Commercial epilation of superfluous hair by x ray has caused some of the most dramatic, extensive and useless burns (Figs. 5, 17, 18). Patients have been seen with burns of the entire lower legs, the outside of the thighs, the axillae, outside of upper arms, entire forearms, hands, back of neck, entire face, and entire front of neck. The prolonged morbidity, suffering and loss of economic and social status endured by these patients cannot be condoned in the face of the slightness of their original complaint of superfluous hair. This commercial procedure cannot be too severely condemned.

Hemangioma and planar warts. As more time elapses the distant effects of radiation treatment will become more apparent, and perhaps in some instances changes in therapy

Fig. 1. Fluoroscopic burn following exposure to locate foreign body. Complete early resection with immediate repair with split graft. One operation, normal function.

or dosage will be instituted. Typical lesions that are treated early and in which later dermatitis and chronic atrophy may result are hemangiomas especially about the face (Figs.

9, 10) and plantar warts. Radiation lesions of the sole of the foot are especially difficult to treat even cross-leg flaps may be necessary for repair (Figs. 15, 16)

Fig. 2. Fluoroscopic burn of doctor a, b. Acute burns on both hands—left worse than right. Patient required six grains of morphine a day. Fig. 3. Dentist's burns. Typical burn of dentist's fingers from holding films in patients' mouths. Resection with immediate split graft. One operation.

It is hoped that none of these statements will be interpreted as underestimating the very great value of radiation therapy and x ray examination for many conditions the x ray is invaluable and indispensable. Recognition and elimination of the unfortunate ultimate results here discussed may lead to eventual wider usefulness of the various radiation procedures.

PATHOGENESIS

Wolbach reported the essential pathological processes which include

- '1. Loss of appendages of the skin
- '2. Replacement of normal collagen by a peculiar dense hyaline collagen rich in elastic fibers and poor in cells
- '3. Obliterative processes in blood vessels of the corium and subcutaneous tissues.
- '4. Necroses of varying sizes in the corium immediately beneath the epidermis. In the earlier stages these are usually in the region of thrombosed telangiectases. In the later stages telangiectasis may be nearly entirely absent.
- '5. In response to necroses of the corium reparative proliferation on the part of the epidermis which may extend beneath the telangiectases or areas of necrosis. "These small necroses containing the thrombosed telangiectases become completely separated from the skin by the layer of regenerated epithelium and persist for a time as dry, dark-colored spots—the coal spots—until cast off. The significance of these processes lies in the fact

Fig. 4. Excrema burn. Wide deep burns of both hands from treatment for excrema. Repair by resection and replacement of most of the skin of both palmar surfaces including fingers. Two operations were necessary. Function was about normal. To have additional work on fingers of right hand.

that they are invariably present in chronic x ray dermatosis even after the lapse of many months or several years since the last exposure to radiation. Malignant properties may be acquired after years of excessive downward proliferation that is called forth by the changes which take place in the corium and subcutaneous tissues.

The blood vessel changes may be of extreme importance. Early there is a marked thickening of the walls of the arterioles and venules at the junction of the dermis and subcutaneous fat (Fig. 6a). The occlusive endophlebitis seems often to be more severe than the endarteritis resulting in back pressure on the subepithelial capillaries with dilatation and telangiectasis (Fig. 6b). Stagnation of

that they are invariably present in chronic x ray dermatosis even after the lapse of many months or several years since the last exposure to radiation. Malignant properties may be acquired after years of excessive downward proliferation that is called forth by the changes which take place in the corium and subcutaneous tissues.

The blood vessel changes may be of extreme importance. Early there is a marked thickening of the walls of the arterioles and venules at the junction of the dermis and subcutaneous fat (Fig 6a). The occlusive endophlebitis seems often to be more severe than the endarteritis, resulting in back pressure on the subepithelial capillaries with dilatation and telangiectasis (Fig 6b). Stagnation of

Fig. 5 Commercial hair remover burn. Excessive burning from commercial x-ray treatment to remove hair. Patient's arms, axillae and legs are completely burned. Treatment consisted of excision, in two stages, of all skin of lower arms and immediate split grafting.

the blood flow in these dilated capillaries is followed by thromboses, which later become organized and in the process may rupture the vessel walls with some leakage of blood cells into the subepithelial spaces. These black

coal spots are grossly visible and are usually several millimeters in diameter. It is well known that the dermis is intolerant of macroscopic foreign bodies (for example fine silk sutures will remain indefinitely in the subcutaneous tissues but they are always cast out of the dermis).

Thus the development of carcinoma in radiation lesions may be about the closest that we have come to the actual knowledge of the formation of carcinoma clinically. The epithelium is continually stimulated to downward growth for so many years to cast off the recurring "coal spots" (Fig. 6c) and to heal the recurring ulcerations that it finally loses the normal growth response (to these foreign body and wound stimuli) and just goes on to malignant change (Fig. 7).

The clinical stages of atrophy, telangiectasis, "coal spots," keratosis, and carcinoma are typical for chronic burns such as those found on physician's hands or such as follow repeated treatments given for acne, goiter or excessive

hair. The progress of the stages is different for different patients and different exposures but generally there is telangiectasis in from 3 to 10 years, coal spots and keratosis in 10 to 15 years, and carcinoma in 20 to 25 years. Malignant change has been noted as early as 3 years, however.

An interesting thing is that in the donor site from which a split graft is taken to repair an x-ray burn the opposite reaction takes place in that the deep epithelial cells de-differentiate to re-cover the bare surface that is left when the skin is split in two.

The carcinomas that develop in radiation burns are usually squamous cell in type though occasional basal cell or basal squamous lesions are seen. The squamous cell lesions can and do metastasize while the basal cell lesions often show rodent ulcer characteristics, with deep local invasion.

X-ray burns are usually heavily contaminated with a wide variety of virulent bacteria. This is due partly to the many tiny crypts and recesses afforded by keratoses, recurrent ulcerations and cast-off coal spots, and partly to the cessation of sweat gland and sebaceous activity with loss of the normal skin-cleaning mechanism. The lesions may be so painful

Fig 6a

... and endophlebitis at junction of tissue with complete occlusion of arteriole. Telangiectasis of subepithelial result of obliterative changes of "Typical coal spot." Dilated with surface epithelium beginning to cast it out. Hyperkeratosis of numerous "coal spots. The newly growing 'under coal spots' the excess of casting them off. Excess probably as a product of the short life span may be brought about by the constant wound stimulus of the "foreign bodies" in the upper left can be seen clotted vessels in the tissue that have already been cast out. b, Development of new tissue from the continual wound stimulus. The epithelium apparently finally invading in general, instead of merely to get rid of "coal spots."

that they are left grossly dirty because the patient simply cannot tolerate the added pain of having the wounds cleaned. This cleansing is an important factor in the consideration of any surgical treatment and its omission was responsible for some grave wound infections before the days of effective chemotherapy. A corollary to this is that these wounds and

areas will not tolerate the local application of strong antiseptics.

TREATMENT OF ACUTE BURNS

Acute burns are usually the result of a single massive dose often with inadequate or no filtration. Such burns are most commonly sustained after fluoroscopy either upon the hands

Fig 10. Atrophy and deformity following radon treatment of hemangioma. Exclusion and repair with cross lip flap. Two operations.

of the doctor (Fig 2) or in patients who have had elusive foreign bodies buried in the tissues.

Even in doctors the true nature of such burns is sometimes not apparent and so the lesion may be mistakenly treated as a severe allergic condition or as a dermatitis medica-

mentosa. These areas are apt to be markedly swollen and edematous, reddened weeping serum and characterized by excruciating deep boring throbbing pain. They typically become worse each day for a week or two, and seem to be refractory toward all treatment. In the worst cases, the skin may turn white

Fig. 8. Widespread involvement following treatment for acne. As usual the tip of the nose being closest to the tube is the most burned. Repair by resection and immediate split grafting. Four operations were necessary to repair both cheeks, whole nose, upper lip.

A corollary to this is that these wounds and

areas will not tolerate the local application of strong antiseptics.

TREATMENT OF ACUTE BURNS

Acute burns are usually the result of a single massive dose, often with inadequate or no filtration. Such burns are most commonly sustained after fluoroscopy either upon the hands

Fig. 14. Athlete's foot burn. Extremely crippling x ray burns following treatment of athlete's foot. Resection of lesion and immediate repair with thick split grafts. Two operations—one over ankle and one over most of heel.

degree. Getting it fresh and keeping the bulky split leaf in place are details that few patients will carry out very long, however.

Burned areas are less painful if they are sealed off from the air by some bland ointment (e.g. cold cream or lanolin, *not autoclaved*) and a loose soft cotton dressing without any gauze next to the skin. Elevation and immobilization of hands may be quite helpful. Strong antiseptics, especially those containing heavy metals, are to be avoided. Gentleness, cleanliness, and the avoidance of irritants are the fundamentals necessary for good local treatment.

The use of ultraviolet or further radiation of any kind is definitely not advisable and is mentioned here only because it has been recommended. There seems to be no justification to use further radiation therapy in an effort to relieve such lesions which are in themselves the result of exposure to too much radiation.

If the burn has been from a single cauterizing dose in which the limits are fairly well defined and ulceration seems likely with little chance of adequate healing, early excision and grafting may be worth trying. The depth of the trouble may not be apparent, however, and there may be difficulty in growing a free skin graft.

TREATMENT OF CHRONIC BURNS

The diagnosis of chronic burns is often missed because the patient may be unaware of the cause of his condition. This fact is true

even in some physicians who do not associate the chronic dermatitis of their hands with the holding of a fluoroscopic screen for a few minutes each week. The power of recovery of the tissues from the long continued effects of radiation seems to be slight or nil, so that the status of a given individual's skin seems to be determined by the cumulative amount of radiation that he has received throughout his life.

The triad of atrophy, telangiectasis, and keratosis of the skin should lead to the diagnosis. About the only condition that is to be

Fig. 15. Fluoroscopic burn. Extremely painful, completely crippling lesion from one fluoroscopic examination following injury. Involvement clear through onto dorsum. Repaired in two operations by wide excision and split grafting.

after a few days (as in a deep fire burn) and then slough leaving a foul greenish-gray sloughing ulcer. In the milder burns, the redness, swelling and pain gradually subside and for a few months at least the skin appears fairly normal.

The pain in acute burns may be so severe as to require hospitalization and heavy sedation. One patient required 6 grains of morphine a day and the tendency here is noteworthy of caution.

As some acutely burned areas recover or at least persist as adequate cover for the part, and as there is not much chance of determining the extent of damage of an acute burn very early operation is seldom indicated.

Local anesthetics are usually unavailing and may add a secondary drug dermatitis. The use of aloe vera (an antipruritic which was formerly used for a variety of skin conditions) has been suggested and if obtainable may relieve itching and some pain to a worthwhile

Fig. 19. Pruritis and treatment. Excessive in element, repaired by excision and immediate grafting. Two operations.

Fig. 20. Fluoroscopic burn. a, left, Wide deep involvement following chest examination. Repaired later in one operation. b, Another patient with similar burn the result of gastrointestinal fluoroscopy but with a direct flap added to cover a deeper involvement.

is that the excision and repair should be done when the area is in relatively good condition—not waiting until ulceration pain and malignant change have occurred. However many patients wait for repair until these stages have occurred so that the greatest surgical problem lies within this group.

Faint telangiectasis and atrophy may not require treatment if it is very slowly progressive but even in this group excision and repair are sometimes indicated for cosmetic improvement.

Bland ointments may soften coal spots and keratoses and seem to stop them for a time, but the underlying pathological changes are progressive and later become manifest. On hands, keratoses develop with the coal spot stage and these may rapidly become malignant. These spots can best be removed in mass and the areas skin-grafted. It is less

desirable but feasible in some patients to do cautery excisions of the individual keratoses as they occur and let the areas heal by secondary intention. These are the unusual lesions for which more radiation is sometimes recommended but it should *not* be used as it is apt to accelerate the progress of the pathological changes. For the same reasons, carcinomas in x ray burns should *not* be treated with more radiation.

When it is decided that a radiated area needs excising the size depth location ulceration and malignant change in the area should be carefully considered. The basic therapy is wide deep excision followed by immediate closure of the wound with the use of free split skin grafts. The following variations in technique are sometimes useful.

1. The wound is left open to be skin-grafted later. This step is taken because these areas

Fig. 6 Sole of foot burn extending so deep that cross leg flap had to be used, rather than free graft. Two operations.

differentiated is sailor's or farmer's skin which is similar but is caused by the cumulative effect of decades of overexposure to sunlight in persons who do not form sufficient melanin to protect themselves (in other words, they do not tan). Differentiation can be made by the history and by the fact that sailor's skin symmetrically affects both forearms, both hands, and the entire face and neck in most patients. Telangiectasis is often predominant in x-ray burns, whereas atrophy and keratosis predominate in sailor's skin. Coal spots rarely occur except in association with x-ray burns. Carcinoma may develop in either.

The progress of a severe chronic x-ray burn through the stages of atrophy, telangiectasis,

coal spots, keratosis and carcinoma is irreversible and inevitable if the patient lives long enough. This course is not affected by the use of any drugs or other means of treatment known at present except the surgical excision and repair of the area. The stages may overlap and the speed of the progress varies greatly so that it is often a major problem to decide when and if to undertake excision. Fast progress in any patient and even slow progress in a young individual are indications for treatment. A paradox of treatment

Fig. 7 Commercial x-ray treatment for removing hair resulting in almost total burns of lower legs.

Fig. 8. Same patient as in Figure 7 shown after repair by wide resection and grafting. Surrounding involved area done at subsequent operation.

they should be examined and watched periodically for possible regional lymph node involvement. One of the main difficulties of course is to get the physician to submit to an adequate operation.

Face. Radiation burns of the face carry the added responsibility of securing not only good repair but a good cosmetic result. The paradox here is that radical operation should be done early before the features have been damaged by the development of carcinoma. At times when patients have been treated for acne or eczema it is necessary to excise and replace the skin of the entire face—nose, cheeks, lids, forehead, eyebrows and chin. If excision can be done early enough so that free skin grafts can be used the functional and cosmetic results are far better.

It has been noticed that the little difference in closeness of the tip of the nose to the x-ray machine usually produces enough more radiation as to cause greater damage here and in addition a resulting chronic mucositis of the nose if not a burn must be treated.

Feet. Radiation lesions of the sole of the foot form a story of their own; there are frequent histories of years of debility and great difficulty of repair. Prophylaxis is as important here as in any region for the disability may be extreme and prolonged.

The rules of treatment are the same—excision and repair. Free split skin grafts can be used even for wide areas if operation is undertaken before ulceration has occurred. Small ulcerations if not too deep can often be repaired by local flaps or free grafts but cross-leg flaps are almost always needed for repair of extensively ulcerated lesions. The idea of cutting into the sole of the opposite foot to secure a graft for the repair of a damaged one is mentioned only because it has been advocated and to suggest that it should never be done.

Fluoroscopic burns of the foot may cause some of the most distressing deep involvements encountered. Where the plantar fascia is involved shreds may be extruded at intervals for months with total disability and considerable pain throughout that time. The deep joint structures as well as the opposite surface of the foot are especially apt to suffer

Fig. 2. Hemangioma treated by radium in childhood (elsewhere with malocclusion). Urethral replacement of entire half of face delayed chest flap.

in these foot lesions. The chronicity of the process far outweighs any value of the fluoroscopic examination.

Perianal area. Perianal and perivulvar burns (usually from treatment of pruritus) offer their special problems in repairing such contaminated areas and dressing such a difficult field (Fig. 19). Excision and immediate or delayed free grafting or the immediate shifting of local flaps inward and the grafting of their sites is usually carried out. Possible troubles from a circular scar near the pectinate line should be considered and avoided if at all possible.

Preoperative preparation may include enemas and laxatives to empty the bowel and oral streptomycin or sulfasuxidine to reduce the bacterial flora. Frequent Sitz baths may help in preparing the local skin.

At operation the stent type of fixation may be used on grafts; long edge sutures are tied over a pad of gauze to immobilize the graft and dressing and the edges are surrounded with zinc oxide or some other impervious ointment. The use of a retention catheter and low residue diet for 7 to 10 days may help greatly in the prevention of soiling. After that period cleaning of the grafted area after each soiling is carried out with the grafts usually becoming quite stable and requiring little further care after a period of 3 weeks.

Relief of pain by operation. Pain in these burns may be so severe and so refractory to

Fig. 1. Abdominal burn following treatment for gastric testal tract lesion. Complete excision, immediate grafting. One operation. 8 days in hospital.

are apt not to have a very good minute (capillary) blood supply (even though blood may pour over the whole field from a few arterioles and venules) and with an inadequate minute blood supply transplanted tissue does not survive.

2 The wound may just be dressed in a split graft and the patient advised that the graft may not take and that the graft may have to be repeated if it is suspected that the blood supply is inadequate.

3 Immediate flap closure of the defect either by adjacent flaps or distant flaps prepared ahead of time may be necessary and definite plans should be made for such a contingency.

4 Delayed closure of defects with pedicle flaps may be indicated. This is true when there is no doubt that the area needs a flap and when the depth of excision is uncertain as for instance around the vertebrae or in any place in which the adjacent nerve supply must be protected.

5 In the presence of exposed bone or tendons pedicle grafts should be used. Free grafts do not do well over bone and will not grow directly on bare bone or bare tendon (if the area is more than a few millimeters wide) whereas pedicle flaps will usually survive and successfully attach themselves in such situations.

There are two essentials: (1) to get rid of the lesion and (2) to repair the area for useful function and appearance.

The persistence of function of skin grafts will be satisfactory if the involved tissue has

been excised widely and deeply enough. Edges should be watched and if deep trouble develops wider and deeper removal and repair may be necessary.

The preparation of wounds for operation consists of local cleansing, the use of mild local antiseptics (such as 1:5,000 aqueous zephiran) and on feet non-wettable agents (such as some of the silicate-gel preparations) may be used to prevent maceration of the surrounding skin under the wet dressings.

These basic steps for repair are used throughout the body but some local areas may be considered separately.

Hands. Chronic a ray burns of the hands occur most often in physicians and dentists and respond well to wide removal of skin and repair with thick split grafts. The heaviest burn may be either on the dorsal or palmar surface but the opposite surface is nearly always involved to some extent. Excessive pain may occur and require heavy sedation. In lesions of very long duration the individual blood supply to the fingers may be of such low quality that care has to be exercised in maintaining what there is available—in not doing too radical operations—not sacrificing both arteries of a finger at one time—not getting bandages too tight. When definite carcinoma has developed very wide deep excision is necessary but since excision cannot be very deep without sacrificing function amputation must always be considered as possibly the best and safest procedure in some patients. These lesions do not always remain local.

sedation as to require immediate wide deep excision of the lesion with or without primary repair. When pain is so outstanding very dramatic relief is usually obtained by excision. The patient upon awakening from the anesthetic and in spite of the discomforts of the operation will volunteer the information that his pain is gone.

Severe pain may occur in lesions on the neck in areas adjacent to bone and in lesions along the vertebrae where root pain may be excessive. One patient with severe abdominal pain who had a large burn of the back was nearly subjected to a laparotomy but was completely relieved of his abdominal pain by deep excision of the ulcer on his back (Fig 20). This is likewise especially true in patients with painful anal lesions.

The pain from excessive radiation about the jaws is one of the most difficult to alleviate.

FINAL REMARKS

These lesions are unhappy ones from every possible aspect and they are more common than is generally believed. Their prevention should be paramount in all instances of exposure. Their occurrence should be recognized early and complete excision and repair should be done before malignant changes occur (Fig 21). Such a regimen will greatly reduce the total amount of disability and suffering in these patients.

It may be repeated that severe lesions are progressive and that surgical treatment should be undertaken before serious ulceration occurs and carcinoma develops.

IMPERFORATE ANUS

A Case Series and Preliminary Report on the One Stage Abdominoperineal Operation

WILLIAM J NORRIS M.D., F.A.C.S., TRUMAN W BROPHY III M.D., F.A.C.S. and
DONALD BRAYTON M.D., F.A.C.S. Los Angeles California

IMPERFORATE anus was recognized and described in the third century A.D. but it was not until 1835 that the operation of perineoplasty with mobilization of the rectal pouch was recommended. In 1844 Velpeau advocated sigmoid colostomy following unsuccessful perineal dissection. With the use of these procedures and primary colostomy, the operative mortality has remained essentially unchanged since 1915 (6, 21).

INCIDENCE

Congenital anomalies of the anus and rectum are said to occur in the ratio of 1:5000 to 1:10000 live births. Males are affected somewhat more often than females. This disparity was greater than 2:1 in this series. It is unusual to have similar anomalies in siblings but this does occur. Two sisters were so affected in the group of cases at hand.

EMBRYOLOGY

The development of the lower rectum, anus and urogenital tract have been described in detail by other authors (1, 2, 4, 6, 7, 13, 14 and 18). In brief, these structures become differentiated between the fifth and eighth weeks of embryonic life. At first the allantoic duct and the hindgut form a common cavity, the cloaca, which is then divided by a downward growth of mesoderm, the urorectal septum, into an anterior portion, the forerunner of bladder and urethra, and a posterior portion, the primitive rectum. The anus is formed by an external invagination, the proctodeum, separated at first from the rectum by the anal membrane, which later ruptures, establishing continuity of the lower gut.

Rectourinary fistulas represent a failure of

the urorectal septum completely to divide the cloaca. In the female, the müllerian ducts, the lower portion of which form the uterus and vagina, descend in the urorectal septum, taking over any fistulous connections, if present.

The external anal sphincter develops from the regional mesoderm and therefore smooth muscle is usually present in the perianal area in spite of anomalous anal development. However, the position and function of this muscle are frequently distorted by the anomaly (4).

TYPES OF ANORECTAL ANOMALY

Malformations of the anus and rectum are usually classified into four main types (13, 14) (Fig. 1). In type I there is a stenosis of the anal mucocutaneous junction or of the lower rectum due to incomplete rupture of the anal membrane. No actual atresia is present. Type II is an imperforate anus with a persistent anal membrane only. Type III is an anomaly in which the rectal pouch ends blindly at a variable distance above the perineum. It is thought to be due to excessive degeneration of the postallantoic portion of the hindgut (13). The anal site is often represented by a dimple in the skin. This type is by far the most common (6, 10, 12, 13, 14, 18). In type IV, the anus and lower rectum are normally developed. The upper rectum ends blindly at a variable distance above this distal portion, probably due to confluence of the superior portion of the rectal ampulla (13).

Fistulas may be present in any one of the four types of anorectal anomaly but are most commonly seen in type III (Fig. 2). In type IV (6, 12, 13, 14, 18), multiple fistulas are extremely rare (13, 14). In males, the fistula may be rectovesical, connecting the rectal pouch with the bladder in the vicinity of the trigone, rectourethral, extending from the

TABLE I.—TYPES OF ANOMALIES

Type of anomaly	Males	Females	Type total	Total fistulas in each type
I				
II				3
III	5		37	26
IV				
Totals	26	5		30

pouch to the prostatic or membranous urethra or rectoperineal a tract leading from the rectum externally to the penneum anterior to the anal dimple. In females, the fistula may be rectovaginal or rectoperineal. Rectourinary or rectouterine fistulas are very uncommon. High rectovaginal fistula does occur although most of these tracts open into the lower third of the vagina or into the vulva immediately anterior to the fourchette. High fistulas include rectourinary and high rectovaginal connections. Lower rectovaginal, rectovulvar or rectoperineal are termed low fistulas.

In this series of 52 cases, there were 2 patients with type I anomaly, 13 of type II and 37 of type III. There was no patient with a type IV defect. A fistula was present in 29 of these cases, or 55.8 per cent (Table I).

The distribution of various fistulas is shown in Table II. Attention is drawn to the fact that all but 3 of the fistulas occurred in patients with a type III anorectal defect, a fistula incidence of 70.3 per cent in this type.

CLINICAL EVALUATION

In general patients with congenital anorectal anomalies fall into two main clinical divisions. The larger group consists of type I cases with extreme stenosis, and the other types without a fistula or with a narrow fistula who enter the hospital with actual or impending intestinal obstruction. The smaller division includes the more common type I case, together with the other types having a low fistula of a size sufficient to pass feces. These enter for correction of the malformation and frequently for relief of chronic partial obstruction with fecal impaction. In this series there were 33 patients of the first or emergency group. The average age of entry was 27.0 hours. There were 12 patients of the second clinical divi-

sion varying in age from 6 days to 3 years, averaging 8.3 months on entry. The type I cases were the youngest patients of this group, the type III cases with low rectovaginal fistulas, the oldest. The 7 remaining patients of the series entered the hospital for secondary operations, the primary procedures having been performed elsewhere.

Of the 33 patients in the potentially obstructed group only 4 showed clinical evidence of actual obstruction. Two of these entered at the age of 48 hours, the others at 60 and 72 hours respectively. All exhibited abdominal distention in moderate degree in testinal patterning was present in 1. Seven of the potentially obstructed patients were subjected to laparotomy at ages varying from 3 to 77 hours and all showed varying degrees of colonic distention at surgery although in only the oldest 2 was clinical abdominal distention noted preoperatively. One-third of the nonemergency group of patients entering at a later date for correction of the anal deformity had chronic partial large intestinal obstruction with fecal impaction palpable abdominally.

The diagnosis of the type of anomaly can be made by inspection and palpation of the anal and urogenital regions (13, 14). A dimple was noted at the anal site in 13 and puckering of anal skin in 2 of 37 cases of type III anomaly. It is felt that one or the other of these signs occurs in a greater percentage than these findings indicate. External fistulas (rectoperineal and low rectovaginal) are readily apparent but rectourinary and high rectovaginal fistulas often escape detection. A careful preoperative gross and microscopic examination of the urine should be made in all patients in whom no external fistula is apparent. However a high narrow fistula may be blocked temporarily with inspissated meconium and produce no

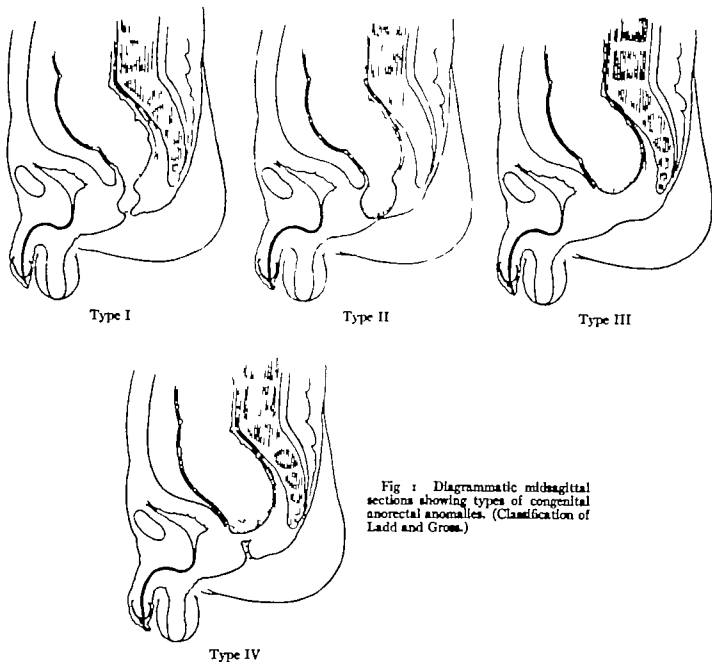

Fig 1. Diagrammatic midsagittal sections showing types of congenital anorectal anomalies. (Classification of Ladd and Gross.)

immediate evidence of its presence (13, 14). Of 14 rectourinary fistulas (all in males) 7 were not diagnosed prior to operation. Although not all of the primary procedures were performed at this hospital this represents an overall diagnostic failure of 50.0 per cent in the early determination of rectourinary fistulas. Of 10 rectovaginal fistulas 2 (both high in the vagina) were not diagnosed preoperatively. Considering the inevitability of retrograde urinary infection when these high fistulas especially those connecting the rectum with the urinary tract remain open (6) early diagnosis and treatment is of primary importance.

ASSOCIATED ANOMALIES

Additional developmental anomalies were found in 24 or 46.1 per cent of this series of cases. Other writers (1, 6, 10, 11, 13, 18) have found the proportion of associated anomalies to vary from 28.0 to 68.7 per cent. Of the 24 cases at hand 19 or 79.2 per cent were males and 18 or 75.0 per cent were patients with type III anal anomalies. This relatively higher incidence of associated anomalies in males with type III anal defects has been noted previously (10). These additional malformations involved the genitourinary system most fre-

Fig. 3. Diagrammatic mid-sagittal sections showing locations of various fistulas in type III imperforate anus: a, rectovaginal; b, rectourethral; c, rectoperineal; and d, rectovaginal.

quently occurring in 14 cases. There were 10 additional gastrointestinal malformations, 8 patients with anomalous cardiac development, 4 with skeletal anomalies, 3 with mongolism and 1 with a defect involving the larynx. The largest number of additional anomalies in any one patient was 5. Death was attributable directly to the associated anomalies in 8 patients; these malformations were contributory in the death of 2. All but 2 of these deaths were in males of type III. This represents a mortality of 15.4 per cent of the entire series. The deaths due to these anomalies are 42.1 per cent of the overall mortality.

Of particular interest are the additional malformations of the gastrointestinal tract, 10 in number, of which 4 were directly respon-

sible for death. Three of the fatal defects were tracheo-esophageal fistulas, the fourth a duodenal atresia. It is said that anal defects are the developmental lesion most commonly associated with esophageal anomalies. Reports of these concurrent malformations are frequent in the literature (11, 13, 21, 22). Awareness of the association and careful search for a possible esophageal defect is important, especially in males with the type III anal anomaly, since the operative correction of the esophageal lesion must take precedence over that for the anal defect.

TREATMENT OF ANORECTAL MALFORMATIONS

Type I anomaly is treated by repeated anal dilatations daily at first decreasing in fre-

quency as the function of the anus approaches normal. Care should be taken to traumatize surrounding tissues as little as possible in order to avoid scar tissue formation. Should the external aperture be very small, cruciate incision of the remaining membrane is indicated. If stenosis is produced by a fold higher in the rectal ampulla, longitudinal division of the structure followed by transverse closure has been advocated (7). Few patients with this type enter the hospital; only 2 are present in this series. One of these died shortly after birth of congenital heart disease; the other has only fair anal function at the age of 12 years. A firm scar is present at the mucocutaneous junction causing incontinence when the stools become loose.

The treatment of type II malformation has consisted of cruciate incision of the obstructing membrane or of excision of the membrane and suture of the anal mucosa to the skin. Both procedures are followed by repeated dilatations. Eleven patients were so treated. Two others were admitted for resection of stenosing scars or bands; one following primary treatment elsewhere, the other following spontaneous rupture of the membrane. Eleven of these patients are now living and well with satisfactory anal function, although one required secondary excision of a perianal scar. There were 2 fatalities. One was due to a congenital laryngeal anomaly; the second who died at home of undetermined cause 1 week following discharge from the hospital is considered an operative death. Three fistulas were present in this group; all of which were rectoperineal in location, small and superficial. All closed spontaneously after being opened at the operation and allowed to heal by granulation.

The classic method for treating the majority of cases of type III anal anomaly is a procedure called proctoplasty or perineoplasty. This operation consists of approaching the rectal pouch from below through a vertical midline perineal incision. The blind rectal end is dissected free from surrounding tissues and drawn downward to be sutured without tension after opening to the skin about the anal site. If the primary proctoplasty is unsuccessful because the operator failed to find the rec-

Fig. 3. Technique of abdominoperineal rectal replacement. A left lower rectus muscle-splitting incision is made (inset). The distended sigmoid colon is allowed to eviscerate.

tal pouch or to mobilize it sufficiently to bring down without tension, high sigmoid colostomy has been advocated. In some cases, usually those in a relatively poor preoperative condition, primary colostomy is performed without an attempt to dissect the perineum.

Fistulas occurring with type III imperforate anus are variously treated. Low fistulas (rectoperineal, rectovulvar, and low rectovaginal) have been successfully closed at the time of the primary proctoplasty by division or excision of the fistulous tract and the mobilizing of the rectum sufficiently to exteriorize the rectal end of the fistula (13). Frequently a low fistula with a stoma adequate for passage of feces is simply dilated to relieve obstruction, correction of the anomaly being postponed until the patient is over 3 years of age. At this time proctoplasty is performed, usually preceded by sigmoid colostomy, which is then closed as a third stage operation at a later date. High fistulas (rectourinary or high rectovaginal) are corrected at an earlier age. Several months after the primary proctoplasty,

Fig. 2. Diagrammatic midsagittal sections showing locations of various fistulas in type III imperforate anus: a, rectovaginal; b, rectourethral; c, rectoperineal; and d, rectovaginal.

quently occurring in 14 cases. There were 10 additional gastrointestinal malformations, 8 patients with anomalous cardiac development, 4 with skeletal anomalies, 3 with mongolism and 1 with a defect involving the larynx. The largest number of additional anomalies in any patient was 5. Death was attributable directly to the associated anomalies in 8 patients; these malformations were contributory in the death of 2. All but 2 of these deaths were in males of type III. This represents a mortality of 15.4 per cent of the entire series. The deaths due to these anomalies are 42.1 per cent of the overall mortality.

Of particular interest are the additional malformations of the gastrointestinal tract in 10 in number of which 4 were directly respon-

sible for death. Three of the fatal defects were tracheo-esophageal fistulas, the fourth a duodenal atresia. It is said that anal defects are the developmental lesion most commonly associated with esophageal anomalies. Reports of these concurrent malformations are frequent in the literature (11, 13, 21, 22). Awareness of the association and careful search for a possible esophageal defect is important especially in males with the type III anal anomaly, since the operative correction of the esophageal lesion must take precedence over that for the anal defect.

TREATMENT OF ANORECTAL MALFORMATIONS

Type I anomaly is treated by repeated anal dilations daily at first decreasing in fre-

Fig 5 The rectal pouch is further released by posterior dissection (inset) (The dotted line represents the dissecting finger) At the completion of this stage of the operation there is sufficient bowel to reach the perineum without tension

cent. Another patient died of peritonitis secondary to bilateral acute streptococcal salpingitis during the interval prior to closure of her rectovaginal fistula several months after a primary dilatation. Three of these 11 patients are still waiting for further operations, 2 new patients having had the primary procedure await the beginning of the various stages of the fistula repair while 4 have been lost to follow up before discharged as cured.

It is evident that in addition to this primary and secondary mortality there is a large and incalculable morbidity expressed in readmissions and total hospitalization involved in the classic treatment of type III anorectal anomalies. For this reason we have recently

attempted to correct the anal deformity and close the fistula in certain of these cases with one operation: an abdominoperineal replacement of the rectum (Figs 3, 4, 5, 6 and 7).

The skin of the infant is prepared on all aspects from axillae to below the knees; he is placed upon a sterile sheet and the feet and legs are wrapped separately in sterile drapes. A left lower rectus, muscle splitting incision is made. The dilated loops of colon are allowed to eviscerate and are covered with warm moist packs. Sufficient gas and meconium within the pelvic colon are gently milked proximally to allow adequate exposure of the pelvic floor. The peritoneal reflexion is incised about the rectum and the dissection is

Fig. 4. Dissection is carried anteriorly about the rectal pouch and the fistula identified (inset). The tract is then divided between clamps.

a sigmoid colostomy is made followed after a varying interval by isolation and division of the fistula usually through an abdominal approach. For rectourinary fistulas a suprapubic cystotomy is frequently performed with this stage. Later the cystotomy tube is removed and finally the colostomy is closed. As the artificial anus tends to contract during the period of disease dilatations or plastic repair of the perianal scar are often necessary following closure of the colostomy.

In this series of 37 cases of type III anorectal anomaly, 34 were subjected to primary operations with 7 deaths—a mortality of 20.6 per

cent. Table III lists the primary procedures used and the mortality of each.

In the literature one finds that the mortality of primary successful proctoplasty varies from 11.7 to 22.2 per cent (13, 18, 24) that of primary colostomy from 18.0 to 25.0 per cent (18, 24) and that of unsuccessful proctoplasty followed by colostomy from 68.7 to 84.6 per cent (13, 24). Except in this last category the fatality rate approximates the average range.

In addition to the primary operations of the present series, 11 patients had 40 secondary "stage" procedures performed with 1 operative death—an additional mortality of 9.1 per

Preoperative and postoperative care is similar to that practiced in atresias elsewhere in the gastrointestinal tract (23). A Levine tube is passed into the stomach in all cases prior to operation (A tracheo-esophageal fistula may be discovered at this time). The stomach is kept empty by means of the tube during the operation and for 12 to 24 hours thereafter. A vein is cannulized prior to operation and electrolytes, blood or plasma given as indicated during the procedure. Open drop ether anesthesia is used. Postoperatively constant intravenous hydration is maintained to give 10 to 15 cubic centimeters of saline per pound per day and total fluids of 50 to 75 cubic centimeters per pound per day. Transfusions of 50 to 75 cubic centimeters are given as indicated. Feedings are started as in the postpyloric regimen after 24 hours and gradually increased as the normal motility of the bowel is attained. Penicillin or streptomycin may be given prophylactically. The anal sutures are removed on the tenth postoperative day. Gentle anal dilatations are begun on the fifth postoperative day and continued daily for several weeks, diminishing in frequency as the anal function approaches normal.

It is felt that the abdominoperineal replacement of the rectum is indicated in all early cases of type III anorectal anomaly with evidence of rectourinary or high rectovaginal fistula, and in all such cases without evidence of fistula, since both the incidence and the error in diagnosis of such fistulas in these patients are known to be high. However, when these

infants are seen late (over 60 hours of age) especially if considerable abdominal distention is present they are probably best treated by primary proctoplasty or colostomy, depending upon the general condition and the distance between the perineum and the rectal pouch as determined by roentgenograms. In such cases where there is little abdominal distention the abdomen may be opened as for the abdominoperineal procedure. If however sigmoid distention precludes adequate exposure of the pelvic floor a high sigmoid colostomy may be carried out and the abdomen closed. Cases of type III anomaly with low narrow rectovaginal or rectoperineal fistulas should have a primary proctoplasty with division and extensorization of the fistula. Less preferably a primary dilatation of a wider

FIG. 6. The assistant holds the infant in exaggerated lithotomy position, and short vertical, midline incision is made through skin and subcutaneous tissue overlying the anal dimple. A clamp is then placed through the exact center of the dimple, spread gently and the ligated rectal end of the fistula drawn through to the exterior.

carried inferiorly to expose the blind rectal end and the fistula (if one exists). This is divided between clamps and ligated with fairly heavy chromic catgut. The ends of the ligature on the rectal side are left long. Further dissection of the pouch continues until the rectum is sufficiently free to be drawn downward to the perineum without tension. A short vertical incision through skin and subcutaneous tissue only is then made in the perineal midline. With a blunt instrument this opening is connected with the superior area of dissection through the center of the anal dimple, thus saving as much of the anal

sphincter as possible. The ligated portion of the rectal pouch is grasped and drawn through the perineal wound. The sigmoid colon completely covers the pelvic pentoneal defect so that no reperitonization is necessary. The abdomen is closed with interrupted figure of eight sutures of fine stainless steel wire uniting pentoneum muscle and fascial layers. Interrupted sutures of nonabsorbable material are used to close the skin. The ligated end of the rectal pouch is removed with scissors after the full thickness of the rectum has been approximated to the skin of the perineal incision with interrupted nonabsorbable sutures.

low fistula may be carried out followed by colostomy and secondary proctoplasty at a later date. The primary abdominoperineal replacement or some other single stage operation is probably indicated in type IV anorectal anomalies when seen early although we have had no experience with them. The operation is definitely contraindicated following attempted, unsuccessful proctoplasty.

This is a preliminary report in that the primary abdominoperineal replacement of the rectum has been performed in only 4 cases. One infant died due to an associated anomaly. The second had normal postoperative bowel and anal function but his course was marked by recurrent periods of cyanosis, fever and occasional abdominal distention. There was a marked and unexplained anemia. A gastrointestinal series at about 5 weeks of age revealed no anatomic nor functional abnormality and there was no evidence of peritonitis.

After 7 weeks the infant expired. Unfortunately no autopsy was obtainable. Although we include this as an operative death, an associated cardiac anomaly appears to be the more likely cause. The 2 other patients are living and well at the ages of 4½ years and 10 months, respectively. The anal function of the elder is normal the perianal scar is soft and a small but functioning sphincter is present. The younger patient has no evidence of an anal sphincter and no voluntary control has yet appeared. The anus admits the fifth finger with ease and the scar remains moderately soft. The operative mortality is, therefore 25 per cent up to this time.

ROENTGENOGRAPHY PRIOR TO OPERATION

Because of the nature of the abdominoperineal procedure the earlier the patient comes to surgery the less the distention and the simpler the operation. The Wangenstein and

Rice technique for obtaining roentgenograms of the abdomen with the infant held head down and a marker at the anal dimple has been found inaccurate before the age of 24 hours by numerous observers (1, 12, 13, 14, 18, 31). The films of 3 of our patients taken at the ages of 2, 13, and 14 hours respectively, illustrated this error. In each case, at laparotomy shortly following this diagnostic procedure the rectal pouch was found to be at the level of or just below the pelvic peritoneal reflexion. In no case had the gas approached this region, according to the films (Fig. 8). To postpone the operation until accurate roentgenograms may be obtainable increases the hazard to the patient by increasing the difficulty of exposure at the time of surgery. The x-ray procedure is somewhat traumatic, especially if the infant is held head down for some minutes and the abdomen massaged in an attempt to cause gas to enter the rectal pouch (32). The films give no information regarding the presence or location of high fistulas. For these reasons it is felt that preoperative roentgenograms may frequently be omitted in infants seen at an early age, in which the abdominoperineal operation is indicated.

RESULTS OF TREATMENT

The results of the treatment of imperforate anus are difficult to evaluate accurately prior to the age of 2 or 2½ years when toilet habits have developed. If the child has control of evacuation even when the feces are loose (as in diarrhea or after catharsis) normal anal function is considered to have been attained. If control is present when the feces are of normal consistency and incontinence occurs only with watery stools the anal function is considered "good." Function is only "fair" if con-

TABLE V—MORTALITY

Figure is based on infants operated upon and includes fatalities following both primary and secondary operations.

trol is lost with soft stools, and "poor" if total incontinence or alternating incontinence and impaction occur. Patients in these last two categories usually require further surgical treatment. The best results are seen in those children who develop a palpable anal sphincter. The preponderance of good results in this series occurred in patients with type II anal anomaly (Table IV).

Some aspects of the mortality have been discussed. Table V presents the fatality statistics in further detail. The total fatality rate for the entire series is 36.5 per cent, the over all operative mortality being 17.3 per cent that from associated anomalies 5.4 per cent and from other causes, 3.8 per cent.

SUMMARY AND CONCLUSIONS

The various types of congenital anal anomalies together with commonly associated fistulas are described. Fifty-two cases taken from the services of Drs. L. Chaffin, J. N. Nichols, K. Smiley and the authors have been studied. In the majority of the patients the rectum was found to end blindly at a varying distance from the perineum, the type III anorectal anomaly. The incidence of fistulas and of associated malformations of other systems is relatively higher within this group of cases than in the other types. The mortality and functional results of treatment are about the same in this series as in others of the literature.

The treatment of the type III case with a rectourinary or high rectovaginal fistula has caused prolonged hospitalization and additional mortality by the use of multiple "stage" operations. A one stage primary procedure has consequently been adopted for certain of these patients. This operation, the abdominoperineal replacement of the rectum, has the advantage of correcting the anal defect and closing the fistula at the same time. The use-

Fig. 8. Roentgenogram of infant with type III imperforate anus at the age of 48 hours, using the Wangenstein and Rice technique. Gas had not entered the pelvic colon sufficiently to localize the rectal pouch. At operation, shortly afterward, the rectum was found to terminate slightly below the pelvic peritoneal reflection. low fistula may be carried out, followed by colostomy and secondary proctoplasty at a later date. The primary abdominoperineal replacement, or some other single stage operation is probably indicated in type IV anorectal anomalies when seen early although we have had no experience with them. The operation is definitely contraindicated following attempted unsuccessful proctoplasty.

This is a preliminary report in that the primary abdominoperineal replacement of the rectum has been performed in only 4 cases. One infant died due to an associated anomaly. The second had normal postoperative bowel and anal function but his course was marked by recurrent periods of cyanosis, fever and occasional abdominal distention. There was a marked and unexplained anemia. A gastrointestinal series at about 5 weeks of age revealed no anatomic nor functional abnormality and there was no evidence of peritonitis.

After 7 weeks the infant expired. Unfortunately no autopsy was obtainable. Although we include this as an operative death an associated cardiac anomaly appears to be the more likely cause. The 2 other patients are living and well at the ages of 4½ years and 10 months respectively. The anal function of the elder is normal the perianal scar is soft and a small but functioning sphincter is present. The younger patient has no evidence of an anal sphincter and no voluntary control has yet appeared. The anus admits the fifth finger with ease and the scar remains moderately soft. The operative mortality is, therefore 25 per cent up to this time.

ROENTGENOGRAPHY PRIOR TO OPERATION

Because of the nature of the abdominoperineal procedure, the earlier the patient comes to surgery the less the distention and the simpler the operation. The Wangenstein and

RESULTS

Isolation of a segment of vein with soft rubber clamps in 8 instances did not produce thrombosis in 15 minutes. Isolation plus the injection of 0.05 cubic centimeter of 0.9 per cent saline in 7 instances produced no thrombosis. Fifty-four veins were used to determine the amount of thrombin necessary to produce coagulation. In 10 radial veins that received 20 units of thrombin clots formed in all. In 14 veins receiving 10 units of thrombin clots were present in 6 or 43 per cent. Forty-seven jugular and femoral veins were used to determine the minimal amount of trypsin necessary to produce thrombosis, less than 0.0001 milligram produced no thrombi in 6 of 7 instances.

Graphic representations of the results of the injections of thrombin and trypsin in the presence of hypoprothrombinemia may be seen in Figure 2. In the thrombin experiments thrombi were present in 6 veins and were absent in 15 veins when the prothrombin level

from the vein and was immediately absorbed by the sponge. In some instances a small pin point clot was observed at the site of the vein puncture but the remaining blood was completely liquid. Any clot other than this was considered to be a thrombus and is so designated in the tabulated results (Tables I and II). In many instances the character of the clot varied from the controls and this fact will be discussed in more detail.

EVALUATION OF HEXACHLOROPHENE AND DETERGENTS AS SUBSTITUTES FOR THE SURGICAL SCRUB

A Biological Technique

W J NUNGESTER, M.D., R. L. THIRLBY M.D., and A. B. VIAL, M.D., Ann Arbor Michigan

THE present study was undertaken in order to evaluate some of the newer cleansing and bactericidal agents as possible substitutes for the conventional surgical scrub.¹ A technique which would eliminate much of the time and irritation that are undesirable features of the 10 minute scrub would obviously be worth while. The agents selected for evaluation included a bactericidal agent² incorporated in soap, and two detergents.^{3, 4}

The literature contains several articles on hexachlorophene (1, 7, 8, 9), all giving favorable reports on the use of this agent incorporated in soap for cleansing skin. The techniques utilized by these workers were essentially variations of Price's method for obtaining colony counts from hands and forearms.

In this study animal inoculation was used to evaluate the agents tested. The examination of hand washings by animal inoculation tends to (a) differentiate potentially pathogenic from purely saprophytic organisms, and (b) to eliminate false bactericidal effects of chemicals only bacteriostatic in nature (3, 4).

To establish a maximum standard reaction of animals to pathogenic bacterial infection the method of Nungether, Jourdonais and Wolf (5) of introducing mucin to decrease the resistance of animals to given infection was utilized. Repeated titrations in which a virulent culture of hemolytic streptococci was injected intraperitoneally into mice with and without mucin revealed that the animals' resistance was reduced about one million fold

when mucin was used. Whereas no less than 0.5 milliliter of the culture was lethal, 0.5 milliliter of a 10^{-4} dilution of the same culture when combined with mucin, provided a fatal dose. Strict saprophytes do not kill mice when injected with mucin.

Four series in all were undertaken. The first two were of a preliminary nature and compared a routine surgical scrub with the use of bar soap with a two minute wash with the use of either Duponol phisoderm or hexachlorophene, no brush being used with the last three agents. One of these series was carried out in the hospital, the subjects being physicians actively engaged in clinical work on the surgical wards and in the operating rooms. The series was short and did not contribute any significant comparative results. However, it did reveal the remarkably low pathogenicity of hand rinsings obtained prior to cleansing. The mean mortality of mice injected with hand rinsings obtained prior to cleansing was 18 per cent as against a mean of 13 per cent mortality produced by all the samples taken after cleansing. The results were derived from 12 cleansings with each agent, all agents being tested concurrently. The differences between the improvements resulting from the use of each cleansing agent were not significant.

In the second series physicians engaged in laboratory duties contaminated their hands with 5 milliliters of a hemolytic streptococcal culture before cleansing with the same agent used in the first series as noted previously. Contamination of the hands and wrists was done in order to provide a greater killing power to the rinsings injected and to place a more severe test upon the cleansing and bactericidal properties of the agents tested. As has been noted, the pathogenicity of bacteria usually present on one's hands and forearms

From the Departments of Surgery and Bacteriology, University of Michigan Medical School, Ann Arbor, Michigan.

¹Control cleansings, as well as surgical scrub, employed bar soap (Ivory).

²Hexachlorophene (G-11) Hexachloro-*di*-hydroxy diphenyl methane, 5 per cent incorporated in bar soap of the Lux type.

³Phisoderm (s) (regular type) containing sodium *t*-octylphenyl ethoxyethyl ether sulfonate.

⁴Duponol (WA paste) 15 per cent in water

Fig. 3. Thrombosis attempted during the fall and rise of the blood prothrombin level in 1 animal.

was below 35 per cent of normal. When the level was above 35 per cent thrombi were present 11 times and absent once. A more marked reduction in the prothrombin reserve was necessary to inhibit coagulation when trypsin was used. When the prothrombin per cent was below 15 per cent of normal, thrombi were present 6 times and absent on 6 occasions. Above 15 per cent, however, in 10 instances thrombi were always present. Two individual experiments are shown in Figures 3 and 4.

COMMENT

The results of the experiments indicate that venous thrombosis produced by a combination of venous stasis and the injection of either thrombin or trypsin may be prevented by reducing the blood prothrombin level. Levels below 35 per cent were necessary in the thrombin induced coagulation and levels below 15 per cent were required to inhibit the trypsin induced thrombosis. It cannot be stated that thrombosis could be inhibited routinely below these levels. On the other hand it can be stated that above these levels, no success was obtained in preventing the formation of thrombi. When coagulation did occur below 35 per cent in the thrombin and 15 per cent in the trypsin experiments

Fig. 4. Thrombosis attempted during the fall and rise of the blood prothrombin level in 1 animal.

the character of the thrombus was different from the controls. Instead of a firm compact thrombus, a loosely adherent mass of fibrin and red cells resembling sludge was encountered.

In clinical practice we have attempted during the past 2 years to maintain the prothrombin level at 20 per cent of normal in the prophylaxis and treatment of venous thrombosis.

CONCLUSIONS

1. This study suggests that venous thrombi experimentally produced may be prevented by reducing the blood prothrombin level below 35 per cent of normal with dicumarol.

2. Blood prothrombin levels above 35 per cent were ineffectual in preventing the formation of thrombi.

TABLE I.—INTRAPERITONEAL INJECTION, WITH MUCIN OF PEPTONE RINSINGS TAKEN AFTER CLEANSING

Type of cleansing	Hexachlorophene	Routine surgical scrub
No. cleansings	36	43
N mice injected	343	445
No. dead	8	36
Mortality per cent	8.0	8.1

P—less than 4%

Table I presents the data from this series. Results show 12.6 per cent mortality following the use of the 10 minute surgical scrub and 8.0 per cent mortality after a 3 minute wash with soap containing 2 per cent hexachlorophene. This difference is statistically significant.

Their value in decreasing transient streptococci. In this series contamination was done as follows

The skin was contaminated on Monday 5 milliliters of the 10 milliliters in each hemolytic streptococcal culture being placed on the hands of a subject using one agent and the other 5 milliliters being placed on the hands of the subject using the other. On the 4 subsequent days no contamination of hands was done. The rest of the method was precisely as in the previous series. Six subjects participated in this experiment each using both agents with at least 10 days intervening between their use.

These data are presented in Table II. It should be noted that the culture used in these tests was more virulent than the strain of hemolytic streptococcus originally employed. The noteworthy variance is that present in the death rate of the animals injected with rinsings obtained on the first and second days subsequent to the day of contamination. This difference is apparently due to the persistence of the artificially implanted transient bacteria after 3 days of scrubbing whereas there was a rapid depression of the pathogenicity of the rinsings from those subjects employing hexachlorophene bar soap. The difference in mortality on the day after contamination is statistically highly significant. In addition, a similarly significant difference persists on the second day after contamination.

TABLE II.—INTRAPERITONEAL INJECTION WITH MUCIN OF PEPTONE RINSINGS TAKEN AFTER CLEANSING CONTAMINATION WITH 5 C C OF STREPTOCOCCUS HEMOLYTICUS CULTURE ON FIRST DAY OF SERIES

	Hexachlorophene 3 minute wash (6 subjects)			Routine surgical scrub 10 minutes (7 subjects)		
	No. of mice injected	Dead	Per cent	No. of mice injected	Dead	Per cent
First day	60	50	83.3	70	60	85.7
Second day	60	7	11.7	70	27	38.6
Third day	60	9	15	70	3	4.3
Fourth day	60	5	8.3	70	0	0
Fifth day	60	8	13.3	70	13	18.6

The possibilities of using hexachlorophene soap for preparing the operative field are apparent. Not only would mechanical cleansing be obtained but the added bactericidal effect would be advantageous. In order to compare the bactericidal effect of hexachlorophene on skin as compared with tincture of iodine, an animal method was used. This was a modification of that used by Kempf and Nungester (4). These authors contaminated a mouse's tail with either a virulent culture of pneumococci or streptococci and, after applying the antiseptic agent to be tested, inserted the amputated tip of the tail into the animal's peritoneal cavity. Our method used the abdominal skin as the test area.

METHOD

1 Under ether anesthesia the abdomen was shaved and swabbed with a 24 hour blood brain heart broth culture of hemolytic streptococci.

2 After a 1 minute interval as measured by a sand glass, the agent being tested (either tincture of iodine U.S.P. or a 1 per cent solution of the monopotassium salt of hexachlorophene in 33 per cent ethyl alcohol) was blotted on the contaminated area. Care was taken not to wipe away the culture when applying the iodine or hexachlorophene solution.

3 After a measured 2 minute interval a 1 by 0.5 centimeter elliptical segment of skin was removed and the peritoneum opened. The skin segment was placed in peritoneal cavity

is remarkably low and to simulate the usual contamination was undertaken.

In this series, each agent, duponal phisoderma hexachlorophene, and soap and brush was used for 15 cleansings. The data for all agents were obtained concurrently. The results obtained in this second preliminary series again suggested that favorable cleansing could be obtained with either detergent or with hexachlorophene soap as compared with the surgical scrub. The mean mortality of animals injected with rinsings taken after contamination and before cleansing was 79 per cent as compared with a mean mortality following cleansing of 27 per cent for all agents tested. Here again the variations between the agents tested were not significant.

The efficacy of this biological method was well illustrated by data derived from the second preliminary series in which contamination of the hands was done prior to cleansing. Twenty four random autopsies were done on animals that had died after having been injected with samples obtained following cleansing. Cultures from the spleens of these animals revealed hemolytic streptococci in 10 cases whereas, in vitro cultures of the peptone water samples that had been injected into these same 10 animals failed to reveal hemolytic streptococci in 5 instances. There is little doubt that in many instances the abundant overgrowth of bacteria accompanying postmortem changes precluded the identification of hemolytic streptococci. This does not devalue the animal inoculation method as all mice dead following injection provide the critical numbers for statistical analysis whether streptococci are or are not identified in the animals.

As a result of these preliminary experiments, two more series were conducted comparing the routine surgical scrub with a 3 minute brushless wash with soap containing hexachlorophene. In the second of these two series the hands and forearms were contaminated prior to cleansing.

PROCEDURE

1 Each subject cleansed with a given agent (10 minute surgical scrub or 3 minute wash with hexachlorophene soap) on each of 5 successive days. The 10 minute surgical scrub

was routine. The 3 minute wash with bar soap containing 2 per cent hexachlorophene involved lathering from fingertips to elbows for 1 minute cleaning fingernails with an orangewood stick for 1 minute while the lather remained on the arms and a third minute was spent relathering the arms and hands, which were then rinsed in running tap water.

2 Each subject rinsed his hands in 200 milliliters of sterile 0.5 per cent peptone water for 1 minute 20 seconds being spent rubbing the palms together 20 seconds rubbing the back of one hand and 20 seconds rubbing the back of the other hand.

3 Immediately thereafter 5 milliliters was taken from each basin of peptone water rinsings and mixed with 5 milliliters of sterile 5 per cent hog gastric mucin. One milliliter of this mixture was then injected intraperitoneally into each of 10 mice. The animals were observed for 5 days and deaths recorded.

In the series in which contamination was done 5 milliliters of a 24 hour blood-brain-heart broth culture were placed in the palms of each subject who then rubbed the culture over all the skin of the hands and wrists. The culture air-dried for 3 minutes after being applied. Such contamination was done prior to cleansing.

COMPARISON OF THE SURGICAL SCRUB WITH BRUSHLESS CLEANSING WHEN SOAP CONTAINING 2 PER CENT HEXACHLOROPHENE IS USED

A statistically significant difference in their cleansing effect on normal skin. Twelve subjects were used all with scrubbing experience 11 with at least a year's surgical training. After an individual used each agent, at least 10 days intervened before his use of the other agent. The subjects used neither antibacterial agents nor prolonged (i.e., 10 minutes) scrubbing of their hands during this interval. This was to allow the skin flora to be re-established (6) and to remove all hexachlorophene from the skin. Seastone has detected traces of hexachlorophene on the skin 48 hours after exposure to this agent in amounts sufficient to act as a bacteriostatic agent the agent being carried from the hands through the wash water to the culture medium.

TABLE III.—RESULTS

	No animals	Deaths	Mortality per cent
Iodine	26	1	42
Hexachlorophene	20	44	67
Control	18	5	24

4. Five-tenths milliliter of sterile mucus was injected intraperitoneally and the wound then closed with cotton sutures.

These animals were observed for 5 days and deaths recorded. A control series was conducted concurrently in which the method was identical except for the application of iodine or hexachlorophene. Table III presents the results of this experiment.

The 42 per cent mortality is similar to that obtained by Kempf and Nungester in their tests in which the animals' tails were used to carry the culture and agent into the peritoneal cavity. Their mortality was 38 per cent when iodine was used and from 85 to 95 per cent when merthiolate, mecresol or phenol was used. These agents were not compared directly in our experiment.

DISCUSSION

These experiments substantiate our recommendation that the routine surgical scrub be eliminated in favor of a 3 minute wash with soap containing hexachlorophene. Such a change is desirable because of the common irritating effects resulting from repeated cleansing with a brush. The low pathogenicity of the skin flora from the hands and forearms is noteworthy. This is indicated by an 18 per cent mortality of mice injected with mucus and skin washings obtained prior to cleansing.

It should be noted that no alcohol rinse was employed in these tests. Attention is drawn to Seastone's statement that the use of an alcohol rinse after cleansing may extract part of the hexachlorophene from the skin.

In conducting this work an attempt was

made to obtain subjective criticism of the different agents being evaluated. Several subjects found duponal somewhat drying and irritating to the skin although no definite sensitivity was noted objectively. Phisoderm was well received, as was the bar soap containing hexachlorophene. No instances of sensitivity to either were observed.

Although data are not sufficient to draw fixed conclusions on the basis of preliminary experiments cleansing with phisoderm (2) and duponal would also appear to have possibilities as substitutes for the surgical scrub. A combination of a detergent and hexachlorophene might be efficacious. In addition use of these agents for preparing the operative field is suggested.

SUMMARY

1. A biologic method for evaluation of agents for cleansing the skin is presented. This technique differentiates the bacteriostatic and bactericidal action of chemicals. The use of animals whose species resistance has been greatly lowered by injection of mucus also serves to determine the potential virulence of skin flora.

2. Under the conditions of these experiments it may be concluded that the use of bar soap containing 2 per cent hexachlorophene for 3 minutes without a brush is superior to the routine two brush, 10 minute surgical scrub.

TENDON TRANSPLANTS FOR IRREPARABLE RADIAL NERVE PARALYSIS

CARLO SCUDERI M.D., Ph.D. F.A.C.S., Chicago, Illinois

THE present paper is based on the personal experience of the author as Chief of Orthopedic Surgery and later as Chief of the Surgical Service while at McGuire General Hospital Richmond, Virginia.

In all 45 cases of tendon transplantation for irreparable radial nerve paralysis were carried out by the author from February 27, 1945 to March 9, 1946. Various operative procedures were used and a clinical evaluation of the procedure made at the time that the patient was being either separated from the Service or transferred to another installation.

REVIEW OF LITERATURE

Operative attempts for the restitution of function by tendon transplants in radial nerve paralysis date back over 50 years.

In 1896 Drobniak did a transplant for the paralysis of the posterior branch of the radial nerve with conservation of the function of the extensor carpi radialis longus. The extensor carpi radialis longus was placed into the common extensors of the fingers.

In 1897 Rochet had a case of partial paralysis of the radial nerve with persistence of function of the extensor carpi radialis longus which was transplanted into the extensor pollicis longus and extensor indicis proprius.

In 1902, Cappelli did a shortening of the extensor carpi radialis longus and transplantation of the flexor carpi ulnaris into the common extensors of the fingers and of the palmaris longus into the extensor indicis proprius.

From the end of the nineteenth century to World War I sporadic case reports and questionable procedures appeared in the literature. In 1917 Sir Robert Jones standardized his operation of tendon transplants for radial nerve paralysis and firmly established a milestone in the method of treatment of this condition. He transplanted the pronator teres into the extensor carpi radialis longus, the flexor carpi

radialis into the extensor pollicis longus and the extensor indicis proprius, and the flexor carpi ulnaris into the extensor tendons of the third, fourth, and fifth fingers.

In civilian life injuries which are of the type to produce irreparable radial nerve paralysis are few and far between. Consequently in the intervening period between World War I and World War II, the only report of a number of cases seen by any one surgeon or any one clinic was from the Mayo Clinic where 23 cases were treated over a period of 26 years. This article written by Young and Lowe gave an excellent review of a long term follow up of patients.

Bonola, in 1936 presented an excellent review of the subject and also an ingenious method of evaluating these cases from a functional standpoint.

During World War II, due to the kind of warfare with previously unknown types of high velocity shells, land mines, and aerial bombs, the injuries to the extremities reached astronomical figures. Consequently, in a relatively short period of time a substantial number of injuries of this type gravitated to specialized centers.

In 1946 Altman and Trott reported on 28 cases from McCloskey General Hospital, in this country, and Zachary reported on 57 cases from Wingfield Morris Hospital in England. These cases were done by various surgeons on the staff.

Lamphier and Littler, in 1947 reported on an undisclosed number of the cases performed at Cushing General Hospital. The procedure they used was the transference of the flexor carpi radialis into the abductor pollicis longus, extensor pollicis longus and brevis, and of the flexor carpi ulnaris into the common extensor tendons to the fingers.

In cases reported by Altman and Trott the pronator teres was inserted into the extensor carpi radialis longus and brevis, the flexor

Fig. The five common types (first, transplants performed) of tendons are graphically shown in II, I, III, II, III and IV. The number of each type of operation performed is listed on the accompanying table.

carpi radialis into the extensor pollicis longus and brevis and the flexor carpi ulnaris into all the extensor tendons of the fingers. They reported uniformly good results in their cases.

In most of the cases reported by Zachary, the pronator teres was transplanted into the extensor carpi radialis longus, the flexor carpi ulnaris into the extensor tendons of the third, fourth and fifth fingers and the flexor carpi radialis into the extensor pollicis longus and extensor indicis proprius. In a careful analysis of these cases he brought out a very im-

portant point with which the writer was able to concur. He noted that if all the flexors of the wrist (flexor carpi ulnaris, flexor carpi radialis and palmaris longus) were transferred, stabilization of the wrist was lost in many instances and often led to incomplete extension of fingers and unnecessary weakening or abolishment of voluntary power of wrist flexion.

REPORT OF PERSONAL CASES

Various methods of tendon transplants were used in this series and careful after studies

Fig. 1b. The less common types of tendon transplants performed in this series are graphically shown in illustrations V, VI, VII, and VIII. This group consists of 6 cases.

were made in order to evaluate their relative efficiency.

Forty five cases were carried out in all. The various types of transplants are presented in Table I and in Figures 1a and 1b.

The study of these patients during the convalescent periods and the analysis of many of the cases by means of movies revealed the following:

1 Combined suture of one transplanted tendon into two or more inactive tendons having different functions (such as suturing

the palmaris longus or the flexor carpi radialis into the extensor pollicis longus and brevis or extensor pollicis longus and extensor indicis proprius) was not as satisfactory as transference into a single thumb tendon.

2 In spite of experimental evidence to the contrary, the flexor carpi ulnaris muscle is perfectly capable of extending the wrist and all the fingers, if properly sutured under the correct amount of tension (Sudeck, in 1944 stated that the working power of the flexor carpi ulnaris was 2 kgm. and that this was

FIG. 1.—The most common types of tendon transfers. I, II, III, and IV. The transfer of the type I operation performed by L. L. Taylor for the Parry-Romberg atrophy.

carpi radialis into the extensor pollicis longus and brevis and the flexor carpi ulnaris into all the extensor tendons of the fingers. They reported uniformly good results in their cases.

In most of the cases reported by Zachary, the pronator teres was transplanted into the extensor carpi radialis longus, the flexor carpi ulnaris into the extensor tendons of the third, fourth, and fifth fingers, and the flexor carpi radialis into the extensor pollicis longus and extensor indicis proprius. In a careful analysis of these cases, he brought out a very im-

portant point, with which the writer was able to concur. He noted that if all the flexors of the wrist, flexor carpi ulnaris, flexor carpi radialis and palmaris longus, were transferred, stabilization of the wrist was lost in many instances and often led to incomplete extension of fingers and unnecessary weakening or abolishment of voluntary power of wrist flexion.

REPORT OF PERSONAL CASES

Various methods of tendon transplants were used in this series and careful after studies

elbow and the extremity washed thoroughly with soap and water. After 10 minutes of good washing with frequent changes of water, alcohol and ether are poured over the part and sterile towels are then placed around the arm from the finger tips to the elbow.

The day of surgery when the patient is on the operating table the extremity is again washed with soap and water then drenched with alcohol and ether. A sterile towel is now placed over the field and the arm elevated. All of the blood is squeezed out of the arm by the use of a Martin constrictor to the upper arm where a blood pressure cuff is pumped up to 300 millimeters of mercury to insure hemostasis. The Martin constrictor is then removed. This leaves a bloodless extremity to be worked upon, gives excellent visibility, is a great time saver and avoids the unnecessary trauma to exposed tendons and their sheaths from repeated sponging.

The field is now prepared with one of the standard operating room antiseptics.

The insertions of the palmaris longus, flexor carpi radialis and flexor carpi ulnaris are easily identified by extension of the wrist. Short longitudinal incisions are made the tendon isolated and then cut free. By pulling gently on the cut tendon, its proximal portion can be palpated in the forearm, 6 to 8 inches proximally, and then through individual short longitudinal incisions each tendon is exposed. The tendon is then drawn from the distal end proximally so that it is freed through the proximal incision. The flexor carpi ulnaris has a very low attachment of muscle fibers frequently down to the last one-half inch of the tendon. The muscle should be sufficiently removed so that about 3 inches of the tendon is free of muscle in order to permit better suture into the recipient tendons and also to provide for better gliding between the subcutaneous fat on one side and the fascia of the arm on the other side.

The hand and forearm are then pronated and the extensor pollicis longus tendon isolated in the "anatomical snuff box." It is completely severed at the level of the distal end of the radius. It is most important that this tendon be accurately identified before it is severed. Retraction of the proper tendon

Fig. 2. The buttonhole technique for the suture of the palmaris longus to the extensor pollicis longus was most satisfactory in the author's experience. Step 1: a slit is made in the extensor pollicis longus just distal to the cut end, and the palmaris longus tendon is drawn through the slit. Step 2, four silk sutures are then used to hold the tendons together. This type of anastomosis is simple, effective, and rapidly performed.

produces extension of the terminal phalanx of the thumb.

A well known principle of tendon transplantation must be kept in mind at this stage of the procedure. A transplanted tendon and muscle will work most efficiently if its action is in a straight line running from the origin of the motor muscle to the insertion of the recipient tendon. Any sharp curves or angulations decrease or completely defeat the transplanted motorized unit. For this reason the author has always attempted to attach the transplanted tendons as far distally as possible. This by necessity required the exposure of the common extensor tendons at the level of the dorsal carpal ligament. This overlying portion of the ligament was routinely removed, so that the anastomosis of the tendons was given the smooth gliding anterior portion of the ligament on the anterior aspect and the abundant subcutaneous fat on the posterior aspect. On no occasion were any adhesions detected in this area nor was there ever seen any posterior or mediolateral displacement of the extensor communis tendons. A number of men have recommended that the tendon anastomosis always be done proximal to the dorsal carpal ligament. This procedure angulates the transplanted tendon and thereby decreases its mechanical efficiency. All of the transplanted tendons are tunneled between the fascia of the forearm on one side and the

sufficient only for extending the digits, as 4 to 5 kgm. of power were required to extend the wrist as well as the digits.)

3. It is most important that the transplanted tendons run in as straight a line as possible from the origin of the muscle to the insertion of the recipient tendon. Acute angles or long sweeping curves of the transplanted tendons decrease their efficiency.

4. The complete severance of the extensor pollicis longus tendon in the 'anatomical snuff box' and the swinging of the loose end anteriorly then suturing it to the transferred palmaris longus tendon gives a most excellent combined extensor and abductor motion to the thumb. In fact it is almost impossible to distinguish the result from the normal thumb function. This observation was accidentally discovered in 1 case as a result of severance of the palmaris longus tendon a little too proximal to its insertion so that it was relatively short and could not reach the extensor pollicis longus tendon in its normal location.

5. Although the transplantation of the flexor carpi radialis into the extensor pollicis longus and extensor indicis proprius, and the flexor carpi ulnaris to the extensor tendons of the third, fourth and fifth fingers gives a wide opening of the thumb and fingers in the extended position, it weakens and in some cases abolishes voluntary flexion of the wrist if the palmaris longus tendon is absent. When the palmaris longus tendon is present (absent in 3 of the 45 cases) it motionizes the thumb very well if sutured to the severed extensor pollicis longus tendon as described previously.

6. All of the tendon transferences done in this series produced marked improvement of the function of the hand regardless of what minor detail of tendon to tendon transference was performed. Only 1 case was considered as a complete failure. Whether or not it was a surgical or psychosomatic failure will probably never be definitely known. This was the case of an officer who did not desire to be separated from the Service until the September semester of college began the following year. He was operated upon July 19 1945. It was impossible to get his co-operation in physiotherapy and occupational therapy postoperatively. A second operation was performed on January 31 1946 for a second tendon transference. By that time such marked fibrosis had resulted in the fingers that the case was ultimately classed as a failure.

PREOPERATIVE CARE

Unless the wrist, fingers, and thumb have free joint motion, the surgeon is handicapped before he starts. It is most important that the hand receive intensive physical therapy in the form of whirlpool baths, heat, and massage until all the joints are freely movable, and the skin soft and pliable. If adhesions of the joints exist prior to surgery it will be almost impossible to correct the joint limitation after surgery. None of the patients in this series were operated upon until the fist could be firmly made actively and full extension of the fingers and thumb was possible, passively.

OPERATIVE TECHNIQUE

The day prior to surgery the finger nails are cut short, the hand and arm shaved up to the

Fig. 3. A, Shows the buttonholing of each extensor tendon at an angle of 45 degrees so that the tendon to the little finger has the most proximal buttonhole and the extensor tendon to the index finger has the most distal slit. B, The flexor carpi ulnaris tendon is slit longitudinally, and half of the tendon is threaded through the buttonhole slits and sutured in place. C, The transverse carpal ligament is completely excised, and the remaining half of the flexor carpi ulnaris tendon is sutured over the top of the tendons. This gives excellent security of the suture line.

POSTOPERATIVE CARE

The postoperative care of these patients is most important. Immobilization in plaster for 16 to 18 days postoperatively is necessary in order to insure good healing of the tendons and also to prevent excessive formation of scar tissue. Earlier immobilization of the tendons produces more adhesions and scar tissue. This was shown experimentally by Mason and Allen.

A cast is used extending from the proximal interphalangeal joint to the elbow with the wrist in the cock up position and the thumb in the mid abduction extension position.

At the end of 16 to 18 days physical therapy is begun. This consists of muscle re-education, whirlpool baths, heat, and gentle massage. The importance of daily physical therapy by a competent therapist cannot be over emphasized. The individual gains confidence easily, muscle re-education becomes simplified, normal interphalangeal and metacarpophalangeal motion is maintained, and a shorter convalescence results.

At the end of 4 weeks from the date of operation, occupational therapy should be instituted. Graduated types of work from the sim-

subcutaneous fat on the more exterior side. This gives an excellent gliding mechanism.

In 20 cases of this series the flexor carpi ulnaris was sutured to all of the common extensor tendons. It was found to be an efficient motorized unit provided that a few points were carefully adhered to.

The flexor carpi ulnaris tendon works best if the anastomosis to the common extensor tendons of the fingers is done so the tendon to the little finger is sutured approximately $\frac{3}{4}$ inch proximal to the suture of the tendon to the index finger. In this fashion the same amount of extension tension could be placed on all of the extensor tendons. The ring and middle finger tendons are anastomosed between the index and little finger tendons so that they maintain the same angle of suturing (the middle finger tendon being sutured $\frac{3}{4}$ inch distal to the level where the ring finger was being sutured (Fig. 2)).

The amount of tension necessary for adequate function is very difficult to determine. Experience is the best teacher. If too much tension is used the wrist cannot be adequately flexed. If not enough tension is used dorsiflexion of the wrist is inadequate.

In none of the cases treated in this series was any ulnar deviation of the wrist noted when extension was initiated by the flexor carpi ulnaris muscle.

When the flexor carpi radialis is used it is drawn subcutaneously around the radius and inserted into the desired thumb or index tendon. The same principles apply to this tendon as to the flexor carpi ulnaris.

After it was once discovered that if the extensor pollicis longus tendon was severed at the 'anatomical snuff box' and drawn anteriorly and anastomosed to the palmaris longus giving an excellent combined thumb function of extension and abduction the procedure alone was used for the rehabilitation of the thumb. In 3 cases of this series the palmaris longus was absent and then the flexor carpi radialis was used.

At the completion of this anastomosis, the line of action must be straight from the origin of the palmaris longus muscle to the insertion of the extensor pollicis longus tendon into the terminal phalanx of the thumb.

It was the author's experience that combined anastomosis into the extensor pollicis longus or brevis, and abductor pollicis longus or any combination of anastomosis of these tendons to a single motorized transplanted unit, decreased the efficiency of the unit considerably. Combined pulls of two or more tendons on the thumb do not work as efficiently because each tendon has a slightly different line of pull and besides has a different amplitude of movement to produce a desired motion of a digit. This point has been well brought out by Bunnell.

Various methods of anastomosis of the tendons were tried. The anastomosis giving the maximum holding power with the fewest number of stitches is by necessity the one desired. The final type of standardized anastomosis used in this series is as follows:

In anastomosing the palmaris longus tendon into the severed extensor pollicis longus tendon the buttonhole technique is used. A small slit is made through the extensor pollicis longus tendon near its severed end, and the palmaris longus tendon is drawn through this opening. The tendons are then sutured to one another by two sutures at the end of each tendon making a side-to-side anastomosis (Fig. 2).

When the anastomosis is made for the flexor carpi ulnaris or radialis, the recipient tendons are buttonholed at the desired level for the anastomosis and a straight Kelly forceps is inserted through all the buttonholes. The motorized tendon is then slit longitudinally and half of it is drawn through the recipient tendons with the forceps. Two interrupted silk sutures are used to fix each tendon. The other half of the slit motorized tendon is then laid over its other half and sutured in place with only two silk sutures at the proximal and distal end of the anastomosis. This gives an excellent mechanical anastomosis with a minimal number of stitches. On one occasion it was necessary to reopen this type of anastomosis in order to put more tension on the motorized tendon. The inspection of the anastomosis showed no excessive scar tissue production, and the anastomosis was covered with what appeared to be a normal tendon sheath (Fig. 3).

Fig 3. A, Shows the buttonholing of each extensor tendon at an angle of 45 degrees so that the tendon to the little finger has the most proximal buttonhole and the extensor tendon to the index finger has the most distal slit. B, The flexor carpi ulnaris tendon is slit longitudinally, and half of the tendon is threaded through the buttonhole slits and sutured in place. C, The transverse carpal ligament is completely excised, and the remaining half of the flexor carpi ulnaris tendon is sutured over the top of the tendons. This gives excellent security of the suture line.

POSTOPERATIVE CARE

The postoperative care of these patients is most important. Immobilization in plaster for 16 to 18 days postoperatively is necessary in order to insure good healing of the tendons and also to prevent excessive formation of scar tissue. Earlier immobilization of the tendons produces more adhesions and scar tissue. This was shown experimentally by Mason and Allen.

A cast is used extending from the proximal interphalangeal joint to the elbow with the wrist in the cock up position and the thumb in the mid abduction extension position.

At the end of 16 to 18 days physical therapy is begun. This consists of muscle re-education, whirlpool baths, heat, and gentle massage. The importance of daily physical therapy by a competent therapist cannot be over emphasized. The individual gains confidence easily; muscle re-education becomes simplified; normal interphalangeal and metacarpophalangeal motion is maintained, and a shorter convalescence results.

At the end of 4 weeks from the date of operation, occupational therapy should be instituted. Graduated types of work from the sim-

ple to the complicated and from the light to the heavy should be carried out. By the aid of a good occupational therapist the muscular hypertrophy and the co-ordination of the wrist fingers and thumb improves. Usually if the patient is co-operative a relatively good hand results in about 3 to 4 months from the date of surgery (Figs. 4, 5, 6). In most cases improvement reaches its peak within a period of approximately 9 months. In a few cases which were performed prior to World War II in civilian practice and which were observed for a few years thereafter the improvement was very little if any after the initial 9 months period.

CONCLUSIONS

1 The transplantation of the palmaris longus tendon into the severed extensor pollicis longus tendon gives an excellent result of abduction-extension power to the thumb. It is most important that the pull of the palmaris longus be in a straight line from the origin of the palmaris longus to the insertion of the extensor pollicis longus tendon into the terminal phalanx of the thumb.

2 The transference of the flexor carpi ulnaris into the extensor tendons of the second, third, fourth and fifth fingers gives good finger and wrist extension. The flexor carpi ulnaris must be sutured at a 45 degree angle to the long axis of the extensor tendons, so that the anastomosis to the extensor tendon of the second finger is about $\frac{3}{4}$ to 1 inch distal to the anastomosis to the extensor tendon of the fifth finger.

The use of the flexor carpi radialis into one of the thumb tendons and the extensor tendon of the index finger is not advocated unless there is an absence of the palmaris longus tendon. Its transference in addition to the flexor carpi ulnaris and the palmaris longus tendons weakens or abolishes voluntary wrist flexion, weakens the stabilization of the wrist so that complete extension of the fingers is difficult, prolongs the operative procedure and adds an unnecessary additional operative risk.

3 The transplanted tendon must exert its pull in as straight a line as possible from the origin of the muscle to the insertion of the recipient tendon. Sharp angles or curves decrease the efficiency of the motorized unit.

4 The transplantation of a single tendon into the extensor pollicis longus is far more efficient than transplantation of a single tendon into two or more thumb or thumb and index finger tendons. Variation of amplitude of each tendon to perform its normal function and the difference of the line of pull correspondingly decrease the efficiency of the unit.

5 Preoperative physical therapy must be carried out until complete range of motion is possible in the interphalangeal and metacarpophalangeal joints of the thumb and fingers. The flexion motion can be performed actively while the extension motions of the fingers and the abduction-extension movements of the

thumb can of course be performed only passively

Transplanted tendons are unable to overcome the restricted movements which are the result of perarticular adhesions of the joints Time spent in preoperative physical therapy pays the greatest dividends and enhances the chances for success in this procedure

6 Postoperative physical therapy and later occupational therapy of increased gradation of amplitude and stress shorten the convalescence Muscle hypertrophy is quicker coordination of fingers and thumb motions are learned in less time and the morale of the patient is kept at its highest level

RUPTURED UTERUS

A Report of 42 Cases

J. E. FITZGERALD, M.D. and AUGUSTA WEBSTER, M.D. F.A.C.S., Chicago, Illinois, and
J. E. FIELDS, M.D. Joliet, Illinois

DURING the 20 years from 1928 to 1947 inclusive there were 42 instances of ruptured uteri at the Cook County Hospital. In this same period 92,226 women were delivered of viable infants. Although rupture of the uterus is rare, it carries an exceedingly high mortality for both mother and baby and therefore the subject seems worthy of review.

In the present series there were 23 maternal deaths or a maternal mortality of 54.76 per cent. The fetal mortality was 79.07 per cent—28 stillborn infants, 1 neonatal death and 5 infants who died in utero undelivered. Nine infants lived a fetal saving of only 20.93 per cent.

In 16 cases the uterus ruptured before the women were brought to the hospital and in 26 instances the rupture occurred in the Cook County Hospital. Twenty-two of the mothers were white and 20 were negro.

Table I shows the distribution as to ages. It will be noted that the largest number of cases was in the age group of 36 to 40 years, inclusive and the next largest in the 21 to 25 year age group.

Thirty-eight ruptures were in multiparous and 4 ruptures were in nulliparous women (Table II).

The individual circumstances vary so much as to etiology, symptoms, degree of shock, diagnosis, and treatment that it is almost impossible to make graphs of any value. We are therefore stating briefly the salient facts in each case. An effort has been made to group the abstracts as to etiology.

In 9 cases rupture occurred following previous cesarean section. In the first 7 reported rupture occurred after previous classical sec-

tions and in Cases 8 and 9 after low cervical sections. (In patients 6 and 8 the original sections were performed at the Cook County Hospital.)

CASE 1 (1933) White secundipara, tertigravida, aged 31 years, at term, cephalic presentation. Bag of waters was intact. The patient had been in labor for 11 hours progressing normally to 7 centimeters and station plus 2 when she suddenly grabbed her abdomen and cried out "I'm tearing." Profound shock ensued. Supravaginal hysterectomy was immediately performed and a transfusion of 1,000 cubic centimeters of blood given. She died of peritonitis on the 11th day after operation. The infant was stillborn.

CASE 2 (1933) White secundipara, tertigravida, aged 32 years, 38 weeks gestation, cephalic presentation. The patient was admitted in mild shock, not in labor. Bag of waters was intact. She had sudden severe constant abdominal pain with marked tenderness over scar and easily palpable fetal parts. Blood transfusion was followed by prompt hysterectomy. Recovery was uneventful. She returned home on the 16th day after operation. The infant was stillborn.

CASE 3 (1940) White primipara, secundigravida, aged 9 years, 38 weeks gestation, cephalic presen-

From the Department of Obstetrics, Cook County Hospital, and the Department of Obstetrics and Gynecology, Northwestern University Medical School.

tation. The patient was admitted in early labor and mild shock. Bag of waters was intact. She had marked tenderness over the old scar and fetal parts were easily palpable. Supracervical hysterectomy was performed and a transfusion of 1000 cubic centimeters of blood was given in the operating room. The patient recovered after a stormy postoperative course. The infant was stillborn at 8½ months.

CASE 4 (1941) Colored primipara secundigravida, aged 21 years 38 weeks gestation cephalic presentation. The patient was admitted in severe shock, not in labor. Bag of waters was intact. During routine visit to prenatal clinic, she had suddenly developed acute pain over an old incision and was hospitalized at once. The infant was removed from the uterine cavity and hysterectomy performed. The patient recovered. The infant lived.

CASE 5 (1946) Colored primipara tertigravida aged 32 years at term cephalic presentation. The patient entered the hospital in good condition in mild labor for 3 hours. Bag of waters was intact. There were no symptoms of rupture but tear was discovered during laparotomy. Porro section was performed for rupture in upper uterine segment. Penicillin and blood were given postoperatively. The patient recovered and was discharged from the hospital on the 12th day after operation. The infant lived.

CASE 6 (1944) Colored tertipara, quadrigravida aged 30 years 30 weeks gestation. The patient was admitted in severe shock with cramps and pains of 7½ hours duration. She had believed herself to have indigestion for which she had taken castor oil. Sudden sharp abdominal pain followed (Fig 1). Immediate hysterectomy was performed and blood and plasma transfusions were given. The patient recovered and returned home on the 17th day after operation. The infant was stillborn.

CASE 7 (1928) White primipara, secundigravida aged 21 years 34 weeks gestation. The patient was admitted in good condition in early labor with a history of previous classical section for generally contracted pelvis. Bag of waters intact. Dilatation was 2 centimeters station minus 4. Preparations were completed for a repeat section but the patient refused surgery. The uterus ruptured 8½ hours after admission. Laparotomy was carried out immediately after rupture with the patient in poor condition. The patient died during surgery. Baby and placenta were in the peritoneal cavity there was a 15 centimeter separation of the fundus with smooth edges. The infant was stillborn.

CASE 8 (1934) Colored primipara, secundigravida aged 16 years at term breech presentation. The patient was admitted in mild labor with fetal heart tones present until bag of waters ruptured. Labor pains ceased and were replaced by a steady, not severe pain which increased in severity in the lower abdomen near the old scar. As soon as the pain became severe laparotomy was done and hysterectomy performed. The patient recovered and returned

Fig. 1. Case 6. Tear at site of old section scar. Note smooth edges.

home on the 12th day after operation. The infant was stillborn.

CASE 9 (1942) Colored quadripara quintigravida, aged 22 years, at term cephalic presentation. The patient was admitted in mild labor, bag of waters was intact, fetal heart tones were present. There were no symptoms of rupture. During repeat cesarean section a 2½ centimeter tear in the lower uterine segment was found with the bag of waters bulging through. The section was completed, the uterus resutured and the patient sterilized. The patient recovered. The infant lived.

Of these patients who had undergone previous cesarean section 6 were in labor and 3 were not upon admission. Two of the patients had such mild symptoms that the rupture of the old scar was not suspected (Cases 5 and 9) but was discovered at the operating table at the time of repeat section.

Six uteri ruptured with transverse presentation.

CASE 10 (1930) White quadripara quintigravida, aged 38 years. The patient was admitted with the bag of waters ruptured and hand and cord prolapsed. The duration of labor was unknown, fetal heart tones were absent. Delivery was accomplished by decapitation; the fetal trunk was removed and the head

From the Department of Obstetrics, Cook County Hospital, and the Department of Obstetrics and Gynecology, Northwestern University Medical School.

tation. The patient was admitted in early labor and mild shock. Bag of waters was intact. She had marked tenderness over the old scar and fetal parts were easily palpable. Supracervical hysterectomy was performed and a transfusion of 1000 cubic centimeters of blood was given in the operating room. The patient recovered after a stormy post-operative course. The infant was stillborn at 8½ months.

CASE 4 (1941) Colored primipara, secundigravida, aged 21 years, 38 weeks gestation, cephalic presentation. The patient was admitted in severe shock, not in labor. Bag of waters was intact. During routine visit to prenatal clinic, she had suddenly developed acute pain over an old incision and was hospitalized at once. The infant was removed from the uterine cavity and hysterectomy performed. The patient recovered. The infant lived.

CASE 5 (1946) Colored primipara, tertigravida, aged 32 years at term, cephalic presentation. The patient entered the hospital in good condition in mild labor for 3 hours. Bag of waters was intact. There were no symptoms of rupture but tear was discovered during laparotomy. Porro section was performed for rupture in upper uterine segment. Penicillin and blood were given postoperatively. The patient recovered and was discharged from the hospital on the 12th day after operation. The infant lived.

CASE 6 (1944) Colored tertipara, quadrigravida, aged 30 years, 30 weeks gestation. The patient was admitted in severe shock with cramps and pains of 7½ hours duration. She had believed herself to have indigestion for which she had taken castor oil. Sudden sharp abdominal pain followed (Fig. 1). Immediate hysterectomy was performed, and blood and plasma transfusions were given. The patient recovered and returned home on the 17th day after operation. The infant was stillborn.

CASE 7 (1938) White primipara, secundigravida, aged 21 years, 34 weeks gestation. The patient was admitted in good condition in early labor with a history of previous classical section for generally contracted pelvis. Bag of waters intact. Dilatation was 2 centimeters station minus 4. Preparations were completed for a repeat section but the patient refused surgery. The uterus ruptured 8½ hours after admission. Laparotomy was carried out immediately after rupture with the patient in poor condition. The patient died during surgery. Baby and placenta were in the peritoneal cavity; there was a 15 centimeter separation of the fundus with smooth edges. The infant was stillborn.

CASE 8 (1934) Colored primipara, secundigravida, aged 16 years, at term breech presentation. The patient was admitted in mild labor with fetal heart tones present until bag of waters ruptured. Labor pains ceased and were replaced by a steady, not severe pain which increased in severity in the lower abdomen near the old scar. As soon as the pain became severe laparotomy was done and hysterectomy performed. The patient recovered and returned

Fig. 1. Case 6. Tear at site of old section scar. Note smooth edges.

home on the 12th day after operation. The infant was stillborn.

CASE 9 (1949) Colored quadripara, quintigravida, aged 22 years at term, cephalic presentation. The patient was admitted in mild labor; bag of waters was intact; fetal heart tones were present. There were no symptoms of rupture. During repeat cesarean section a 2½ centimeter tear in the lower uterine segment was found with the bag of waters bulging through. The section was completed, the uterus resutured, and the patient sterilized. The patient recovered. The infant lived.

Of these patients who had undergone previous cesarean section, 6 were in labor and 3 were not upon admission. Two of the patients had such mild symptoms that the rupture of the old scar was not suspected (Cases 5 and 9) but was discovered at the operating table at the time of repeat section.

Six uteri ruptured with transverse presentation.

CASE 10 (1930) White quadripara, quintigravida, aged 38 years. The patient was admitted with the bag of waters ruptured and hand and cord prolapsed. The duration of labor was unknown; fetal heart tones were absent. Delivery was accomplished by decapitation; the fetal trunk was removed and the head

RUPTURED UTERUS

A Report of 42 Cases

J. E. FITZGERALD, M.D. and AUGUSTA WEBSTER, M.D., F.A.C.S. Chicago, Illinois, and
J. E. FIELDS, M.D. Joliet, Illinois

DURING the 20 years from 1928 to 1947 inclusive there were 42 instances of ruptured uteri at the Cook County Hospital. In this same period 92,226 women were delivered of viable infants. Although rupture of the uterus is rare it carries an exceedingly high mortality for both mother and baby and therefore the subject seems worthy of review.

In the present series there were 23 maternal deaths or a maternal mortality of 54.76 per cent. The fetal mortality was 79.07 per cent—28 stillborn infants, 1 neonatal death and 5 infants who died in utero undelivered. Nine infants lived, a fetal saving of only 20.93 per cent.

In 16 cases the uterus ruptured before the women were brought to the hospital and in 26 instances the rupture occurred in the Cook County Hospital. Twenty-two of the mothers were white and 20 were negro.

Table I shows the distribution as to ages. It will be noted that the largest number of cases was in the age group of 36 to 40 years, inclusive and the next largest in the 21 to 25 year age group.

Thirty-eight ruptures were in multiparous and 4 ruptures were in nulliparous women (Table II).

The individual circumstances vary so much as to etiology, symptoms, degree of shock, diagnosis and treatment that it is almost impossible to make graphs of any value. We are therefore, stating briefly the salient facts in each case. An effort has been made to group the abstracts as to etiology.

In 9 cases rupture occurred following previous cesarean section. In the first 7 reported rupture occurred after previous classical sec-

tions and in Cases 8 and 9 after low cervical sections. (In patients 6 and 8 the original sections were performed at the Cook County Hospital).

CASE 1 (1933) White secundipara tertigravida, aged 2 years at term cephalic presentation. Bag of waters was intact. The patient had been in labor for 1 hour, progressing normally to 7 centimeters and station plus 2 when she suddenly grabbed her abdomen and cried out. In tearing. Profound shock ensued. Supravaginal hysterectomy was immediately performed and a transfusion of 1,000 cubic centimeters of blood given. She died of peritonitis on the 11th day after operation. The infant was stillborn.

CASE 2 (1933) White secundipara tertigravida, aged 31 years, 38 weeks gestation cephalic presentation. The patient was admitted in mild shock, not in labor. Bag of waters was intact. She had sudden severe constant abdominal pain with marked tenderness over scar and easily palpable fetal parts. Blood transfusion was followed by prompt hysterectomy. Recovery was uneventful. She returned home on the 16th day after operation. The infant was stillborn.

CASE 3 (1940) White primipara secundigravida, aged 19 years, 38 weeks gestation cephalic presen-

From the Department of Obstetrics, Cook County Hospital, and the Department of Obstetrics and Gynecology, Northwestern University Medical School.

CASE 17 (1933) White decipara duodecigravida, aged 33 years cephalic presentation. The patient was admitted with the cord prolapsed and having been in labor for 7 hours. Fetal heart tones were absent. Delivery was accomplished 8 hours later by version and extraction when dilatation was complete. Rupture of the lower uterine segment was found. Immediate hysterectomy was performed followed by blood transfusion. The patient died of peritonitis on the 10th day after operation. The infant was still born.

CASE 18 (1928) White septipara octigravida, aged 38 years. The patient was admitted in hard labor pains 2 to 3 minutes apart. Fetal heart tones were present but disappeared during labor. Twelve hours later the cervix was completely dilated station minus 1. Attempted delivery with Kielland forceps failed; version and extraction followed. Exploration revealed a tear in the right lower uterine segment. Immediate hysterectomy was performed. The mother died of bronchopneumonia $3\frac{1}{2}$ days after operation. The infant was stillborn.

Ironically Case 16 was mishandled according to good obstetric practice but the mother survived. In the presence of bleeding from what was thought to be a placenta previa the cervix was *manually dilated* and version and extraction were performed. This procedure is to be condemned. In Case 17 the cervix was completely dilated when the version was performed but the patient died of peritonitis on the tenth postoperative day. Craniotomy was the procedure of choice in this latter instance since the baby was known to be dead with the cord prolapsed for 8 hours. In Case 18 a craniotomy was also preferable to version since the baby was known to be dead and for ceps delivery had failed. There is no excuse for jeopardizing the life of the mother when it is known that the baby is dead.

There were 4 cases in which oxytocics seem to have been the cause of rupture. 1 patient was given ergot and 3 patients were given pituitrin all before admission to the Cook County Hospital.

CASE 19 (1929) White nonipara decigravida aged 38 years cephalic presentation, floating. The patient was admitted after having been in labor at home for 4 days. She had been attended by a midwife who gave her "black medicine." On admission the patient had no pains, fetal heart tones were absent. Sterile vaginal examination revealed a cervical tear extending beyond the reach of the examining hand. Immediate hysterectomy was performed. The patient died of hemorrhagic purulent peritonitis on the 5th day after operation. The infant was stillborn.

CASE 20 (1938) White sextipara nonigravida aged 36 years face presentation. The patient was admitted in shock after having been in labor at home for 36 hours. Fetal heart tones were absent. On the afternoon of admission her physician had called and given her $\frac{1}{4}$ cubic centimeter of pituitrin following which she had had violent pains which stopped suddenly. Delivery was effected by version and extraction followed by blood transfusion. The patient died 2 hours and 50 minutes after admission before surgery could be performed. The infant weighing 11 pounds 7 ounces was stillborn.

CASE 21 (1939) Colored tertipara (one set of twins) tertigravida aged 34 years. The patient was admitted with head and shoulders delivered after labor of $3\frac{1}{2}$ hours at home. Her physician had administered 1 ampul of pituitrin and was unable to deliver the other shoulder. En route to the hospital the other shoulder delivered spontaneously. The patient went into shock 25 minutes after delivery was completed in the hospital. Two blood transfusions were given for shock but she did not respond. She died 2 hours and 15 minutes following rupture of lower uterine segment. The infant weighing 12 pounds 6 1/2 ounces was stillborn.

CASE 22 (1940) White sextipara, septigravida, aged 38 years. The patient was admitted in severe shock after having been in labor at home for 27 hours. Her physician stated that dilatation had been complete for 8 hours; he had given her pituitrin 2 minims twice. Four hours after the second dose the patient had had sharp pain causing her to double up. Laparotomy was carried out immediately and blood transfusions were given for shock. She survived this surgery and on the 28th day after operation returned home with a vesicovaginal fistula. She died of ascending infection 6 months later following a genitourinary operation when ureteral transplants were made into the sigmoid. The infant was stillborn.

In the ruptures attributed to oxytocics all 4 mothers and 4 babies lost their lives. In Case 20 the management of the patient after she arrived in the hospital in shock is to be criticized. The history of violent pains following the administration of $\frac{1}{4}$ cubic centimeter of pituitrin and then of sudden cessation of the pains makes the diagnosis of ruptured uterus obvious. A version and extraction procedure was contraindicated. Treatment of the shock and immediate laparotomy was the procedure of choice. What small chance the woman had to survive was destroyed by the additional trauma of the version and the failure to operate upon her promptly.

There are 6 cases which can be classified as more or less prolonged labors and probably disproportions.

extracted with a tenaculum without difficulty. A vaginal examination revealed laceration of the right broad ligament. There was no bleeding and no packing was inserted. The patient was not operated upon. She died 3 days postpartum of serofibrinous peritonitis. The infant was stillborn.

CASE 11 (1932) White quintipara, sextigravida, aged 31 years. The patient was admitted with the bag of waters ruptured and hand prolapsed. The duration of labor was unknown but a private physician had attempted version and extraction in the home. The cervix was completely dilated on admission and fetal heart tones were absent. Decapitation was done, placenta was not expelled, and exploration revealed that it was not in the uterus. Immediate laparotomy was performed for complete laceration extending from the cervix to within 2 centimeters of the fundus. The patient died of peritonitis on the 7th day after operation. The infant was stillborn.

CASE 12 (1933) White quintipara, septigravida, aged 24 years. The patient was admitted with the bag of waters ruptured and hand prolapsed. Fetal heart tones were absent. She had been in labor for 7 hours. Delivery was effected by version and extraction following which she immediately went into shock. Immediate hysterectomy was carried out. She recovered and returned home on the 5th day after operation. The infant lived.

CASE 13 (1940) White quintipara, sextigravida, aged 30 years. The patient was admitted after having been in labor for 10 hours 5 minutes. Fetal heart tones were absent, bag of waters was ruptured. There was slight vaginal bleeding, the head was high on the right, the detached placenta was felt on the left and a tear was felt in the uterine wall. The abdominal aorta was compressed by the examining hand until hysterectomy was performed. The patient made an uneventful recovery and returned home on the 13th day after operation. The infant was stillborn.

CASE 14 (1943) White secundipara, tertigravida, aged 33 years, transverse presentation. The patient was admitted after having been in labor for 3 hours. The bag of waters was intact. She had had a vaginal plastic and Sturmdorf operation 4 years before. The patient was in the operating room being anesthetized for cesarean section when the cord and arm prolapsed. Version and extraction were carried out through the completely dilated cervix. Immediate total hysterectomy was performed, the tear in the posterior vaginal wall was sutured, 1500 cubic centimeters of blood and 500 cubic centimeters of plasma were administered. The patient died 30 hours after operation. The infant died.

CASE 15 (1928) White tertipara, quadrigavida, aged 36 years. The patient was admitted with a history of marked respiratory distress and of cyanosis for 2 days. The bag of waters was ruptured, fetal heart tones were questionable. She was in labor for 24 hours with severe pains. When the pains ceased sudden "cardiac decompensation" followed. Morphine sulfate, trophine and digitalis were ad-

ministered. Twelve hours after admission the patient was losing ground. The cervix was 8 centimeters dilated, the hand prolapsed, a version and extraction was done without difficulty. The patient died immediately following delivery, there was a tear in the right fundus. The stillborn infant weighed 10 pounds 2 ounces.

Two of the women with transverse presentations and known dead babies were delivered by decapitation: 1 was delivered by cesarean section and 3 by version and extraction. All were in labor when they arrived at the hospital. There were 4 stillbirths, 1 neonatal death and 4 mothers were lost. In Case 11 version had been attempted by a physician in the home; this patient died of peritonitis on the seventh postoperative day. In Case 14 a previous vaginal plastic operation had been performed and a cesarean section was planned. While the patient was being anesthetized for surgery a cord and arm prolapsed. A vaginal examination revealed complete dilatation and a version and extraction procedure was done, resulting in a tear in the lower uterine segment. In spite of immediate surgery and the administration of 1500 cubic centimeters of blood and 500 cubic centimeters of plasma, the patient died of shock postoperatively. In Case 15 apparently rupture had occurred at home and the subsequent shock was erroneously interpreted as cardiac decompensation. Had her true condition been recognized on admission to the hospital she might have been saved with blood transfusions and prompt surgery.

There were 3 other cases of version and extraction: Cases 16, 17 and 18, which with Cases 12, 13 and 14, total 6 cases of ruptured uterus attributable to version and extraction.

CASE 16 (1929) White quintipara, sextigravida, aged 37 years, cephalic presentation, station minus 3. The patient was admitted after having been in labor 1 hour for 30 hours and attended by a physician. The bag of waters had ruptured 16 hours previously. She had had 9 pains for 1 hour before admission. Fetal heart tones were absent, there was moderate bleeding from the placenta previa. The cervix was dilated manually. Version and extraction were carried out with forceps on the aftercoming head. The patient went into shock. Sterile vaginal examination revealed a tear. Surgery was not done. The patient recovered and returned home on the 16th postpartum day. The stillborn infant weighed 8 pounds 8 ounces.

CASE 17 (1933) White decipara duodecigravida, aged 33 years cephalic presentation. The patient was admitted with the cord prolapsed and having been in labor for 7 hours. Fetal heart tones were absent. Delivery was accomplished 8 hours later by version and extraction when dilatation was complete. Rupture of the lower uterine segment was found. Immediate hysterectomy was performed followed by blood transfusion. The patient died of peritonitis on the 10th day after operation. The infant was still born.

CASE 18 (1928) White septipara, octigravida, aged 38 years. The patient was admitted in hard labor pains 2 to 3 minutes apart. Fetal heart tones were present but disappeared during labor. Twelve hours later the cervix was completely dilated station minus 1. Attempted delivery with Kielland forceps failed. Version and extraction followed. Exploration revealed a tear in the right lower uterine segment. Immediate hysterectomy was performed. The mother died of bronchopneumonia 3½ days after operation. The infant was stillborn.

Ironically Case 16 was mishandled according to good obstetric practice but the mother survived. In the presence of bleeding from what was thought to be a placenta previa the cervix was manually dilated and version and extraction were performed. This procedure is to be condemned. In Case 17 the cervix was completely dilated when the version was performed but the patient died of peritonitis on the tenth postoperative day. Craniotomy was the procedure of choice in this latter instance since the baby was known to be dead with the cord prolapsed for 8 hours. In Case 18 a craniotomy was also preferable to version since the baby was known to be dead and forceps delivery had failed. There is no excuse for jeopardizing the life of the mother when it is known that the baby is dead.

There were 4 cases in which oxytocics seem to have been the cause of rupture. 1 patient was given ergot and 3 patients were given pituitrin all before admission to the Cook County Hospital.

CASE 19 (1929) White nonipara decigravida aged 38 years cephalic presentation floating. The patient was admitted after having been in labor at home for 4 days. She had been attended by a midwife who gave her "black medicine." On admission the patient had no pains fetal heart tones were absent. Sterile vaginal examination revealed a cervical tear extending beyond the reach of the examining hand. Immediate hysterectomy was performed. The patient died of hemorrhagic purulent peritonitis on the 5th day after operation. The infant was stillborn.

CASE 20 (1938) White sextipara, nonigravida, aged 36 years face presentation. The patient was admitted in shock after having been in labor at home for 36 hours. Fetal heart tones were absent. On the afternoon of admission her physician had called and given her 4 cubic centimeter of pituitrin following which she had had violent pains which stopped suddenly. Delivery was effected by version and extraction followed by blood transfusion. The patient died 2 hours and 50 minutes after admission before surgery could be performed. The infant weighing 11 pounds 7 ounces was stillborn.

CASE 21 (1939) Colored tertipara (one set of twins) tertigravida, aged 34 years. The patient was admitted with head and shoulders delivered after labor of 3½ hours at home. Her physician had administered 1 ampul of pituitrin and was unable to deliver the other shoulder. En route to the hospital the other shoulder delivered spontaneously. The patient went into shock 25 minutes after delivery was completed in the hospital. Two blood transfusions were given for shock but she did not respond. She died 2 hours and 15 minutes following rupture of lower uterine segment. The infant weighing 12 pounds 6¼ ounces was stillborn.

CASE 22 (1940) White sextipara septigravida, aged 38 years. The patient was admitted in severe shock after having been in labor at home for 27 hours. Her physician stated that dilatation had been complete for 8 hours. He had given her pituitrin 3 minims twice. Four hours after the second dose the patient had had sharp pain causing her to double up. Laparotomy was carried out immediately and blood transfusions were given for shock. She survived this surgery and on the 28th day after operation returned home with a vesicovaginal fistula. She died of ascending infection 6 months later following a genitourinary operation when ureteral transplants were made into the sigmoid. The infant was stillborn.

In the ruptures attributed to oxytocics all 4 mothers and 4 babies lost their lives. In Case 20 the management of the patient after she arrived in the hospital in shock is to be criticized. The history of violent pains following the administration of ¼ cubic centimeter of pituitrin and then of sudden cessation of the pains makes the diagnosis of ruptured uterus obvious. A version and extraction procedure was contraindicated. Treatment of the shock and immediate laparotomy was the procedure of choice. What small chance the woman had to survive was destroyed by the additional trauma of the version and the failure to operate upon her promptly.

There are 6 cases which can be classified as more or less prolonged labors and probably disproportions.

FIG. CASE — Gummert April 11

CASE 3 (101). White multipara, aged 45, was frank breech presentation. The infant was admitted in shock after having been laboring for weeks. Bag of waters was ruptured before onset of labor. She had had severe pain 10 hours before admission. The uterine contractions stopped suddenly. Embryo was carried out intact and associated with a Brown Book. There was a small amount of blood. Her condition was poor. A tear in the lower uterine segment. The patient recovered after a brief postoperative course and returned home with a healthy infant. The placenta was preserved.

CASE 4 (102). Colored multipara, aged 31 years. This patient had been in labor for 10 hours when she was admitted with ruptured bag of waters when she was only 10 hours in labor. The fetal head went out of the pelvis and the parts were easily palpable. A cesarean hysterectomy was performed for the same reason in the lower uterine segment. She recovered and returned home in the 10th day after operation. The placenta was preserved.

CASE 5 (103). White multipara, aged 31 years. The patient was in labor for 10 hours when the cervix was dilated to 10 centimeters. The fetal head went out of the pelvis and the parts were easily palpable. A cesarean hysterectomy was performed for the same reason in the lower uterine segment. She recovered and returned home in the 10th day after operation. The placenta was preserved.

t
C
la
been
was
at

term and she returned home on operation. The infant was stillborn. Colored multipara, aged 35 years. Upon admission after labor of 16 hours her pulse was 100, but the cervix was completely ruptured. Shock progressed as the patient lay for delivery. The fetal parts were palpable and the fetal heart tones were not heard. A cesarean hysterectomy was performed immediately with the right lower uterine segment. The fetal parts were in the peritoneal cavity. Peritonitis on the 6th day after operation. The patient weighed 10 pounds and was stillborn. Colored multipara, primipara. The patient was in labor for 60 hours when the fetal heart tones were not heard. Shock was effected by craniotomy. She was given supportive treatment but rupture was not diagnosed. On the 1st day postoperative examination revealed a small wall and pelvic peritonitis.

Colored multipara, primipara. Upon admission patient had been in mild labor for 15 hours with a cervical section was carried out. The placenta was 5 cm. in diameter and a tear was found in the lower uterine segment. The uterus was resected. The patient returned home in the 10th day. The infant lived.

All but 1 of the babies in the group of prolonged labors were stillborn, and 1 mother was lost. Four of these patients were multiparous (para 5, 6, 8, and 10). Illustrative of a point that is well known but often forgotten, namely, that a multiparous patient will not necessarily deliver successfully simply because she has previously delivered. In 4 of these Cases, 1 and 2, rupture probably occurred outside of the hospital but were overlooked in our own labor rooms. In Case 4, a multipara was allowed to labor for 10 hours without proper evaluation.

There were 3 primiparas among the patients who had prolonged labors. One Case 5 was in labor 10 hours delivered by craniotomy and the mother died of peritonitis on her twelfth postpartum day; the other primipara, Case 6, was delivered by cesarean section and a tear was discovered in the lower uterine segment in the course of the surgery. The uterus was resected, a questionable procedure and the patient made an uneventful recovery.

There were 2 disproportions due to hydrocephalus in multiparous patients one a secundipara and one a sextipara, resulting in the deaths of both mothers and both babies.

CASE 29 (1930) Colored sextipara, septigravida, aged 33 years. This patient was admitted in mild labor with pains 10 minutes apart. Twelve hours later the uterus became tetanic and the classical signs of threatened rupture were present. A craniotomy was performed for the hydrocephalus 12 yards of gauze packing was used for the postpartum hemorrhage. The patient died on the delivery table of hemorrhage from a cervical tear extending into the broad ligament. The infant was stillborn.

CASE 30 (1944) White secundipara, tertigravida, aged 34 years cephalic presentation floating. The patient was admitted with severe pains after 40 hours of labor at home. The fetal head was perforated through the 4 centimeter cervix with a Smellie perforator 500 cubic centimeters of serous fluid escaped and the head collapsed. Shock ensued 30 minutes after the head was perforated. The patient was given oxygen, plasma, aminophylline. She did not respond to shock treatment and died undelivered 1 hour 25 minutes after admission. The tear in the lower uterine segment was discovered at postmortem examination.

In 2 cases there appeared to be a defect in the fundus of the uterus

CASE 31 (1934) Colored nullipara, primigravida, aged 38 years. The patient was admitted not in labor, with bag of waters intact, fetal heart tones not heard. The patient had had 1 day periods for 5 months followed by amenorrhea for 3 months progressive abdominal enlargement and persistent abdominal cramps. Her condition had been diagnosed as fibroids or ovarian cyst. At laparotomy the fetus was protruding through the fundus with the top of the fundus gone. Recovery was uneventful and she returned home on the 10th day after operation. The infant lived.

CASE 32 (1932) Colored tertipara, quadriga, aged 31 years. The patient was admitted in shock not in labor at 5 months gestation. Her pregnancy had been normal except for occasional pain until 1 hour before admission when she had had intense abdominal pain, vomited, and fainted. Her abdomen was tympanitic, distended and there was no mass up to the umbilicus. Immediate supracervical hysterectomy was performed for perforation of the uterine wall by the placenta. The uterine wall was paper thin. Recovery was uneventful and the patient returned home on the 11th day after operation. The infant was stillborn.

In the 38 year old nullipara, the symptoms and findings were misleading and the patient was operated upon by the gynecologic service

with a diagnosis of pelvic tumor. The infant was premature and half of its body was protruding through a defect in the fundus of the uterus. The placenta was normally attached. Both mother and baby survived.

In Case 32 the patient was a tertipara, who came to the hospital in shock. At abdominal section the placenta was found to have perforated or eroded the uterine fundus and was lying in the abdominal cavity. The 5 month fetus was dead of course but the mother made an uneventful recovery.

In 4 cases the ruptured uterus seems to have been associated with unusually severe uterine contractions and/or rapid labor the so-called precipitant type of labor.

CASE 33 (1936) Colored secundipara, tertigravida, aged 24 years. The patient had a normal spontaneous delivery after a labor of 13 hours 50 minutes during which time she had severe pains post partum bleeding was present. The cervical tear was repaired. Three transfusions were given hysterectomy for tear in the lower uterine segment was performed 19 hours postpartum. She had a stormy post operative course and returned home on the 16th day after operation. The infant lived.

CASE 34 (1937) Colored quintipara, septigravida, aged 28 years. The patient was admitted in moderate labor the cervix dilated to 3 centimeters station minus 1 in 1 hour the cervix was dilated to 5 centimeters in the presence of severe pains. Shock ensued 1 hour later the abdomen was distended and very tender, uterus was palpated below the umbilicus. Immediate laparotomy was performed stimulants and a transfusion of 1000 cubic centimeters of blood were given in the operating room. The patient died 1 hour after surgery in spite of more blood and stimulants. Twin infants were stillborn.

CASE 35 (1947) Colored sextipara, septigravida, aged 32 years. The patient had been in labor for 3 hours 50 minutes during which time the fetal heart tones disappeared. Breech delivery was attempted to bleed and the uterus became doughy. For 12 hours conservative treatment was followed, then sterile vaginal examination revealed a tear in the left side of the cervix and lower uterine segment. Laparotomy was performed and 3 transfusions of 1000 cc. of blood were given. The patient recovered and returned home on the 12th day after operation. The infant was stillborn.

CASE 36 (1933) White octipara, duodecigravida, aged 38 years. The patient had had severe pains for 2 hours 40 minutes before spontaneous delivery. Two hours postpartum she went into profound shock from vaginal bleeding. Vaginal examination revealed a deep tear into the lower uterine segment.

The patient died before the anticipated surgery could be performed. The infant lived.

All of the women who had a precipitant labor were multiparous (para 2 5 6 and 8). In 3 instances, the labor was less than 4 hours long and there are constant references in the nurses notes to severe pains. Two of these mothers died (Cases 34 and 36). The cause of death apparently was shock and hemorrhage. One death occurred before transfusion could be administered or surgery could be done.

Five ruptures were due to trauma of various sorts.

CASE 37 (1932) White nullipara, primigravida, aged 31 years. The patient was admitted with a 7 months gestation, positive Horner's sign, fetal heart tones were absent. She had a mild hypertension and pus in the urine. A 7 centimeter bag which was inserted came out spontaneously but the patient had no pains. The bag of waters ruptured and she went into shock. Supportive treatment was given but she died of peritonitis following lower uterine segment perforation 52 hours after bag induction. Fetus and placenta were in the peritoneal cavity.

CASE 38 (1936) White multipara, decigravida, aged 45 years. While scrubbing the floor 10½ hours before admission the patient developed severe sharp pain in the lower abdomen, vaginal bleeding and weakness followed, and she was brought to the hospital in shock. Immediate laparotomy was performed but blood was not available. She died 3 hours after admission and 1 hour after surgery. The infant was stillborn.

In Case 37 with a dead fetus of 7 months gestation a 7 centimeter bag was inserted. The patient died undelivered of peritonitis apparently due to a perforation of the uterine wall by the bag.

waters intact. Spontaneous delivery of the 6 month fetus occurred. Morphine sulfate and external heat (for acute alcoholic stupor with "cardiac decompensation") were administered. She died 8 hours after delivery. Postmortem examination revealed a traumatic fundal rupture. The infant was stillborn.

CASE 40 (1940) Colored tertipara, tertigravida, aged 22 years. Breech delivery occurred at home while she was unattended. Placenta was retained for 2 hours. Relatives pulled on the cord then a physician attempted to express the placenta by Credé's method but failed, finally manual removal was carried out at home. Upon admission the patient was bleeding and had cramping pain. Three transfusions were administered for shock but the rupture was not diagnosed and no operation was attempted. She died of purulent peritonitis and endometritis 66 hours after admission with perforation of the fundus and some placental tissue in the peritoneal cavity. The infant lived.

CASE 41 (1940) White primipara, secundigravida, aged 28 years. The patient was admitted because of toxemia with a blood pressure of 170/115. Medical induction failed four times and labor was induced by stripping membranes. Bag of waters ruptured spontaneously and fetal heart tones disappeared. An attempt to convert brow failed and delivery was effected by craniotomy and cleidotomy. Total labor lasted 14 hours 30 minutes. Supportive treatment with blood transfusions, sulfanilamide intravenous fluids, and Levine suction was carried out. The rupture was not diagnosed and not operated upon. The patient died of rupture of the uterus with infection, hemorrhage, and generalized anemia, 5 days postpartum. The infant was stillborn.

One patient Case 39 fell down the stairs while intoxicated. Her serious condition was masked by her alcoholic stupor and she expired unoperated upon 8 hours after entrance.

In Case 40 the manual removal of the retained placenta at home resulted in death.

Four days after admission medical induction with castor oil and quinine resulted in mild labor at 10:00 p.m. on November 18 1947 pains were at 10 minute intervals. An hour later the patient became restless, at 1:00 a.m. the blood pressure rose to 200/124 and the fetal heart tones disappeared. The cervix was effaced, dilatation 3 centimeters and station minus 2 the uterus relaxed normally between pains. At 1:50 a.m. her blood pressure was 165/105 she was co-operative at 4:30 a.m. with a pulse of 88. At 5:30 a.m. she was extremely restless and died at 5:40 a.m. undelivered. Though labor was apparently progressing normally and she was treated for hypertension she died during labor.

This patient's clinical course suggested a nonconvulsive eclampsia and at postmortem examination it was discovered that there was also a ruptured uterus. After studying the microscopic sections, the pathology department was of the opinion that the toxemia was a large contributing factor to the cause of death.

SUMMARY

In a critical analysis of the material we find that there were 25 instances of ruptured uterus in the first 10 years (1928-1937) during which period 40 327 viable infants were delivered an incidence of 1 in 1 613. In 11 of these patients rupture had already occurred on entrance to the hospital—2 from defective uterus, 2 from external trauma, 5 from prolonged labor (1 after receiving black medicine*) 1 rupture after a previous classical section and 1 after an attempted version and extraction in the home. During this decade 11 of these patients lived and 14 died. The cause of death was peritonitis in 7 cases, shock and hemorrhage in 5, bronchopneumonia in 1, and undiagnosed in 1 (masked by alcoholic stupor).

In the second 10 years (1938-1947) there were 17 cases of ruptured uterus during which time 51 899 patients were delivered of viable infants making an incidence of 1 in 3 054. In 8 of this group rupture had already occurred upon admission. Three patients had received puerperal infection on the outside, 2 had had previous classical sections and 1 a previous low cervical section. 1 had had a manual removal of the placenta, 1 was a neglected transverse. In this decade 9 women survived and 8 died. Four deaths were attributed to shock and hemorrhage and in 4 others no diagnosis was made and no operation performed.

TABLE III.—MORTALITY

	No. cases	Per cent

Died	23	54.76
Infants		
Lived	9	20.93
Died undelivered	5	11.63
Stillborn	28	65.12
Neonatal death.	1	2.32

*One set of twins.

The fact that the incidence was reduced by half in the latter 10 years would seem to indicate that better obstetrics is being done throughout the Chicago area. However, the infrequency of the incidence in the second period reduced the diagnostic acuity resulting in 4 undiagnosed cases with death in each. The 7 fatalities due to peritonitis in the first decade might have been reduced in number had antibiotics and chemotherapy been available. There were 5 deaths due to shock and hemorrhage in the first decade and 4 in the second indicating that even when adequate blood is available ruptured uterus is an exceedingly dangerous condition and frequently fatal.

There were 13 ruptures in the upper uterine segment, 22 in the lower uterine segment and 7 instances in which the location of the rupture was not described.

Twenty-eight women were operated upon, 18 of whom survived and 10 died. In the 6 instances in which the rupture was diagnosed, surgery was not accomplished because the course of the patients was so rapidly downhill. None of these survived. Two patients, whose condition was diagnosed, were electively not operated upon. One of these died and 1 recovered. In 6 cases in which the condition was not diagnosed and operation not performed, all patients died. The only appreciable salvage was in the group in which diagnosis was made and operation performed—64.28 per cent of these patients survived. In the group not operated upon only 1 patient (7.18 per cent) was saved. From these figures it is evident that there is no advantage in surgical delay and very little possibility of improving the patient's condition until the cause of the hemorrhage is eliminated.

CONCLUSIONS

1 Forty two cases of ruptured uteri (an incidence of 1:3196) observed at the Cook County Hospital during a 20 year period, 1928-1948 inclusive are reported and analyzed.

2 The maternal mortality was 54.76 per cent and the infant mortality was 79.07 per cent.

3 Careful observation of the intranatal patient and good obstetric practice would prevent most ruptures.

4. Diagnostic acuity prompt surgery plus the administration of adequate blood and judicious use of the available chemotherapeutics and antibiotics would decrease the mortality from this condition.

DEXTRAN

An Experimental Plasma Substitute

FENNELL P. TURNER, M.D. BYRON C. BUTLER, M.D., MARGARET E. SMITH, Ph.D.,
and JOHN SCUDDER, M.D. F.A.C.S., New York, New York

PARTIALLY hydrolyzed dextran administered intravenously as a 6 per cent solution in normal saline has recently been proposed as a plasma substitute in the treatment of shock and hemorrhage. Following chemical and physiological studies at the University of Upsala under the direction of Tiselius (11) its clinical trial was first reported by Grönwall and Ingelman in 1945 (12)

Physical chemistry of dextran Dextran is a water soluble high molecular natural polysaccharide first described in the nineteenth century and later found to be a common contaminant of beet sugar. It is prepared commercially by dialysis from solutions of saccharose infected by *Leuconostoc mesenteroides* and purified by repeated precipitation with alcohol. The dextran molecule corresponds to the formula $(C_6H_{10}O_5)_n$ with the glucose units connected by a gentiobiose (1-6 glucosidic) linkage (33). Its suggested structure consists of a long main chain of glucopyranose units with shorter side chains each composed of about 5 such units giving a postulated thickness of about 10 glucopyranose molecules (23), or about 50 angstroms. Study with the electron microscope reveals a 'thread like structure' which is usually branched and even when quite diluted seems to have no appreciable tendency to divide into smaller parts. The rough estimate of the molecular thickness of 30 to 100 angstrom units was however at the limit of the resolving power of the electron microscope used (17, 18). The raw material is only partially soluble in water and the resulting solutions are very viscid. It has a slow electrophoretic migration toward the positive electrode, a specific rotation of 195 degrees

and a molecular weight of many millions. By carefully controlled partial hydrolysis a modified dextran is obtained which has a nonuniform molecular weight of between 100,000 and 200,000 and passes through capillary walls slowly. This modified dextran in a 6 per cent solution has been proposed as a 'plasma substitute' by Grönwall and coworkers. The following data describe the physical chemical properties of the dextran modified for intravenous therapy. The colloidal osmotic pressure (300 to 400 mm H₂O) is equivalent to that of normal blood plasma. Isoelectric point, pH 5.9 to 6.1; nitrogen content, 0.003 to 0.01 milligram per cubic centimeter; viscosity, 3 to 4 with an Oswald viscometer at 37 degrees Centigrade and the buffer capacity 6 to 7 cubic centimeters of tenth molar sodium hydroxide. The dextran sedimentation constant (determined in the ultra centrifuge) at a concentration of 0.7 per cent varies between 1.5×10^{-13} to 20×10^{-13} , and the diffusion constant varies between 0.2×10^{-7} to 8×10^{-7} .

Immunology of dextran Grönwall and Ingelman (11) carried out a brief immunological study on dextran. Rabbits were injected with 2 cubic centimeters of 0.5 per cent dextran solution every fifth day for a period of 2 months. The sera were then tested for precipitin formation by addition of dextran solution of varying concentration. None occurred. No mention was made as to whether pure dextran or the hydrolyzed product was used in these studies. Neill and Hefre, however, had previously found that pure dextran is a serologically active polysaccharide (14, 30). They reported the formation of serologically active dextran from sucrose solution by various strains of nonhemolytic streptococci isolated from the blood of patients with subacute bacterial endocarditis from several strains of group 'H' throat streptococci, and from

From the Surgical Pathology Laboratory of the College of Physicians and Surgeons, Columbia University and the Department of Surgery, Presbyterian Hospital, New York.

Presented by title at the Clinical Congress of the American College of Surgeons, New York, September 6-12, 1947.

strains of *Streptococcus salivarius* isolated from the throat and feces. Cross-immunological relationships of the dextran 30 formed occurred with several strains of *Leuconostoc mesenteroides* and with type 2 type 12 and type 30 pneumococci. Consequently in view of the frequent contamination of commercial sugars with leuconostoc bacteria and also with dextran itself and because of the frequency with which pneumococcal and streptococcal infections occur it would not be surprising if a great many people were found who would harbor antibodies capable of reacting with unhydrolyzed dextran. In support of this theory a majority of people, skin tested by Neill and Hehre¹ with unhydrolyzed dextran gave positive reactions in high dilution. Complete hydrolysis of the dextran molecules prevented this reaction. Whether dextran itself is capable of stimulating the formation of specific antibodies was not stated.

Physiological studies. Extensive studies on dextran and its behavior after parenteral administration have been carried out by Grönwall and Ingelman (12). Unhydrolyzed dextran in solutions of 1 to 3 per cent were injected into rabbits with resultant albuminuria. Repeated injections caused anuria and death in an unstated number of dogs. Microscopic studies revealed thrombosis of capillaries in the liver and kidneys with surrounding areas of anemic necrosis. Later on testing solutions of partially hydrolyzed dextran it was discovered that a dextran of medium molecular weight, in the range of 100,000 to 200,000 still retained its beneficial hemodynamic effects and could be given with safety to experimental animals. Because of the asymmetry of the dextran molecule such molecular size was necessary in order to prevent rapid passage through the glomerular membranes.² This modified dextran solution was then given to rabbits and dogs as replacement therapy after experimental hemorrhage. No deleterious reactions were noticed nor was there any gross or microscopic evidence of storage in the tissues. The concentration of dextran in both

the blood and urine was investigated. After administration the plasma dextran level decreased rapidly for a few hours then the rate of excretion became a relatively straight line curve reaching zero within 4 days. This early fall in the plasma dextran concentration is due to the rapid excretion through the glomeruli of the smaller dextran molecules, the mean molecular weight of which was calculated to be from 50,000 to 60,000.

One undesirable consequence observed following dextran was the greater tendency toward pseudoagglutination of the red blood cells and the associated increase in sedimentation velocity. Such changes bore a direct relationship to both the concentration of the dextran solution used and the size of its molecules. In vivo experiments, however, revealed that the relationships between the dextran level in the plasma and the sedimentation rate varied in different individuals. Grönwall and Ingelman concluded that although an increased sedimentation rate is, in itself not harmful the occurrence of injurious reactions secondary to this agglutination tendency is yet a possibility and that a decision could naturally not be expected before the dextran solutions have been injected in great amounts into humans and the sedimentation reaction studied with respect to the dextran content of the blood. This same effect, of course had been usually observed following the infusion of many other plasma substitutes such as gum arabic, pectin and gelatin.

Clinical testing of dextran. Initial clinical testing was carried out by Grönwall and Ingelman in 1943 at the University of Uppsala, and later at the Central Hospital in Örebro under the direction of G. Bohmanson and O. Wilander. Finally large scale clinical trials were conducted at Örebro at Stigberget Hospital and the Serafimer Hospital in Stockholm under Grönwall and Thorsén, and also at St. Göran's Hospital in Stockholm by Rosenkvist. Throughout this period 22 different preparations and about 1,000 bottles were used (3). Each preparation before being released had been tested on terminal cancer cases in Stigberget Hospital.

Prior to March, 1945 many batches were discarded because of allergic and pyrogenic

¹Personal communication.

²When measurement of the relative viscosity of dextran solutions was found to be a reliable test for the degree of hydrolysis, this method was employed to determine the suitability of the different preparations.

Fig. 1. Clinical response to macrose.

Fig. 2. Blood changes after macrose infusion.

reactions. Since then only occasional preparations have been deleted for this reason. As a result of the studies at Örebro in 1943 the composition of the dextran preparation was gradually modified the molecular size was reduced the viscosity was decreased from 4.5 to 5.2 to between 3 and 4 and the saline content lowered from 3 to 0.9 per cent. This new solution was introduced in 1944 and it is the preparation now employed in Sweden.

THE CLINICAL STUDIES CARRIED OUT AT THE PRESBYTERIAN HOSPITAL

Thirty chosen volunteer patients received macrose solution intravenously. One patient, a terminal cancer case received 1000 cubic centimeters of the solution a few days prior to death. The autopsy findings in this case have not been presented in this paper because of the presence of advanced bilateral hydronephrosis consequent to the spread of the carcinomatous process from the cervix to the adnexa and the neighboring tissues and lymph nodes. This condition unfortunately, served to obscure any renal changes which might have been found as a result of the infusion of macrose. Twenty five patients received as

much as 500 cubic centimeters each the infusions being given by the drip method in not less than 30 minutes. No seriously ill patient was chosen. Careful clinical observations were made both during the infusion and for several days thereafter. Temperature, pulse, respiration and blood pressure were recorded at frequent intervals. Urinalyses (routine) hematocrit capillary specific gravity erythrocyte sedimentation rate blood grouping plasma and urine dextran level blood volume study plasma protein level and electrolyte studies were carried out in selected patients.

A résumé of a typical case is presented.

CASE 6. W.R. aged 16 years, male, white. Unit No 837242. Diagnosis ankylosis of jaw following infection of both temporomandibular joints at the age of 3. Patient was admitted to the hospital July 16 1946.

On July 17 a cartilage graft taken from a rib was transferred to the mandible. The postoperative course was not complicated.

On July 23 the patient was given an intravenous infusion of 500 cubic centimeters of 6.0 per cent macrose over a period of 30 minutes. There was no immediate clinical reaction to the infusion. Two hours after termination there was a slight rise in both pulse and temperature with the latter returning to normal at the end of 24 hours (Fig. 1). The blood

TABLE I.—REACTIONS TO MACROSE SOLUTION IN CASE 6

	Pre-macro		Post-macro			
	Pre-capillary			4	48	7
			HOURS			
Plasma derived (grams %)		25	5		15	(1)

Red cell volume (ml)	20			22.00		
Body weight (kg)				70	75.4	75.6

pressure did not change significantly. At the end of 4 hours a gain of 1.2 kilogram of body weight occurred whereas the plasma volume increased only 2.3 cubic centimeters.

There was an immediate drop and secondary rise in hematocrit, peripheral blood specific gravity and plasma proteins (Fig. 2 and Table I) indicating a transient hemodilution. In the 24 and 48 hour specimens hemodilution was again present. The sedimentation rate doubled its initial value and remained elevated. The dextran level fell rapidly at uniform rate. There was no significant change in the electrolytes studied.

The patient was discharged from the hospital on July 26.

This case is presented to illustrate the various changes which took place in the blood chemistry. An interesting feature is the temporary hemoconcentration noticed at the 4 hour sample. This is what was found in those patients who reacted to the macrose solution. Those who had no reaction as a general rule showed hemodilution. Another feature is the gain in weight exhibited over a period of several days a phenomenon noted in several patients.

SUMMARY OF CLINICAL STUDIES

1 *Clinical observations* In several instances the blood pressure declined somewhat following the infusion in others it was accompanied by a slight increase together with a greater rise in pulse pressure. Correspond-

ingly small increases in temperature pulse and respiration were noted. In only 3 cases was the fall in blood pressure sufficiently alarming to require therapy. There were no shaking chills or spikes in fever. Flushing of the face and neck, urticaria, and a few other symptoms were experienced in several of the patients.

2 *The hematocrit* The hematocrit determinations in 19 cases are incorporated in a scattergraph (Fig. 3). Seven of these had reactions following the administration of macrose and separate graphs were made of these 7 patients. Hemoconcentration was observed in these reactors with definite hemodilution occurring later. Twelve nonreactors, on the other hand showed immediate hemodilution which was maintained from 24 to 48 hours.

3 *The specific gravity of capillary blood* Capillary blood specific gravity was measured at the bedside in 19 patients. A similar hemodilution of peripheral blood occurred in the nonreactors as was noticed in the venous blood hematocrit determinations. Similarly those patients who had reactions showed capillary hemoconcentration which persisted for at least 4 hours. These changes are recorded by means of a scattergraph in Figure 3.

4 *Erythrocyte sedimentation rate* The corrected erythrocyte sedimentation rate was investigated in 14 cases. These findings are de-

Fig. 3. Effect of macrose upon the hematocrit and specific gravity of capillary blood.

picted by means of a scattergraph in Figure 4. In all there was an immediate rise in the sedimentation velocity. The subsequent decline in the erythrocyte sedimentation rate to the original values could not be definitely correlated with the decrease in the plasma dextran level. An *in vitro* experiment demonstrated however that with any given blood sample a rough correlation between the erythrocyte sedimentation velocity and the concentration of dextran did exist (Fig. 5).

5 Plasma dextran levels. Plasma dextran determinations were carried out in 12 cases. The highest levels were found in the 15 minute specimens and in 1 case it was 0.84 gram per cent. The concentrations fell rapidly for the first few hours and then assumed a more gradual but uniform rate of fall. At 24 hours the plasma dextran was approximately one half of the postinfusion level (Fig. 4). By the third day a very low concentration of dextran remained in the plasma.

6 Blood grouping. The blood groups were typed before and immediately after the macrose infusion in 3 cases: whole blood on slides

Fig. 4. Effect of macrose upon erythrocyte sedimentation rates.

and cell suspensions in saline being used. No difficulty was encountered in obtaining the correct blood group.

7 Urinalyses. Urinary dextran determinations although not reliable quantitatively indicated qualitatively that dextran passed into the urine during the first 24 hours but very little was excreted during the second 24 hour period in 3 of the intensively studied cases. Routine urinalyses before and for sev-

Fig. 5. Effect of varying concentration of dextran on sedimentation rate *in vitro*.

Fig. 6. Blood volume after macrose.

eral days after the infusion revealed no important changes.

8 Plasma volume Plasma volume was measured in 7 cases. These values are recorded in graph form in Figure 6. At the end of 24 hours the plasma volume of these 7 cases was an average of 370 cubic centimeters greater than it had been prior to the infusions. None of these patients had had reactions.

9 Plasma proteins Plasma proteins were analyzed in 6 patients. These are shown in Figure 7. The drop in plasma proteins roughly parallels the hemodilution as observed by means of the hematocrit and capillary blood specific gravity.

10 Electrolytes In 7 cases the concentration of sodium potassium chlorides, and bicarbonate ions were determined before and at intervals after the infusion of macrose. Both the sodium and potassium ions decreased the latter more than the former due to the sodium contained in the infusion. After the first hour the sodium concentration continued to fall and that of the potassium ion to rise. At the 48 hour postinfusion sample the values had returned to normal.

The chlorides were little affected. Immediately after the macrose there was a small rise due no doubt to the chloride ion in the infusion. A slight acidosis existed in the cases studied. Following macrose this condition

was improved by the end of the 4 hour period. On the whole the variations in the electrolytes in these 7 patients was not significant (Fig. 8). More such studies are needed.

11 Reactions to macrose Of the 30 patients given infusions of macrose there were 10 who had definite reactions. Four were females and 6 males. Six received the full 500 cubic centimeters of the 6 per cent macrose solution. In 4 cases the infusion was stopped after 400 cubic centimeters, 20 cubic centimeters, 400 cubic centimeters and 75 cubic centimeters respectively because of the advent of reactions. These reactions have been divided roughly into 3 different groups (1) skin reaction (flushing pruritus and urticaria) 6 cases (2) circulatory reaction (cyanosis and fall in blood pressure) 3 cases (3) asthmatic reactions, 1 case. Nineteen of the 20 remaining cases received the full 500 cubic centimeters of macrose solution intravenously without symptoms. The twentieth case received 1000 cubic centimeters (500 c.c. on 2 successive days). Those patients who had reactions of one kind or another also had significant changes in the temperature pulse respiration or blood pressure. Other symptoms which may or may not be significant are headache 3 cases drowsiness, 3 cases and restlessness 2 cases. In 7 of the 10 who had reactions and in whom hematocrits and peripheral whole blood specific gravity tests were carried out hemoconcentration was observed. Hemodilution on the other hand was the rule for all those who did not have reactions. In the non-reactors blood studies were carried out in 12 of the 20 and hemodilution in some degree was noted in each. The changes in the hematocrit and in the specific gravity of capillary blood of both those with reactions and those without reactions are presented in Figure 3. Average values are recorded for both those patients who had reactions and those who did not. As the groups presented are statistically small and as the preinfusion values of the hematocrits and specific gravity determinations varied widely from patient to patient this graph is open to criticism. On the other hand the general trend observed is what is found on individual analysis of any of the different cases. As allergic manifestations character

Fig. 7. Changes in plasma proteins (biuret) after macrose.

istically show hemoconcentration it is likely that the reactions observed are related and are either of anaphylactic or anaphylactoid nature.¹

A résumé of Case 30 is presented. This patient experienced a severe asthmatic reaction.

J. M. aged 21 years, male, white, Unit No. 669788. Diagnosis: recurrent osteomyelitis. Patient was admitted to the hospital July 22, 1946. Discharged August 18, 1946.

This patient had developed an osteomyelitis of the right femur and left radius in March, 1942 and had subsequently been admitted to the hospital on four separate occasions for treatment. A fifth admission in January, 1944 was because of bronchial asthma, influenza and bronchopneumonia. Sputum cultures at this time were positive for *Pneumococcus* type 20. His past history was irrelevant except for "hives" as an infant and an unsubstantiated history of hay fever for two summers. Physical examination showed a healthy young male with positive findings limited to the right hip and the left wrist. Culture of pus from sinus of right hip was positive for *Staphylococcus aureus*.

On July 22, incision and drainage of an abscess of the right hip was carried out. His postoperative condition was good. On July 24, upon completion of the routine preliminary control tests, an infusion of 6 per cent macrose was started at 9:05 a.m. The rate of the infusion was approximately 60 drops per minute. Within a very few minutes the patient's face and neck became flushed and he began to cough repeatedly. Auscultation of the chest revealed a few

expiratory wheezes. The macrose infusion was stopped immediately (not more than 20 c.c. had been given) and the patient was given 3 minims of 1:1000 adrenalin by hypodermic. When it was seen that the patient was becoming increasingly dyspneic and cyanotic, oxygen by mask was instituted and a second 3 minims of adrenalin was given. Following this therapy there was a gradual lessening of the dyspnea so that one hour later all symptoms had disappeared.

Fig. 8. Effect of macrose upon the plasma electrolytes.

¹Sterile infusion sets were used throughout. Baxter Number 18-R, Number 11-R, and Number 8 sterile 1 lb. and needle sets were used. Reactions were obtained with each of the three different recipient sets.

²Bottle No. 33, lot No. 55 control no. B2 2, infusion set Baxter No. 8-R.

Fig. 9. Macrosc infusion following exsanguination.

Since he received only 20 cubic centimeters of macrose no significant concentration of dextran in the plasma was detected. The sedimentation rate did not change until 24 hours later when a significant rise occurred. There was an immediate rise in the hematocrit followed by a fall back to normal in the 4 hour specimen. There occurred no appreciable change in the specific gravity of peripheral blood or the plasma protein concentration. Blood volume before and 24 hours after macrose was little altered. The variations in electrolytes were only minor. Plasma sodium fell during the first 4 hours and returned to normal at the end of 24 hours. There was a slight increase in the plasma potassium between the sample taken at the 4 and 24 hour periods. There was no alteration of body weight during the first day. The patient was discharged from the hospital on the 15th day after operation. No late sequelae were noted either in the hospital or in the out-patient department.

PATHOLOGICAL STUDIES AT THE PRESBYTERIAN HOSPITAL

Resuscitation of dogs with macrose and subsequent autopsy findings.

Six dogs were bled an estimated 50 per cent of their blood volume and were immediately given an equal volume of 6 per cent macrose. The experimental procedure was similar both to that used by Ivy and his coworkers in 1943 and to the method adopted by Buttle, Kelwick, and Schweitzer in cats, 1940.

Under procaine local anesthesia, the jugular (internal) vein and common carotid artery on one side

were exposed. The carotid artery was then cannulated and the blood allowed to flow into a graduated cylinder until the animal stopped breathing or until the arterial bleeding was reduced to a slow drip. When this state was reached the animals were given a rapid infusion into the internal jugular vein of a volume of macrose equal to that of the blood lost.

At 1, 4, and 24 hours following the infusion and then every other day up to the 13th day jugular vein blood was secured for hematocrit, plasma dextan, protein and specific gravity.

Results. These 6 dogs lost on the average as a result of their bleeding 42 per cent of their total blood volume¹. After receiving 400 to 500 cubic centimeters of macrose they were all able to walk unaided. In fact the clinical response of the dogs to the infusion was quite dramatic. Of the 6 dogs, only 1 died. This animal had pneumonia, responded well to the infusion but then gradually weakened and after exhibiting increasing drowsiness, was found dead in his cage 3 hours after the infusion.

The blood studies on 4 of these dogs are present in Figure 9. The hematocrit dropped to a low of 15.8 per cent and rose very slowly to near the initial level at the end of 2 weeks. The plasma proteins had an equally sharp fall but recovered more quickly with some

¹The calculated blood volumes are determined by the classical method used by Ivy et al (6) - 9.5 per cent of body weight.

Fig. 10. a, b, c (dogs 2, 4, 6) 14 days, 11 days, and 5 days after infusions. Spleens. There is moderate reticulo-

endothelial hyperplasia with the formation of multinucleated giant cells. $\times 325$

figures near the preliminary level at the end of 1 week. The plasma dextran levels decreased from levels as high as 4.1 grams per cent immediately after the infusion to a very low level by the fifth and sixth days. No marked change was found in plasma specific gravity determinations carried out before and for several days after the infusion.

Autopsy studies Each of the 6 dogs was subjected to autopsy and microscopic sections were prepared. Dog 5 with pneumonia died 3 hours after the infusion. Dogs 1, 2, 3, 4, and 6 appeared strong and in general good health and were sacrificed on the 19th, 14th, 13th, 11th, and 5th days respectively after the infusions.

Autopsy studies on dog 5 revealed no gross changes of interest other than a general anemia and pallor of all the tissues and a nodular consolidation of the right middle and right lower lobes and of the left lower lobe. Histological studies confirmed the diagnosis of a diffuse lobular pneumonia of severe degree.

Autopsies on the other 5 dogs were carried out at the same time. The tissues were grossly normal in appearance and the organs were of normal size and weight. There was no evidence of edema and no increases in peritoneal, pericardial, or pleural fluids. General pallor

of the tissues was evident. Specimens for histological study were taken from the livers, spleens, kidneys, and lungs.

Microscopic examination¹ Sections of lungs revealed no change. The spleens of all 5 dogs (Fig. 10) showed evidence of moderate reticuloendothelial hyperplasia together with the formation of multinucleated giant cells of epithelioid type. These cells resembled megakaryocytes. The livers of dogs 3 and 4 presented multiple small areas of midzonal focal necrosis (Fig. 11). The liver of dog 1 exhibited several small focal collections of mononuclear cells without evidence of necrosis. The kidneys of dog 3 appeared normal with exception of slight dilatation of some of the tubules and some of Bowman's capsules. The kidneys of the other 4 dogs (Figs. 12, 13) exhibited varying degrees of focal glomerular and tubular damage with atrophy, necrosis, and some epithelial proliferation of the glomerular tufts, minimal hyalinization of the loops, edema, vacuolization, fatty and colloidal degeneration of tubular cells, and dilatation of the tubules and of the Bowman's capsules. Less than 10 per cent of the total glomeruli and tubules were involved by this process. Eosinophilic hyaline debris and clumps of pinkish-purple amorphous material arranged sometimes in concentric rings were found within a number of glomeruli. Similar debris and clumps of epithelial cells in various stages of necrosis and calcification were present in some of the collecting tubules. Special stains for iron and calcium were employed and they

Fig 10. a, b, c (dogs 2, 4, 6) 14 days, 11 days, and 5 days after infusions. Spleens. There is moderate reticulo-

endothelial hyperplasia with the formation of multinucleated giant cells. $\times 325$

figures near the preliminary level at the end of 1 week. The plasma dextran levels decreased from levels as high as 4.1 grams per cent immediately after the infusion to a very low level by the fifth and sixth days. No marked change was found in plasma specific gravity determinations carried out before and for several days after the infusion.

Autopsy studies Each of the 6 dogs was subjected to autopsy and microscopic sections were prepared. Dog 5 with pneumonia died 3 hours after the infusion. Dogs 1, 2, 3, 4 and 6 appeared strong and in general good health and were sacrificed on the 19th, 14th, 13th, 11th and 5th days, respectively after the infusions.

Autopsy studies on dog 5 revealed no gross changes of interest other than a general anemia and pallor of all the tissues and a nodular consolidation of the right middle and right lower lobes and of the left lower lobe. Histological studies confirmed the diagnosis of a diffuse lobular pneumonia of severe degree.

Autopsies on the other 5 dogs were carried out at the same time. The tissues were grossly normal in appearance and the organs were of normal size and weight. There was no evidence of edema and no increases in peritoneal, pericardial or pleural fluids. General pallor

of the tissues was evident. Specimens for histological study were taken from the livers, spleens, kidneys and lungs.

Microscopic examination¹ Sections of lungs revealed no change. The spleens of all 5 dogs (Fig 10) showed evidence of moderate reticuloendothelial hyperplasia together with the formation of multinucleated giant cells of epithelioid type. These cells resembled megakaryocytes. The livers of dogs 3 and 4 presented multiple small areas of midzonal focal necrosis (Fig 11). The liver of dog 1 exhibited several small focal collections of mononuclear cells without evidence of necrosis. The kidneys of dog 3 appeared normal with exception of slight dilatation of some of the tubules and some of Bowman's capsules. The kidneys of the other 4 dogs (Figs 12, 13) exhibited varying degrees of focal glomerular and tubular damage with atrophy, necrosis and some epithelial proliferation of the glomerular tufts, minimal hyalinization of the loops of edema, vacuolization, fatty and colloidal degeneration of tubular cells and dilatation of the tubules and of the Bowman's capsules. Less than 10 per cent of the total glomeruli and tubules were involved by this process. Eosinophilic hyaline debris and clumps of pinkish purple amorphous material arranged sometimes in concentric rings were found within a number of glomeruli. Similar debris and clumps of epithelial cells in various stages of necrosis and calcification were present in some of the collecting tubules. Special stains for iron and calcium were employed and they

c confirmed the presence of these substances in this amorphous debris. Both the lower and upper portions of the nephron were involved in this degenerative process. The fatty degeneration however involved only the proximal convoluted tubule. That the glomerular damage was of recent date was evidenced by the lack of organization or scar formation.

DISCUSSION

The attributes of an ideal plasma substitute have been summarized by Amberson, Moon, Cohn, Scudder (38) and others. Briefly such an agent should have: A colloidal osmotic pressure of plasma proteins (300 to 400 mm. of water); large molecular size with molecules of symmetrical shape; low viscosity; chemical stability in the wet and dried states; an ionic strength of physiological proportions; a high buffer capacity; and a pH near that of blood. It should be nontoxic, nonantigenic, easily metabolized, not retained as a foreign body and possess the power of restoring protoplasmic irritability. Finally it should withstand sterilization, transportation, and storage without deterioration. A 6 per cent solution of partially hydrolyzed dextran fulfills many of these strict prerequisites but not all. One striking deficiency is the long and highly asymmetrical molecular structure.

One harmful effect of this asymmetry is the greatly increased erythrocyte sedimentation velocity observed in all the patients given macrose. This effect is a characteristic of many macromolecular substances. In 1918 Fåhræus demonstrated that the sedimentation rate was correlated with changes in certain plasma constituents especially fibrinogen and globulin and in 1921 Fåhræus published an exhaustive historical review and experimental study on the suspension stability of the blood and reported that gum arabic and other macromolecular substances produced pseudoagglutination and consequently increased the sedimentation velocity. This work, together with that of Karsner and Hazlik and of others, has been augmented in recent years so that now Meyer and associates (39) believe that probably all highly asymmetrical molecules of large size will cause an increase in the sedimentation rate when added to normal blood. The reasons for this phenomenon are not definitely known. However it has been observed in many instances to be reversible and it also has been observed that chemical and enzymatic breakdown and depolymerization of these high molecular weight substances will prevent any such increase in the agglutinability.

ity of red blood cells (28) Nungester and Klein reported that the addition of type 3 Pneumococcus polysaccharide to normal blood would also increase the sedimentation rate and that type specific antiserum would abolish this effect As dextrans are serologically active bacterial products (14) we now have a second known bacterial product which will increase the erythrocyte sedimentation rate It is likely that many such substances will be found in the future

The extent to which this macromolecular substance of asymmetrical shape is stored in the body and its catabolism are not yet known. In vitro experiments have thus far revealed only a slow reduction with starch splitting enzymes (12) and as no evidences of accumulation have heretofore been detected in experimental animals it is believed that a gradual enzymatic destruction of the molecule does take place Slow excretion or breakdown of the dextran molecules is, of course desirable In the treatment of the shock state one is primarily interested in restoring the circulat

ing blood volume to normal and in maintaining it at that level until the body is able to compensate for the loss of fluid volume through its own compensatory mechanisms It is only when there is severe reduction in blood volume tissue anoxia, and capillary damage that prompt therapy is mandatory employing plasma or a plasma substitute until blood is available Such aid is needed for only a short time and as a rule for not more than 12 hours It is known that regeneration or restoration of plasma proteins after blood loss takes place rapidly if shock is not present (25) As much as 10 to 29 per cent of the normal plasma proteins enters the circulation in the first 12 hours and a similar amount during the second 12 hours (8) Our own experiments with dogs discussed in this paper tend to confirm these observations

Is partially hydrolyzed dextran toxic? The histological findings observed in a series of 6 dogs who received macrose solution intravenously have been described Some of these changes are not reversible but were minimal

and only focal in nature. In comparison with the Swedish group who observed no pathologic alterations in the tissues, the amount of macrose solution used in our animals was relatively high. These changes are somewhat similar to those found by others investigating several colloidal plasma substitutes.

Hueper contends that certain macromolecular substances employed as plasma substitutes (acacia, polyvinyl alcohol pectin) are pathogenic when administered intravenously. He has presented evidence revealing organic changes to be frequently found and characterized by storage in the reticuloendothelial system, degenerative vascular changes often identical with atheromatous or arteriosclerotic lesions, and degenerative and proliferative changes in the glomeruli. Poppe¹ associates have also observed pathol-

changes following the administration of macromolecular substances.

Is partially hydrolyzed dextran antigenic? This question cannot be answered at this time; the reader however is referred to the experimental work of Neill and Hehre. Our own experience which includes 10 reactions in a series of 30 cases, leads us to believe that these reactions were of allergic nature. Whether chemical modification of the dextran so-

serological activity (3) The reactions were not anaphylactic but anaphylactoid in nature, and consequent to the cellular damage produced by the action of this macromolecular substance. It is not believed that the presence of protein impurities was likely because the nitrogen content of the bottle of macrose used in Case 30 was determined in duplicate and assayed to be only 0.0051 and 0.0050 milligram per cubic centimeter. Aerobic and anaerobic cultures were also carried out on 6 bottles of macrose 2 of which caused allergic manifestations. These were negative for leucocytosis and other bacteria. By way of further analysis blood sera from 4 patients who had received dextran were then sent to Neill and Hehre for study. These sera were taken 7, 11, 24, and 27 days after the macrose infusions. Precipitin reactions were carried out with negative results.¹ A culture of *Staphylococcus aureus* from patient 30 with osteomyelitis was also submitted to Neill and Hehre. It was found not to produce dextran diate asthmatic reaction to the dextran infusion had been admitted to the hospital in January 1944 with a diagnosis of bronchial asthma and bronchopneumonia. His sputum cultures at that time revealed large numbers of *Pneumococcus* type 20. This is of interest as Neill and Hehre had shown immunological relationships between *Pneumococcus* type 20 and dextran. No similar relationship was traced in any of the other reactors.

In 3 of these cases the more common symptoms and manifestations of allergy (such as asthma, urticaria) were absent. Instead they presented signs of cardiovascular collapse with a drop in blood pressure, cyanosis, and in 1 patient definite lowering of temperature of the extremities. All required supportive therapy oxygen by mask and 5 per cent glucose and saline. Hemoconcentration was present in each. Plasma sodium, potassium, chlorides and carbon dioxide determinations were carried out in Case 19 but no significant changes were found.

It is likely that here again we have an anaphylactoid or anaphylactoid reaction but without clinical involvement of a different tissue. It is

¹Personal communication.

of interest to recall at this point the work of Hanzlik and Karsner who in 1920 had shown that many colloidal substances on intravenous administration will give rise to anaphylactoid phenomena of circulatory and respiratory nature.

Cyanosis was an interesting phenomenon noticed in several of these cases. This discoloration was at first discounted because blood volume studies by means of the Evans blue dye technique were being carried out. However in other patients who did not have these blood volume measurements cyanosis of mild degree was also observed. In all cases blood samples drawn after the macrose infusion appeared darker than did the preliminary blood specimen. Shaking this blood would lighten the color but later after settling had taken place the blood would again become darker than its control. In patient 19 where cyanosis was an important feature together with vascular collapse an analysis of the oxygen carrying capacity revealed a normal value of 18.9 volumes per cent. In carrying out this analysis however the chemist remarked that it took abnormally long for the blood to be in the speed of oxygenation of the erythrocytes has been observed both in the human and in the experimental animal after polyvinyl alcohol methyl cellulose, acacia, and gelatin (6, 19, 26). A similar discoloration of blood was noticed when Nungester added *Pneumococcus* polysaccharide to blood. Christie, Phatak, and Olney reported in 1935 that although the carbon dioxide content of the blood after administration of acacia decreased proportionately with the hemodilution as observed by Hanzlik, the oxygen content fell at the end of 1 hour to a more marked degree than would be expected and that this effect persisted for more than 24 hours. This effect has been attributed by Hueper to the formation of surface films of the macromolecular matter on the erythrocytes with resulting impairment of the gaseous interchange across the interface.

Two other possible reasons for the cyanosis in these cases are related to the well known effect of macromolecular substances in increasing the coagulation of erythrocytes as first noted by Hanzlik and Karsner in 1920 and

Fåhræus in 1921 (1) Thus conglutination could result in a decreased functioning surface area for use in the interchange of gases. (2) It also might result in slowing and obstructing the flow of blood in the smaller capillaries. Fåhræus, Parkins, Hopps, and Youngner and Nungester all have reported the microscopic visualization of capillary blood flow following the administration of various colloidal solutions and plasma substitutes. Each of these authors noted that pseudoagglutination of red blood cells took place. Their observations, however, show no unanimity of opinion as to whether or not slowing of the blood flow actually did take place as a result of this agglutination.

CONCLUSIONS

1. Thirty volunteer patients at the Presbyterian Hospital were given infusions of macrose—a 6 per cent solution of partially hydrolyzed dextran. The lot number of the solution used in each case was B2-2. Ten of these patients had reactions of either anaphylactic or anaphylactoid nature. A striking increase in sedimentation rate was noted in all. These reactions are believed to be specifically related to the molecular structure of the dextran molecule and its concentration in the plasma. A possibility exists that some undiscovered impurity was present in this solution but in view of the work of Neill and Hehre we feel that the weight of evidence incriminates the dextran molecule itself.

2. No great changes in the levels of the various blood electrolytes were found following the administration of dextran solution. Studies were carried out on the plasma sodium, potassium, chlorides, and carbon dioxide.

3. Satisfactory hemodilution and increase in plasma volume was noted after macrose. This effect persisted for a period of at least 24 hours.

4. Plasma proteins regenerated rapidly following exsanguination and replacement of the blood loss with macrose solution.

5. Autopsy studies on 6 dogs who received macrose, Lot B2-2 in large quantities revealed focal degenerative lesions in the livers and kidneys and minimal reticuloendothelial hyperplasia in the spleen.

NOTE.—The clinical testing of macrose solution was carried out at The Presbyterian Hospital in the City of New York on the Second Surgical Division of the late Dr. Hugh Auchincloss, between June 5, 1945, and July 5, 1946. In all, 30 patients received macrose solution intravenously. Because of the severity of the reaction encountered, in Case 30 with recurrent osteomyelitis, it was considered unwise to continue the clinical testing of this batch of solution beyond this date.

Methods for determinations

The *hemocrits* were centrifuged in Sanford-Magath tubes for one hour at 3,000 r.p.m. using heparin as an anticoagulant (36).

The *sedimentation rates* were determined by the Rourke-Ernest method (35).

The *concentration of macrose in plasma* was determined by the method of Harry Hint, Pharmacia, Ltd. (unpublished) as adapted by Margaret E. Smith for the Evelyn photoelectric colorimeter.

The *whole blood specific gravity determinations* were obtained by the method described by Barbour and Hamilton (3).

The *plasma volume determinations* were done by the dye (T-824 or Evans blue) dilution method of Gregersen (4).

The *plasma proteins* were determined by the biuret method of Kingley (2) as modified by Mchl (27) and adapted for use with the Evelyn photoelectric colorimeter.

The *carbon dioxide combining power* was determined by the method of Van Slyke and Neill (30).

The *plasma chlorides* were determined by the potentiometric titration method (34).

The *plasma sodium levels* were obtained by the gravimetric method of Butler and Tuttle (4).

The *potassium analyses* were done by modification of the argentocobaltinitrite method (37).

CYTOLOGIC EXAMINATION OF SPUTUM AND BRONCHIAL SE- CRETIONS IN DIAGNOSIS OF BRONCHOGENIC CARCINOMA

IT is becoming evident that primary carcinoma of the lung is a much commoner lesion than has been recognized in the past. In part this results from the inaccessibility of a good portion of the bronchial tree to ordinary bronchoscopic methods. It has been claimed that the cytologic examination of sputum and bronchial secretions results in many more definitive diagnoses of cancer of the lung.

The rationale for the examination of secretions throughout the body for carcinoma depends on the exfoliation of carcinoma cells from malignant tumors having a free surface. Cancer cells differ from normal cells by having large nuclei, in irregularity in size of cell and nucleus, altered nuclear cytoplasmic ratio, hyperchromatism and large nucleoli.

This principle was noted by Papanicolaou¹ in 1928 while working with vaginal secretions.

Up to 1935 only an occasional diagnosis of carcinoma of the lung had been made by the examination of the sputum and usually then when a fragment of tumor was identified in the sputum. In 1935 Dudgeon and Wrigley² devised a special technique for the cytologic examination of sputum. This method involved the fixation of wet films in Schaudinn's solution and staining with hematoxylin and eosin. By this means they were able to demonstrate malignant cells in 63 per cent of 58 cases of proved bronchogenic carcinoma. Barrett³ in 1938 and Gower⁴ in 1943 reported positive results of examination of sputum in 68 and 64 per cent of cases, respectively. A monograph was written on the subject by Wandall⁵ of Copenhagen in 1944. He found that the sputum contained cancer cells in 84 per cent of 100 cases of proved bronchogenic carcinoma. Results of bronchoscopic biopsy were positive in 55 per cent of patients who were studied in this manner. A study of secretions removed bronchoscopically from patients was carried out by Herbut and Clerf⁶ in 1946. They reported positive results in 82.4 per cent of 57 cases of proved bronchogenic carcinoma. It was felt by Herbut and Clerf that sputum was an inaccurate and too time-consuming material for study. Papanicolaou¹ in 1946 reported positive results from the examination

of sputum in 88 per cent of 25 cases of proved bronchogenic carcinoma. Woolner and McDonald examined sputum, bronchial secretions and bronchial washings and have felt that all materials should be utilized. During this time they have made a positive diagnosis of cancer cells in approximately 325 cases.¹⁻⁶ The stain which they have employed has been hematoxylin and eosin.

Bronchial washings are obtained by instilling 5 cubic centimeters of saline solution into the affected bronchus and recovering the material. This can be centrifuged and the sediment stained after smearing. Bronchial secretions as obtained through the bronchoscope can be handled in comparable fashion to sputum. The advantages of bronchial secretions and bronchial washings are that material can be more or less selectively obtained from the affected bronchus. The specimen is undiluted with extraneous material such as one obtains from the mouth and other parts of the lung. It has the further advantage that it makes possible the examination of patients who cannot produce sputum and it takes less time to examine than does sputum. The most obvious advantage of sputum is its ease of collection and the facility with which one can obtain multiple specimens for examination. In cytologic work examination of multiple specimens is very important.

The authors have employed the smear technique rather than placing the material in a paraffin block and sectioning. Probably the

most important part of the technique is the inclusion of Papanicolaou's suggestion namely wet fixation of the smears in a fixative (50 per cent ether and 50 per cent of 95 per cent ethyl alcohol). It becomes very obvious that considerable experience is necessary to run a cytologic laboratory. The average time required for the examination of a single smear of sputum is ten minutes; five smears are examined from each sputum and in cases in which cancer cells cannot be found three specimens of sputum have been examined with a total average examination time of two and one half hours. If the patient is ambulatory he is given 30 cubic centimeters of 95 per cent ethyl alcohol in a bottle and the sputum is collected in this fixative. This obviates the necessity of obtaining fresh material which is very difficult particularly on an out-patient service.

In Woolner and McDonald's first 300 positive specimens of sputum and bronchial secretions they had 4 proved false positives, 3 of which occurred in the first 150 cases. The vast majority of positive cases proved to be primary bronchogenic carcinoma. They demonstrated that cells were exfoliated in many cases of alveolar carcinoma, but only occasionally in metastatic carcinoma and never in adenoma of the bronchus. Occasionally positive cells could be recovered in cases of cancer of the larynx and of the esophagus.

Of those patients in this group who underwent bronchoscopy, positive tissue was obtained in 55 per cent of incidences. It would appear therefore, that the cytologic examination of sputum and bronchial secretions is of definite aid in the diagnosis of primary carcinoma of the lung.

In an endeavor to determine the false negative error, they investigated a group of 588 cases in which cytologic examination was carried out during the time 100 positive re-

sults were obtained. The final clinical diagnosis in this group of cases proved to be bronchogenic carcinoma 147 cases indeterminate probably nonneoplastic, 39 cases probably metastatic carcinoma 30 cases adenoma of the bronchus 5 cases nonneoplastic pulmonary disease 367 cases. The smear technique thus resulted in 68 per cent positive results a figure which would closely approximate that of the English workers. It would appear that the false positive error should be less than 2 per cent while the false negative error is about 30 per cent. Under such circumstances, the method will prove to be a valuable diagnostic aid in cases of cancer of the lung.

THE RISK OF SURGICAL OPERATION

AN inevitable question to be dealt with whenever surgical operation is being considered is its risk. The patient may ask directly how dangerous the operation is, the point may be covered implicitly in the discussion or the patient may leave the question entirely to the surgeon's best judgment. The risk of operation is frequently difficult to weigh the danger must be balanced against the probable benefit an intensely personal relationship between surgeon and patient is involved, yet other members of the patient's family other possible patients and other physicians may be concerned in the decision. All these points create an intellectual challenge of the first order for the surgeon, and the challenge is just as real in relation to the surgical treatment of advancing and otherwise incurable disease as in "elective" operations.

In the first place it is obvious that the patient consulting a particular surgeon is concerned with the risk of operation as performed

by that particular surgeon with his particular skill and facilities. Morbidity or mortality figures from other clinics may have little bearing on the case at hand. In this connection we should note a source of error prevalent in medical graduate teaching. The error might be called a confusion of identity. For example, an experienced gynecological surgeon may report from a large clinic that the mortality rate of total hysterectomy is only a fraction of a per cent higher than that of supravaginal hysterectomy and further may show that the incidence of carcinoma in the remaining vaginal stump more than nullifies the slight additional risk of total hysterectomy. Or a surgeon with a mortality rate of one per cent for subtotal gastric resection for supposedly benign gastric ulcer may report an incidence of 10 per cent for carcinoma in the removed specimens and conclude that all chronic gastric ulcers should be treated by subtotal gastric resection. For the two surgeons the facts are present and the conclusions valid. However when the conclusions are passed with the weight of authority to surgeons throughout the country serious harm may be done. The point may be missed that sound practice for a specialist in a large teaching center may not be safe practice for the average surgeon.

In the next place the patient is concerned with the operative risk for him as an individual and although he may be interested in the results his surgeon achieved in the last one hundred cases the significant point is the personal factor. What is his physiological reserve and how do his age and associated diseases affect his chances? How does his obesity hypertension coronary sclerosis, or pulmonary emphysema influence the risk of operation? Statistical abstractions would have little place in helping the average patient make up his mind in favor of surgical operation. The experienced surgeon is well aware

of the importance of having his patient come to operation with mental composure, a factor which in itself may affect the outcome.

Assessment of the risk of operation is complicated by the continuous forward motion of surgery and what may have seemed a reasonable hazard ten years ago may no longer be defensible. In the space of a few years after the discovery of vitamin K the mortality rate for operations on the bile ducts of jaundiced patients fell to one half or less. Sulfonamides, penicillin and streptomycin have changed the picture overnight and broadened the scope of surgery. Improvements in anesthesia and the knowledge of how to treat depleted or shocked patients have lessened the risk of operation and require constant re-evaluation of the question of surgical risk. Development of the residency training system reduces operative hazards and postoperative morbidity. Thus the surgeon is called on to estimate not a fixed value but a factor which is changing with general improvements in surgery as well as with his own increasing skill and experience. It is the obligation of referring physicians to keep these matters in mind also. It would be inexcusable for gastroenterologists for example to weigh the indications for colectomy in chronic ulcerative colitis in terms of the operative risk of twenty years ago.

The problem has special applications in relation to the uncommon surgical lesion the new operation or the specially complicated procedure. There are those who urge that the operative repair of strictures of the common duct should be done in a few centers by surgeons with unusual experience in the field. The operations for correction of vascular or of cardiac anomalies or the shunt operations for portal hypertension or resection of duodenum and pancreas tend to be practiced in only a few clinics, and unquestionably the results are better in a few rather than many

hands. Should all patients who need such specialized surgery be referred to certain centers? The question is not easy for there are personal social and economic factors involved as well as problems of graduate education and medical research. Nevertheless for the surgeon with less experience who is called upon to perform such procedures the question has ethical and moral aspects for he may sincerely feel that the patient is asking to be subjected to a greater risk than might result in a center for such surgery.

Since the risk of any major surgical operation will depend among other things on the condition of the patient the surgeon can influence the results in a series of cases by the extent to which he screens his patients and rejects poor risk cases. A too cautious attitude and anxious regard for mortality statistics on the part of the surgeon are not wholly commendable for presumably he should be bent on doing the most good for the most patients. Nevertheless it is possible to discredit an operative procedure by applying it as a last resort measure in desperate cases. Referring physicians as well as the laity in the community may lose interest, with the result that entirely suitable cases are not given their chance. This point is of special importance in smaller communities and in hospitals for chronic disease notably in hospitals for tuberculosis. Furthermore, the surgeon himself may become disheartened and abandon the procedure. And yet if a patient has one chance in ten of surviving an operation which promises cure and no chance of surviving without it, should he not be operated on? In bald form the question may seem easy but the problem in practice is never so clear-cut.

Here is but one illustration of the intellectual challenge of surgery and of the comprehensive demands on the surgeon's personal qualifications

THE CASE OF THE ECCENTRIC LEXICOGRAPHER

ESTHER H VINCENT Evanston Illinois

SAMUEL JOHNSON so famous for his intellectual abilities, is almost equally famous for his physical disabilities. Indeed it was something of a shock to look upon him for the first time. Huge and grotesque, his tall, stooped figure was topped by a massive head with heavy scarred features, the thick-lipped mouth keeping up a continuous business of opening and shutting. His great body was never quiet—the fingers twirling, the hands twisting, the feet shuffling, the trunk rolling about. His clothes, thrown on anyhow, presented a shabby medley of ill-fitting wig, wrinkled coat, soiled shirt, falling stockings and scuffed shoes. And yet, except for Shakespeare, no writer of English has a larger or more eager assembly of scholarly fans.

When Sam was born in Lichfield in 1709, his father Michael was already past fifty-two and his mother Sarah was past forty. They had been married for some three years, and Samuel was the first of their two children. Besides keeping a bookshop at Lichfield, industrious Michael sometimes sold books in a stall at Birmingham, sometimes at other nearby towns. Michael wasn't much of a business-man and, although he achieved a few local honors, he and Sarah were almost always hearing the wolf at the door. Sarah was inclined to be a bit arrogant about her family being better than Michael's, but the only member known to us is her nephew, the notorious 'Parson Ford' said to be the clergyman sitting next to the punch bowl in Hogarth's *Modern Midnight Conversation*.

Michael had a large, robust body and a strong active mind, both of which he handed down to Samuel. But along with this goodly heritage went a 'vile melancholy' that plagued the both of them all their days. Sarah seems to have been a woman of unique understanding and of deep religious feeling. Both Michael and Sarah lived to a good old age, Sarah reaching the age of ninety.

From the Archibald Church Library, Northwestern University Medical School.

The infant Samuel was far from promising. Born almost dead, he was unable so much as to cry out for a considerable time. But the man midwife declared, 'Here is a brave boy!' Dr. Samuel Swinfen, the Johnson's young lodger and one of Sam's godfathers, said that he never knew of any child so difficult to rear. The baby stayed for some ten weeks at the house of a wet nurse who was blamed for his sore eyes. The eye trouble was probably tuberculous keratitis, but of course Michael and Sarah couldn't have been expected to realize it. A few weeks after birth, Sam developed some sort of lesion on his body also, and while he was still nursing an 'issue' was cut in his left arm and left open until he was six. Some time in his second year he was taken to a neighboring town to be examined by an oculist, and the next year to London. There, on the advice of Sir John Floyer, the distinguished physician, young Sam was touched for scrofula by Queen Anne, whom the child ever after remembered fearfully as 'a lady in diamonds and a long black hood.'

The little fellow was sent to a dame school and then to grammar schools at Lichfield and Stourbridge. Foolishly proud of him, Michael continually tried to make him 'show off,' thus causing the intelligent lad no end of humiliation. His phenomenal memory was considered a fair field for exploitation by his teachers also. Even his school fellows recognized the clumsy, diseased boy's intellectual superiority, and three of them used to mount him on their shoulders and carry him to school.

Two years were spent in 'lounging' in binding, selling and reading books, and in making friends with Gilbert Walmesley and David Garrick. In 1728 young Johnson went up to Oxford, probably as result of a legacy left to his mother at that time. He stayed at the University for little more than a year, leaving for two reasons—too little money and too much melancholy. Hitherto he had compensated for poverty, disfigurement, and inability at sports by means of his intellect and a

The infant Samuel was far from promising. Born almost dead he was unable so much as to cry out for a considerable time. But the man midwife declared. Here is a brave boy! Dr Samuel Swinfin the Johnson's young lodger and one of Sam's godfathers, said that he never knew of any child so difficult to rear. The baby stayed for some ten weeks at the house of a wet nurse who was blamed for his sore eyes. The eye trouble was probably tuberculous keratitis, but of course Michael and Sarah couldn't have been expected to realize it. A few weeks after birth Sam developed some sort of lesion on his body, also and while he was still nursing an issue was cut in his left arm and left open until he was six. Some time in his second year he was taken to a neighboring town to be examined by an oculist and the next year to London. There on the advice of Sir John Floyer the distinguished physician young Sam was touched for scrofula by Queen Anne, whom the child ever after remembered fearfully as a lady in diamonds and a long black hood.

The little fellow was sent to a dame school and then to grammar schools at Lichfield and Stourbridge. Foolishly proud of him, Michael continually tried to make him show off thus causing the intelligent lad no end of humiliation. His phenomenal memory was considered a fair field for exploitation by his teachers, also. Even his school fellows recognized the clumsy diseased boy's intellectual superiority and three of them used to mount him on their shoulders and carry him to school.

Two years were spent in lounging in binding selling and reading books, and in making friends with Gilbert Walmesley and David Garrick. In 1728, young Johnson went up to Oxford, probably as result of a legacy left to his mother at that time. He stayed at the University for little more than a year leaving for two reasons—too little money and too much melancholy. Hitherto he had compensated for poverty, disfigurement, and inability at sports by means of his intellect and a

certain gay wit that he was accustomed to use with much gusto. But now there came a sudden change. While on a short visit home Johnson evidently suffered some mental crisis or accumulation of crises, and thereafter suffered eternal sadness. Oddly enough his gaiety kept company with his melancholy making him a paradox, a pessimist with an enormous zest for life.

His mental depression drove him to seek relief from Dr Swinfen then of Birmingham, who so admired Johnson's self-written "case-report" that, forgetful of professional ethics, he showed it to several friends. According to Boswell, Johnson "felt himself overwhelmed with a horrible hypochondria, with perpetual irritation, fretfulness, and impatience and with a dejection, gloom, and despair which made existence a misery. He attributed to paternal inheritance the melancholy which made him mad all his life at least not sober." It was the indiscreet Dr Swinfen who suggested to the poor youth that his melancholy might some day lead to madness. But in spite of his fear of insanity and death, the courageous Sam yet maintained his gorgeous appetite for learning, literature, good food and good company.

On leaving Oxford, Johnson got a series of teaching jobs, none of them very satisfactory, and made his start in the literary field by writing essays, prefaces, and the like. In 1731 his father died, leaving his ailing business to Sarah and their younger son Nathaniel. About this time too, Samuel met his future wife, Tetty Porter a widow twenty years his senior and the mother of three children. Their mutual attraction is still a mystery but marry they did, in 1735, and lived happily together until Tetty's death in 1752 just as Johnson was beginning to be famous.

Meanwhile, Johnson, handicapped by an unprepossessing appearance, an indolent melancholy poor eyesight and poor hearing, tried to set up a school of his own near Lichfield. This school lasted less than two years, but one of the few pupils was the dramatic David Garrick. Soon after brother Nathaniel died, possibly by his own hand, and Tetty's daughter eventually went to live with the old mother.

Samuel was drawn inevitably to the big city where he rambled along on his literary way writing, grubbing, planning, talking and living hugely amid the elegant squalor of Hanoverian London. At first sight strangers sometimes mistook him for an idiot, as did Hogarth, who first saw him at the house of novelist Samuel Richardson, "standing at a window in the room, shaking his head and rolling himself about in a ridiculous manner. Hogarth was struck with amaze-

ment when Johnson began to talk. Talking was necessary to Johnson, and in order to assure himself of a permanent audience, he founded a social club which later became the famous Ivy Lane Club. His list of friends grew long and interestingly varied—Garrick, Reynolds, Goldsmith, Edmund Burke and the gay Topham Beauclerk. Among the ten charter members of the Club were three physicians, William McGhie, almost the only Scotsman that Johnson ever could endure, young Edmund Barker and "Dear Balhurst, the 'good hater' whom Johnson loved.

In that day medicine existed for the benefit of its practitioners. In ordinary cases the physician did not bother to make a personal call. He used an intermediary an apothecary who reported the symptoms and received the Latin-written "bill" which specified the treatment. The apothecary then administered to the patient the clysters, purges, or emetics, and only called a barber-surgeon or a cupper when bleeding or cupping were necessary. The physician himself came only in serious cases and then charged a guinea or two-thirds of a guinea per mile. Consequently the poor had to depend on unlicensed practitioners and quacks. Many people dosed themselves according to their own ideas. Johnson was not alone in his faith in Dr James's Powder for Fevers and Other Inflammatory Distempers, "a dangerous mixture of antimony and phosphate of lime, concocted by an old home-town friend.

Johnson loved the company of medical men and often said that they did more good to mankind without a prospect of reward than any profession of men whatever. He knew William Heberden, whom he regarded as "ultimus Romanorum, the last of the learned physicians. Then there was Dr Nugent, Burke's father-in-law and Dr Fordyce a St. Thomas's staff member a great gourmand, and the author of a popular textbook of medicine. When Johnson thought himself seriously ill, he sometimes consulted his old friend, Dr Thomas Lawrence, a past-president of the Royal College of Physicians. Lawrence and Johnson had a fellow-feeling for one another as both were the victims of strange tics and convulsions, and both were hard of hearing. Usually however Johnson sought the advice of a member of his own household, Robert Levett.

Levett was one of those queer dependents whom Johnson gathered around him partly to serve as an outlet for his natural compassion, partly to keep him company after the death of Tetty. Levett and poor blind Anna Williams, together with the negro servant Francis Barber were the permanent occupants of that nest of odd birds

that kindly Samuel kept in his house. Levett was an uncouth fellow, a forlorn, middle-aged hanger on who had been apprenticed to a Hull draper had gleaned some medical lore from a neighbor had drugged in London to make money enough to take him to Paris, where he worked as a waiter in cafés frequented by surgeons. For five years he got free tickets to the best French lectures on the medical sciences. Then he returned to London where he healed the poor for a crust of bread a glass of gin, a few coins, or whatever they had to give him. He continued to attend such lectures as were free, and may be said to have gained his medical education by ear.

Johnson had very definite ideas on the subject of medicine and his views were considerably ahead of most of the physicians of his time. He disapproved of periodical bleeding and also of the current eighteenth century practice of polypharmacy. He fancied himself as a writer of prescriptions, not only for his own ills, but for those of his friends. To rheumatic Bennett Langton he sent a formula for sulphur mustard seed, sugar and infusion of the root of lovage. To Dr Lawrence, who suffered hemiplegia and aphasia, he suggested electrical treatments, and to Miss Boothby he prescribed powdered dry orange peel for dyspepsia.

He seems never to have paid fees, once remarking 'Illness is of little expense to me, thanks to the generosity of my physicians. He may have given them books in exchange for treatment, for when Dr Warren attended him in his last illness, he said 'Sir you come at the eleventh hour but you shall be paid the same as your fellow labourers. Francis, put into Dr Warren's coach a copy of the *Lives*. As a patient he was most trying, constantly interfering with his treatment. Long suffering Dr Lawrence once cried 'If he would come and beat me once a week, I could bear it. But to hear his complaints is more than I can support.' Johnson kept a Latin diary of the state of his health and of the effect upon it of the remedies used.

Never a worshipper of Bacchus, Johnson eventually gave up alcoholic drinks altogether and substituted tea-drinking to the extent of fifteen or sixteen cups a day. During his later years, tea, talk and lemonade were his only solace. Smoking he never cared for.

The world has reason to be grateful to George III, whose well-intentioned stupidity finally blundered into giving the Great Moralist a pension. Within five years of gaining economic security, Samuel had moved into a comfortable house, had met Boswell had begun his happy friendship

with the Thrales, had founded with Sir Joshua Reynolds, the famous Club and had begun the series of visits and ramblings that reached their climax in the tour to the Hebrides. He had now become a public personage, often satirized and caricatured, but nevertheless a sort of British institution. At his morning receptions he drank tea in bed and declaimed between sips. At noon he would dine in a tavern, stay until late after noon drink more tea at the house of a friend, and eventually retire supperless to his home to read and write far into the night.

Dr John Lettsom says of him at this period, In company I neither found him austere nor dogmatical he certainly was not polite, but he was not rude. He was sometimes jocular but you felt as if you were playing with a lion's paw. His body was large, his features strong his face scarred and furrowed with scrophula. He had a heavy look but when he spoke it was like lightning out of a dark cloud.

His last days were embittered by the death of Henry Thrale and by the defection of Henry's widow Hester. Apoplexy claimed the food-loving Henry and Mrs Thrale, probably Johnson's dearest friend, instead of centering her life around Johnson as he had expected, became infatuated with a young Italian singer named Pozzi, and was lost to Johnson as well as to English society.

Johnson was a robust man, but not a healthy one. He never knew a day's complete ease in his life. But in spite of his ailments, he had great muscular strength was a big eater and was capable of sitting up to all hours. When he was sixty he bathed in the sea at Brighton in October. At sixty five he had an attack of gout, and at sixty-seven he had another attack, together with difficult and laborous respiration for which he was bled rather heavily. The next year he said, 'The hand of time or disease is heavy upon me. I pass restless and uneasy nights, harassed with convulsions of my breast, and flatulencies of my stomach.

At the age of forty-six he had had laryngitis, but no further respiratory diseases until he was sixty three, when he was plagued by a winter cough which recurred at intervals for some years. Venesection was the treatment. Asthma laid him low during the winter of 1781-82 and for the rest of his life he breathed with difficulty. Opium brought him great relief and his dose rose to three grains daily. But on his seventy-second birthday he thought he had more bodily strength and vigor than was common.

Dropsy was first noticed in 1783 by Sir Lucas Pepys. Diagnosis of sarcocele was made by Per

civall Pott in consultation with William Cruikshank, and it was put up to Cruikshank to make an excision. But Cruikshank was afraid of operative shock, and while he delayed, "the sarcocele ran off at an orifice made for mere experiment." At seventy-four Johnson had a stroke. He wrote to Mrs. Thrale

"I went to bed, and in a short time awoke and sat up as has long been my custom, when I felt a confusion and indistinctness in my head, which lasted, I suppose, about half a minute. I was alarmed, and prayed God that however He might affect my body He would spare my understanding. This prayer that I might try the integrity of my faculties, I made in Latin verse. The lines were not very good, but I knew them not to be very good, I made them easily and concluded myself to be unimpaired in my faculties. Soon after I perceived that I had suffered a paralytic stroke, and my speech was taken from me.

He tried to treat himself with wine, thinking to rouse the vocal organs. Surprised at his own apathy he sent for Brocklesby and Heberden, who blistered him and gave him salts of hartshorn. Recovery from the hemiplegia and aphasia was rapid and complete.

Later in the year gout plagued him again, and he had an attack of spasmodic asthma of great violence that forced him to sit up all night. Dropsy became grave increasing to the thighs, and by February of 1784 was so extensive that Johnson had Boswell consult five Edinburgh physicians, including Cullen, Hope and Moore. The five, despite the disadvantage of long-distance prescribing, recommended squills, which Johnson took with such vigor as to produce unpleasant reactions. His only other remedy was rhubarb, then a rare and costly drug. He was aware now of precordial constriction on exposure to cold, and had to take tincture of laudanum for night dyspnea. "My diseases are an asthma, and a dropsy, and what is less curable seventy-five," he said.

About the middle of March, after a day of prayer and fasting, Johnson had a urinary crisis, passed twenty pints of urine and became free from the dropsy that had kept him indoors for over a hundred days. After a trip to Oxford and Lichfield which tired still further his already tired heart, the dropsy returned but was controlled by drugs and rest until November. In December the edema was so great that his legs were incised. To poor Cruikshank he cried, "Deeper deeper, I will abide the consequence. You are afraid of your reputation but that is nothing to me!" Still not satisfied that the incisions were deep enough, he got a lancet and cut himself again and then thrust a pair of scissors into the calf of each leg. Because of this action a rumor started that he had committed suicide.

When Dr. Warren expressed the hope that he was better the death-fearing Johnson bravely replied, "No sir you cannot conceive with what acceleration I advance towards death!" And when Dr. Brocklesby told him that there was no hope for him, he said, "I will take no more physic, not even my opiates for I have prayed that I may render up my soul to God unclouded. And so he died.

A post-mortem examination was performed in the Library of the Royal College of Physicians two days after death by Dr. James Wilson, Cruikshank and Heberden being present. The lungs did not collapse but remained distended apparently without the power of contraction. The air cells on the lung surface were much enlarged, and the right lobe adhered strongly to the diaphragm. No water was found in the thorax cavity. The heart was very large and the valves of the aorta were beginning to ossify. Not more than the usual amount of fluid was in the pericardium. Incipient peritoneal inflammation and ascites appeared in the peritoneum. The liver and spleen were large and firm, the spleen having almost the feel of cartilage. The gall bladder contained a stone the size of a pigeon's egg. The account also mentions "hydatids" in the right kidney and destruction of the left kidney with two very large hydatids formed in its place. These were probably common renal cysts, not distinguished from hydatids until 1793, when Matthew Baillie published his book on morbid anatomy.

The story is that of a man with good family history who acquired gout and a hypertension leading to a transient stroke. Emphysema aggravated the symptoms of heart failure. Rest, squills and opium brought some relief but too much travel brought on another attack, and death ensued.

Like many literary men, Johnson suffered much from impaired vision. Fanny Burney spoke of him as looking at the books in her father's library "almost touching the backs of them with his eyelashes as he read their titles. His short sight would explain his lack of interest in pictures, sculpture and architecture, just as his defective hearing would explain his lack of interest in music. According to Treves his poor vision was due to a leucomatous change in the cornea as a result of tuberculous keratitis, probably connected with the tuberculous glands in his neck. In spite of treatment, the sight of the left eye was lost. Johnson was very sensitive about his myopia and never wore spectacles. Twice in his life his right eye became inflamed from much reading of small print.

His gastrointestinal symptoms were probably the result of his erratic eating. His gallstone may have been pure cholesterol, but the adhesions found between the folds of the jejunum could have been caused by cholecystitis.

Some endocrine disorder may have produced his bulky form and massive features. Probably there was some degree of hyperpituitarism combined with some hypothyroidism. His hands were not unduly large.

A strong sense of inferiority could very well result from a childhood such as Johnson's. Scrofula and defective vision combined with a clumsy body kept him from mixing with other boys at games. His ego instincts could find outlet only in intellectual distinction. He no doubt found partial compensation, too, in fantasy and in the friendship of young handsome gay men like Beauclerk, for instance. His melancholy and his tics were marks of his frustrations. His melancholy he tried to mitigate by constant companionship—he had a morbid dread of being alone. His tics were only habit spasms or motor tics. As he walked along a street, he felt obsessed to touch certain posts, turning back if he missed one.

The suggestion has been made that Johnson was sexually impotent. To be sure he married

but his bride was an elderly widow, and he may have felt that he could marry her without doing her any injustice. Boswell says that he was invariably chaste, but also that his amorous side was very strong and that he used to take women to taverns in order to hear them relate their stories. This could have been an indirect method of sexual satisfaction. And his declared wish not to have children could have been a rationalization of his knowledge that he never could have any. Be that as it may, he certainly suffered from some inner emotional conflict which tormented him all his days.

He was buried in Westminster Abbey among the great of Britain—a true-born Englishman of the eighteenth century.

REVIEWS OF NEW BOOKS

THE book *British Surgical Practice* is the third in a series of volumes two of which have been reviewed previously. The subjects presented alphabetically, extend from "Caesarean Section" through Erythema.

Once again there is a profusion of illustrations throughout the book which are pleasing in their simplicity and add a great deal to the clarity of the work. The chapter on caesarean section is well outlined. In fact, the entire book continues what is hoped will be the practice throughout all the volumes namely that of supplying not only clear chapter and subchapter titles but also convenient marginal index labels. Perhaps the most significant part of the chapter on caesarean section is the full list of indications. In any discussion of this topic the indications come in for close scrutiny and apparently in all cases surgeons are subject to criticism should promiscuity be the practice. The usual varieties of the operation are outlined in a simple clear fashion, and the illustrations are well done.

It is interesting to note that an entire chapter is devoted to tumors of the carotid body. Recently in the United States, authorities have been outspoken in their frank admission of theories which have heretofore been held rather secret. Lahey is now emphasizing repeatedly and his lead is being followed by other authorities, that when such a tumor involves the great vessels in such a way that a sacrifice of the vessels will result in not only a high incidence of hemiplegia but also a forbidding mortality rate, such treatment is decidedly out of order. The author of this chapter agrees with the middle group of American surgeons who feel that only so per cent of such tumors are malignant in the first place. One will recall the argument used in this country today by some outstanding authorities that there is a possibility of malignancy in 50 per cent. The diagnosis of carotid body tumor is made quite evident, and the treatment suggested agrees very closely with that accepted at present in this country, namely that if exploration reveals too great a risk in considering removal, the surgeon should be satisfied with biopsy alone.

There is some general discussion on cellulitis, lymphangitis, erysipelas and so forth. This discussion is divided into two parts namely that on general infections and that on localizing infections, such as those in the pelvis. Chemotherapy is mentioned but there is a notable lack of discussion in regard to penicillin and streptomycin. One derives the impression that the chapter was written prior to the

general availability of the latter agents, although in the discussion of the cases of pelvic cellulitis it appears that penicillin has indeed come in for its logical usage.

A chapter on the cervical rib and the scalenus syndrome is complete and offers a good bibliography especially referring to the work of Adson.

Perhaps a bit out of place in this volume, from the viewpoint of the casual American surgeon, is the inclusion of a discussion of chemical warfare and its surgical aspects. Probably those persons who were not subject to the mass bombings would not be as apprehensive about the possibilities but one can appreciate the thoughts that must have gone through the mind of the British surgeon at that time. The discussion is timely and agrees well with the material promulgated during the recent war by not only the American army and navy medical departments, but also the civilian defense groups.

There is a separate chapter on chemotherapy which is delightful the average volume on surgery would overlook such a handy outline. The selection of the various drugs is discussed their methods of administration are rendered crystal clear their toxic effects are pointed out and the beneficial results to be expected from the chemotherapeutic agents are discussed with frankness.

There is a section on coagulants and anticoagulants. The preliminary outline of the mechanisms of clotting and bleeding as well as a discussion of the prothrombin factors, is very timely. The various agents for coagulation are mentioned briefly with a short characterization of each. The reader is not told, but one gets the impression that perhaps in Great Britain these agents are employed more widely than they are at present in the United States. The anticoagulants, namely heparin and dicumarol, are given proper space. Fortunately there is a good list of references here which those seriously interested would do well to employ.

In the chapter on colitis the outstanding feature is the illustrations regarding various procedures to be used occasionally. Several types of colectomy and appendectomy are stressed. Recently it has been stated in the United States by many authorities that "open operations" upon the colon itself have little place in cases of colitis. It is felt that since the disease is usually so generalized in the colon, the correct part of the intestine to be employed is the ileum. This is not made clear in the present volume. Ileostomy which is employed extensively in the United States comes in for a rather thorough discussion later in the chapter. The illustrations once again are very good and the technique is given thorough discussion. Fortunately there is also a discussion of the appliances that may be used, together with

BRITISH SURGICAL PRACTICE. Under the General Editorship of Sir Ernest Rock Carling, F.R.C.S., F.R.C.P. and J. Paterson Ross, M.S., F.R.C.S. Volume 3. London: Butterworth & Co., Ltd. 82 Leaden: The C. V. Mosby Co. 918.

agents for protecting the skin. Apparently the British surgeons experience the same types of complication that we experience in this country—namely, prolapse of the ileum, formation of abscesses and fistulas and intestinal obstruction. The writer is well advised in generalizing his statements in regard to colectomy in this disease. The exact time interval between ileostomy and colostomy remains controversial, although there is more and more tendency now toward uniformity. The possibility of carcinoma arising in the diseased colon is mentioned along with other complications which should remind the surgeon to resort to colectomy at the optimal time.

There is a rather long and complete chapter on carcinoma of the colon by no less an authority than Sir Hugh Devine. This offers almost all that the average practitioner needs to know about the field today. In addition to the thorough discussion of the clinical features of the disease, the various methods of dealing surgically with carcinomas located at different points of the colon are outlined. It is difficult to guess just when this chapter was written. The role of chemotherapy is given full credit and the failure of penicillin to be effective against the *Bacillus coli* is stressed. However the operative techniques seem rather old fashioned and in fact, in many centers in the United States today would be considered so. The so called extraperitoneal resection of the terminal part of the ileum and right portion of the colon leaving a double barreled stoma is now largely reserved for emergency use in this country. Actually the wide acceptance of one stage resection with primary anastomosis has been one of the most gratifying advances in this field of surgery. Devine admits that the modern adjuncts to preoperative care may indeed change the picture somewhat, but he expresses the opinion that these adjuncts are to be used to render his already safe operation even safer. His method of immediate anastomosis performed in low lying lesions of the colon always requires previous defunctionalization of the colon with its attendant complications—prolonged morbidity and a factor which can be overlooked easily in the final analysis—a mortality rate which must be computed on a many stage operation. Even today the proponents of the multiple stage operation will quote a mortality rate which represents the resection only. All clinics are aware of the accidents admittedly uncommon which attend crushing the colostomy spur and in addition to this, the leaks which can be observed after an intraperitoneal closure of the colonic stoma. The controversy probably still rages but no one can deny that in the leading centers throughout the United States today qualified surgeons are so pleased with primary resection and immediate anastomosis (without the use of a "vent" or "safety valve") performed in the selected case of the properly prepared patient that they are certain they will never have to return to the more obsolete method. Devine omits discussion of carcinoma high in the rectum but his views are so completely covered in his other articles to which he re-

fers in this chapter that the careful student will become quite familiar with it.

In a chapter on megacolon the treatment presented concerns itself entirely with sympathectomy. Certain authorities in this country notably Dixon are now teaching that resection of the involved intestine wherever possible will give a more satisfactory result.

There are many chapters dealing with items that can scarcely be of interest to the average surgeon, which will serve as a handy reference in an uncommon instance. These include conjunctivitis, eye injuries, operations about the ear and labyrinth and so forth.

The chapter on diverticula of the alimentary tract is good in that it points out that almost the entire tract may be involved.

There is an interesting section on endometriosis which embraces several of the leading theories on the cause of this condition. The clinical picture is made rather clear cut and the treatment agrees with that taught in the United States. Of special importance is the author's advice to leave intestinal lesions alone unless there is actually acute obstruction since the intestinal lesions will regress after oophorectomy. The young surgeon will be well advised to leave alone those lesions which are too extensive to remove without damage to vital structures since termination of the ovarian function will control the disease. In the author's words: "There is no justification for attempting to eradicate the disease if the operation is likely to endanger the patient's life. The list of references for this topic is disappointingly short."

There are some chapters devoted to aids to diagnosis which include peroral endoscopy as well as cystoscopy and sigmoidoscopy. The trend in the United States today is toward collaboration in diagnosis since every field is now so complicated and intricate that it is difficult for any one man to master all of the modern ramifications of all fields. Therefore, a busy surgeon may do well to seek diagnostic help from a qualified colleague when it comes to the expert manipulation of an instrument which must be applied in what is admittedly a blind procedure. The world literature is notably lacking but the memories of the older surgeons are replete when it comes to recalling distressing and even fatal accidents which have occurred in the injudicious use of these blind procedures.

E. S. JUMP, JR.

THE third edition of *Control of Pain in Childbirth*¹ is considerably enlarged and improved. There are now 522 pages as contrasted with 356 pages in the first edition. Special attention is paid to the technique of caudal and continuous caudal analgesia, spinal and continuous spinal analgesia, and the saddle block spinal analgesia. There is also a discussion of the use of demerol during labor.

¹CONTROL OF PAIN IN CHILD BIRTH. By Clifford B. Lull, M.D. F.A.C.S., F.I.C.S., and Robert G. Hingston, M.D. F.I.C.S., F.A.C.A., F.I.C.A., with an introduction by N. W. W. Vaux, M.D. 3rd ed. Philadelphia: J. B. Lippincott Co., 1948.

The arrangement of the chapters is essentially the same as it has been. The last 25 pages of the text are devoted to an interesting article on "An Analysis of Newborn Mortality and Morbidity With Controls in New York, Philadelphia, and Memphis with Continuous Caudal Anesthesia" which was written by Hingson, Edwards, Lull, Whitacre and Franklin. Many new illustrations and charts have been added.

This book is useful because it contains a huge amount of valuable data which are analyzed in an unbiased manner. Likewise there are included in the book several sections prepared by collaborators who are experts in special methods of administering pain relief to women in labor. This book is highly recommended to all who are interested in obstetrics and anesthesia.

SUBMUCOUS LIPOMA OF THE COLON —

A Correction

A LETTER from Dr. Charles W. Mayo advises that an error was made in the manuscript for the article entitled "Submucous Lipoma of the Colon" by himself and Dr. Donald F. Cress in the March 1949 issue of SURGERY GYNECOLOGY AND OBSTETRICS. Paragraph 3, page 309 should read as follows:

Comfort reported 28 cases of submucous lipoma of the gastrointestinal tract, most of which were found at necropsy. However, there were 3 cases in

which operation had been performed prior to 1928. In these 3 cases 1 lipoma was situated in the sigmoid 1 in the hepatic flexure and 1 in the ascending colon. Pemberton and McCormack reported 3 additional cases of submucous lipoma in which operation had been performed between 1928 and 1936. In this series 1 of the lipomas was situated in the hepatic flexure 1 in the descending colon and 1 in the ascending colon. The 19 cases which we are reporting in this paper make a total of 35 in which operation was performed at the Mayo Clinic up to and through the year 1947. Some of the cases in this total series have been reported individually previously.

Various other types of nails, pins, screws, and bolts are used by the other 18 surgeons (5 20 22 31 33 34, 36 51 59, 60 62 79, 80, 83 86 87 88, 103 105 106 120 133, 140 142 143 149 and 163).

When the fracture is impacted in the abduction type, some operators use a conservative splintage without operation (38 50 57 78 and 108).

La Ferte performs a McMurray type of osteotomy for all fresh fractures of the femoral neck.

As mentioned an attempt has been made to anticipate those fractures which will not heal because of the plane of the fracture line through the femoral neck. It is believed that when the fracture tends to be vertical, that is, parallel with the long axis of the shaft of the femur the prognosis for union is bad even with accurate reduction and proper pinning of the fragments. Accordingly some surgeons are now performing an immediate osteotomy with or without internal fixation for this type of fracture (13 68 73 85, 109 112 and 147).

Results of operation for femoral neck fractures. Boyd and George (15 15a) reviewed 360 cases of fracture of the neck of the femur treated by operation, and found a mortality of 7 per cent, bony union in 84.7 per cent, and aseptic necrosis of the femoral head in 60 per cent of the patients with nonunion and in 33 per cent of those with union. These authors state that internal fixation is the treatment of choice for acute femoral neck fractures, because the mortality is lower the patient is more comfortable medical complications are less frequent, the percentage of senile psychosis is greatly reduced, the cost of hospitalization is diminished and the percentage of bony union is greater than with any other method."

EXTRACAPSULAR (INTERTROCHANTERIC) FRACTURES

It has previously been thought that intertrochanteric fractures of the femur should be treated by traction or other conservative methods (7 89 and 138).

While nonunion of intertrochanteric fractures rarely occurs, malunion commonly occurs. Further the mortality for intertrochanteric fractures is higher than that for femoral neck fractures (18 32, and 119).

Operative treatment of intertrochanteric fractures. One hundred and four replies to the questionnaire concerning the treatment of intertrochanteric fractures were received. Eighty three of the orthopedic surgeons prefer to treat intertrochanteric fractures of the femur by internal fixation. Twenty six of these 83 use the Smith-Petersen nail and the

Thornton plate (10, 13, 39, 43, 52 65 66, 67, 77 78 82 84, 96 102 107 109 114, 117 125 130, 147 154, 160 and 164). 20 use the N-nail (21 40, 47 54, 55, 56 90, 93 94, 95, 99, 111 119 137 140, 143 144 150a, and 156). 2 use the Moore-Blount blade-plate (8 9 11 42 45 46 49 57 58 61 62 72 74, 79 83 85 91 101 105 108, 124, 133 136 141 142, and 162). 3 use the Smith-Petersen nail and the McLaughlin plate (97 98, and 126) and 6 use the Jewett nail (14 23, 26 26a, 38 71 88 122 and 127).

Nonoperative treatment of intertrochanteric fractures. Twenty-one surgeons prefer conservative treatment of intertrochanteric fractures.

The most popular type of conservative treatment is skeletal Russell traction (4 6, 44 70, 89, 112 115 132 138 155 157 and 157a). Other forms of external fixation used are the Roger Andersen well leg splint (113 121, and 161) Thomason double leg plaster cast (18) Buck's extension (20) pantaloons cast (32 34) Wilkie boots (37) the Whitman cast (152) and the hang ing cast (118).

Results of treatment of intertrochanteric fractures. From a study of 133 consecutive cases of intertrochanteric fractures of the femur 38 of which were treated by traction and 95 by internal fixation, Cleveland Bosworth, and Thompson (26, 26a) found that (1) internal fixation reduced the hospital mortality to 12.6 per cent as compared to 34 per cent after treatment in traction and (2) severe senile mental deterioration occurred in 2.1 per cent of the patients following internal fixation as compared to 11 per cent of the patients treated by traction.

O'Brien, Shy and Bublis (110) reviewed 103 consecutive cases of patients with trochanteric fractures of the femur treated by operation and internal fixation, the most commonly used agent was the Neufeld nail-plate. The mortality was 21.4 per cent. Follow-up examination of 50 patients revealed excellent results in 74 per cent.

Nonunion of fractures of the femoral neck. The value of early and accurate reduction of these fractures by the proper application of the internal fixative agent and the prohibition of weight bearing until evidence of union on roentgen-ray examination has been manifested, and the incidence of nonunion has been decreased. To secure the best results, the following principles, expressed by Thomson should be kept in mind

1. The hips must be quite accurately reduced.
2. If the head is in a little valgus with the neck, our ratio for success is better.
3. A very long pin which will pass almost straight up from the shaft well into the head

through the lower portion of the neck gives more secure fixation than any other method.

However nonunion of femoral neck fractures still presents a big problem. According to Boyd and George (15), Cleveland (23) and Dickson (39a) 13.5 per cent, 16 per cent and from 18 to 20 per cent, respectively of the fractures of the femoral neck operated upon go on to nonunion.

The majority of surgeons corresponded with prefer to perform a McMurray type of osteotomy most of them fixing the fragments with a blade-plate (11) for nonunion of femoral neck fractures when the femoral head is alive (3, 10, 11, 12, 13, 23, 38, 40, 41, 42, 43, 44, 50, 51, 52, 54, 56, 58, 63, 64, 65, 67, 70, 72, 73, 75, 77, 82, 84, 85, 90, 92, 95, 96, 100, 101, 102, 105, 109, 112, 114, 117, 120, 121, 126, 128, 130, 137, 138, 139, 141, 144, 146, 151, 157a, 160 and 161).

Other types of operation which are in use are bone grafting with or without pins (1, 4, 21, 34, 83, 122, 132, 140 and 164) the Brachett reconstruction operation (16, 49, 93 and 107) Shantz osteotomy (39, 78, 123 and 124) Leadbetter osteotomy (99, 131, 156 and 159) and the Whitman reconstruction operation (81, 133 and 163).

McLaughlin (98) writes, "Many patients with failure of bony union need no treatment. A patient with fibrous union provided the pain is not too severe may be able to get around with a cane or a walking caliper brace."

Aseptic necrosis of the femoral head. Aseptic necrosis of the femoral head occurs most commonly after nonunion of femoral neck fractures but also develops after union of the fragments.

Boyd and George (15a) found the incidence of aseptic necrosis of the head of the femur to be 32.6 per cent among the patients that obtained union, while 59.3 per cent of the hips with non union showed aseptic necrosis.

Aseptic necrosis or degenerative arthritis of the femoral head after union of the femoral neck fracture has occurred should be treated by the prevention of weight bearing on the extremity to give the femoral head an opportunity to regenerate. Aseptic necrosis of the femoral head associated with nonunion of the intracapsular fracture of the neck of the femur is probably best treated by one of the reconstruction operations or arthrodesis of the hip joint.

The operative procedures now used for this condition are the Whitman reconstruction operation (72, 84, 95, 128, 146, and 153) the Colonna reconstruction operation (27, 28, 62, 102 and 126) the McMurray type of osteotomy (13, 55, 110 and 140), vitalium mold arthroplasty (4, 10, 55 and 135), and trochanteric arthroplasty (158).

SUMMARY

Internal fixation is the treatment of choice for intracapsular and extracapsular fractures of the neck of the femur. The Smith Petersen nail is used by most orthopedic surgeons for the internal fixation of femoral neck fractures. The Smith Petersen nail, the Neufeld nail blade, and the Moore Blount blade plate are used most frequently in the operative treatment of intertrochanteric fractures.

The early operative treatment of femoral neck fractures with accurate reduction of the fragments and prohibition of weight bearing until bony union has taken place will probably reduce the incidence of nonunion of the fracture and of aseptic necrosis of the femoral head. Immediate osteotomy for the vertical type of femoral neck fractures may be the answer to this problem.

The McMurray type of osteotomy usually with the blade-plate to fix the fragments is most generally used for treating nonunion of femoral neck fractures.

There is no generally accepted operative procedure for the treatment of aseptic necrosis of the femoral head.

SURGERY OF THE HEAD AND NECK

HEAD

Tumors of the Lower Jaw (Tumores da mandíbula)
Mário Kroetz and Alberto Coutinho *Rev. br. ol. cancerol.* 947 5.

The following classification of tumors of the mandible adopted by the National Cancer Service of Brazil, is offered by the authors:

1 Tumors of dental origin (a) odontogenic cyst follicular radicular or periodontal (b) adamantinoma (c) odontoma.

2 Mesenchymal tumors (a) fibroma, (b) chondroma, (c) osteofibroma, (d) osteoma, (e) sarcoma fibrosarcoma, chondrosarcoma, osteogenic sarcoma or reticulosarcoma (F) giant tumor or myeloid sarcoma.

3 Myeloplaxoma

4 Myeloma

5 Metastatic tumors epithelial or mesenchymal

6 Pseudotumors (a) fibrous osteitis Recklinghausen's disease Paget's disease or osseous leontiasis, (b) lymphogranulomatosis (c) osteomyelitis (d) syphilis, (e) tuberculosis.

Of 9050 patients, 44 had primary tumors of the lower jaw. The histologic examination established the diagnosis of a giant cell tumor in 11 cases, adamantinoma in 6, odontogenic cyst in 5, fibroma in 18, osteoma in 1 case and osteomyelitis in 3 cases.

The case histories are well illustrated.

The authors advocate the treatment of tumors of the jaw with electrocoagulation, by the so-called Kroetz technique. The coagulated bone segment is left *in situ*. As a rule, the sequestrum is eliminated spontaneously in about 8 weeks, which leaves a bridge of fibrous tissue that gradually becomes ossified. This type of treatment is employed by the authors in the majority of primary and secondary tumors of the lower jaw. *Journal of the N. A. S. D.*

ENT

Sidelights on the Inferior Oblique Muscle J. R. LLOYD ANDERSON. *Br. J. Ophth.* 1945 3 653.

In the first portion of this article the author considers the anatomical features of the inferior oblique muscle and discusses in considerable detail the relationship of this muscle to the inferior rectus muscle. The sheaths of the muscles are most important in relation to surgery.

In the second portion he discusses the surgical approach to the muscle both for myomectomy and recession. The insertion of the muscle is not always constant as considerable variation has been noted.

Overaction of the inferior oblique muscle may be due to (1) asymmetry in the balance or in insertions

of the superior or inferior oblique muscles and (2) secondary overaction due to paresis of the homolateral superior oblique or contralateral superior rectus muscle.

The diagnosis is best made by the cover test and in various fields.

The treatment for overaction is broken down into several types: (1) tenotomy at source of the muscle, (2) tenotomy at insertion of the muscle, (3) recession at insertion of the muscle, and (4) altered insertion of the horizontal rectus muscles.

Weakness of the inferior oblique muscle is then considered and treatment is outlined as follows: (1) strengthening of the affected muscle by advancement at its bony origin, (2) making a tuck or resection at the insertion of the muscle, (3) weakening of the contralateral yoke muscle and (4) weakening of the homolateral antagonist muscle.

Large horizontal errors must be corrected before the critical defects are attacked.

Accurate diagnosis is necessary for satisfactory treatment. *EARL H. MARR, M.D.*

Osteoma Involving the Orbit FRANK W. NEWELL
Am. J. Ophth. 945, 3: 123

The author discusses osteoma involving the orbit. An osteoma frequently originates in the nasal accessory sinuses and may invade the orbit (resulting in ocular disability) before localizing signs appear in the sinus.

Ocular involvement occurs most frequently when the original growth is in the sphenoid or in the ethmoid sinus, less commonly when in the frontal, and rarely when in the maxillary sinus.

Osteomas are hard glistening rounded tumors which present numerous facets that follow the outlines of the sinuses and other structures against which they impinge during growth. They may be sessile or pedunculated. They may be quiescent for long periods of time or become very large without symptoms. The tumors are covered with normal perosteum which extends into the substance of the growths. There are 3 main classes of true osteomas: the eburnated (ivory hard), the compact (resembling normal bone) and the spongiouse (the most immature type).

Osteomas should be distinguished from bony hyperplasia of the bones of the skull which occurs as hyperostosis in dural endothelioma. In the latter the marrow spaces of the bone are filled with tumor cells the invasion of which causes the bony overgrowth.

The symptoms and signs of osteoma are cerebral, nasal and ocular and they depend upon the site of origin. Cerebral disturbances include mental de-

iciency, vertigo various sensorimotor disturbances, convulsions cerebral pneumatocele, and increased intracranial pressure.

Intracranial difficulties are usually produced by sphenoidal growths. Occlusion of a sinus (with resultant infection) usually occurs with tumors of the frontal sinus. Anosmia indicates cerebral extension with involvement of the olfactory nerve.

Ocular signs are usually associated with ethmoidal and sphenoidal tumors. Extension into the orbit usually results in progressive exophthalmos. Sphenoidal osteomas may affect the optic nerve and result in optic atrophy papillitis or papilledema. An ethmoidal tumor may produce papillitis generally attributed to involvement of the blood supply to the optic nerve.

The diagnosis is based on roentgenographic evidence of a well circumscribed bony tumor originating in a sinus and the absence of increased thickness of other bones of the skull. Diagnosis of osteoma of the frontal or maxillary sinus is simple diagnosis of a sphenoidal tumor rests on microscopic study of the tumor because a dural endothelioma may produce a similar picture. This also applies to tumors originating in the ethmoid sinus although a localized bony tumor at this site without hyperostosis of the roof of the orbit or sphenoid ridge is most likely an osteoma. Moreover dural endotheliomas occur after while benign osteomas frequently occur before the age of 30 years.

Seven cases are presented in 2 of them the tumors originated in the ethmoidal sinus in 1 in the sphenoidal body and in 4 in the frontal sinus. The tumors arising from the ethmoid were successfully removed, the tumor arising from the sphenoid was considered inoperable. Death resulted from internal hydrocephalus.

JOSHUA ZUCKERMAN, M.D.

The Present Position of the Problem of the Intraocular Fluid and Pressure. SIR STEWART DUKK ELDER and H. DAYSON *Brit. J. Ophth.*, 1948, 32: 553

The authors discuss the nature of the aqueous humor and the present position of the problem of the intraocular fluid and pressure. It appears that the intraocular fluid is more than a simple dialysate in equilibrium with the capillary plasma. This is confirmed by a study of nitrogenous substances urea penetrates more slowly than glucose although it has much the smaller molecule. The chemical composition of a substance is more important as a determinant of rate of penetration of the barrier than is its molecular size. Whatever cellular activity is present is localized in the lining epithelium of the eye mainly in the ciliary region.

The actual mechanism is more complicated than dialysis it differentiates between substances on a chemical basis, and the blood aqueous barrier differs in different localities of the eyeball. In the case of sugars entrance into the anterior chamber through the iris is easy entrance into the vitreous is slower. Certain substances, e.g., sodium and potassium enter

the vitreous from all parts of its periphery by way of the choroidal and retinal circulations. This finding reveals the analogy between the capillaries of the cerebral and those of the retinal vascular systems.

Although the simple dialysis theory appears to be wrong the fairly close similarities in chemical composition of aqueous humor and plasma indicates that the simple physical factors of diffusion and osmosis are operative. Some degree of unidirectional permeability and the capacity for maintaining concentration gradients exist. The energy necessary for such modifications depends upon a difference of potential between the ciliary stroma and epithelium by oxidative and reductive processes due to the presence of the respiratory enzyme in the latter. This activity of the ciliary epithelium as a result of the excess of pressure results in a driving pressure of fluid into the eye. Fluid is forced into the eye with a pressure-head of from 50 to 75 mm. Hg. Because there is no counterpressure the intraocular pressure must equal this driving pressure unless there is a leakage of fluid out of the eye.

An alternative theory is the following: the aqueous may be elaborated entirely within the cells of the ciliary epithelium and possibly in other cellular linings of the eye. The fluid is extruded into the posterior chamber as a primary aqueous humor. If completely developed the aqueous would appear to be a simple dialysate in spite of its secretory origin. However the aqueous humor does not remain in the eye long enough for this diffusion equilibrium to be established but an intermediate state is achieved. In this state it has strong characteristics of a dialysate betraying its secretory origin namely an osmotic pressure greater than that of the plasma, a higher concentration of sodium and chloride than required of a dialysate, a low concentration of urea, and a high concentration of ascorbic acid.

It is concluded that in the present state of our knowledge no final conclusion can be reached. More extensive and detailed experimental work is necessary.

JOSHUA ZUCKERMAN, M.D.

A Contribution to the Microscopical Anatomy of the Sympathizing Eye. R. AYLICK GREENE. *Brit. J. Ophth.*, 1948 32: 545

The author describes the microscopic anatomy of the sympathizing eye. He points out that the character of the histologic changes is not identical in exciting and in sympathetic eyes.

He presents 13 sympathizing eyes in all of which the original perforating injury to the exciting eye was an intraocular operation. He found that the character and distribution of the inflammatory changes in the various parts of the sympathizing eyes are not related to the duration of the disease. Neither is there any relationship between the length of time elapsing between the injury to the exciting eye and the onset of inflammation in the sympathizing eye.

In 7 cases the infiltrating inflammatory cells were lymphocytes and plasma cells in 6 cases there were

epithelioid cells and in 3 of the latter there were giant cells.

Iridocyclitis was the constant common factor in all cases. The choroid was found to be normal in 5 cases, while in 6 cases there were areas of infiltration consisting of lymphocytes and plasma cells only. Epithelioid cells occurred in the choroid in 3 cases and giant cells in only 1 case. The areas of choroidal infiltration consisted of localized patches in the outer layers of the choroid; the capillary layer was free except in one case in which the whole thickness of the choroid was involved. The posterior section of the choroid immediately surrounding the optic disc was consistently the most densely infiltrated part. Both findings are in accordance with the conditions usually found in exciting eyes. These are salient characteristics of sympathetic diseases.

In most cases there were some inflammatory cells in the vitreous. The optic nerve was normal in 5 cases and edematous in 8 in which the sheaths of the central vessels showed lymphocytic infiltration. The sheath of the optic nerve was infiltrated in 1 case only and the sheaths of the ciliary vessels were infiltrated in 4 cases.

Sporadic rupture of the lens was found in 3 cases. Organized plastic exudate in the anterior chamber occurred in 3 cases. In none of the cases did the infiltration in the iris reveal any particular tendency to be situated in the posterior layers, and there were no Fuchs-Dalen bodies.

Greeves concludes that on microscopic examination no special characteristic of the sympathetic inflammatory process is found invariably in the sympathizing eye.

JOSEPH ZUCKERMAN M.D.

EAR

The Development of the Auditory Ossicles, the Otic Capsule, and the Extracapsular Tissues. BARRY J. AMON, THOMPSON H. BART, and EARL W. CAULDWELL. *Ann. Otol. Rhinol.* 9:42, 57-603.

Concurrent steps in the morphogenesis of the ossicles, otic capsule, and pericapsular portions of the temporal bone were studied in serial sections of 300 temporal bones.

In the otic capsule, the first of 14 ossification centers appears early in the fourth lunar month (120 mm. C.R.). These centers fuse to form a complete capsule prior to the middle of intrauterine life (155 mm.). Thus, adult dimensions of the capsule are attained at approximately the same time the stapes attains full size. Growth is precluded by the fusion of the numerous centers of ossification between which there occur no zones for epiphyseal expansion. However the otic capsule is not yet histologically mature nor is it embedded in the extracapsular osseous tissue which lends typical form to the so-called petrous portion of the temporal bone.

Of the three layers of the capsule, the inner or endosteal, stratum is the simplest. It forms a mere shell for the labyrinthine canals, cochlea, and vesti-

bule. It is complete at midterm and undergoes a further increase in size.

The outer periosteal layer appears in the cochlear region of the capsule during the eighteenth week (147 mm.) and is complete before the eighth month (246 mm.). In the canalicular part of the capsule it appears later (183 mm.) and spreads beyond the limits of the original capsule, toward the mastoid region. It continues to expand as an extracapsular addition, until puberty.

Of the three layers the middle (intrachondria and endochondral tissues combined) is the most complex in structure. In both cochlear and canalicular divisions of the capsule intrachondrial bone appears in the 147 mm. fetus; this immature osseous tissue attains maximum distribution within a period of about 6 weeks after primary appearance (in the 215 mm. fetus). Around the cochlea intrachondria bone retains fundamental form up to the 246 mm. stage. Thereupon the formation of endochondral bone is initiated as a thin deposit over the islands of intrachondrial tissue without other alteration of the spicules upon which deposition of the replacement bone takes place. At term the process is suddenly accelerated continuing through early infancy with such alacrity that the cochlear region resembles closely that of an adult bone. In the region of the canals there is no such initial lag in development. The deposition of endochondral bone around the canals is rapid up to the stage of 7 or 8 months (270 mm.), with subsequent slow deceleration. Activity begins in the region of the superior semicircular canal followed by the posterior and lateral canals; the intervening tissue is the last to be formed in endochondral bone.

The intercanalicular area never becomes converted into bone of fully petrous character. It retains marrow spaces which may persist in the adult ear or may be replaced beginning in the seventh month (246 mm. stage) by pneumatic spaces which spread from the tympanic antrum. When such invasion by mucous membrane progresses so rapidly as to be complete in the young child (3 years old) except for this portion of the capsule, pneumatization is restricted to bone of periosteal nature which was added peripherally to the primordial osseous capsule. In other words, except in the territory named, the process of mucosal invasion leaves untouched that portion of the capsule which existed in the midterm fetus.

In the interval between periosteal and endosteal layers where marrow might be expected to occur, such tissue is usually replaced by bone of endochondral character thereby rendering the capsule relatively solid, or petrous. The interstices are subsequently invaded by mucous membrane derived from the tympanic cavity. Concurrently periosteal bone, added to the capsule in the latter half of fetal life, is similarly invaded to form the air cells of the apical and related portions of the temporal bone.

After branchial inception of the auditory ossicles, cartilaginous growth occurs rapidly. At 23 mm. the

Incus is separating from the malleus and the stapes has become independent of Reichert's cartilage. Single ossification centers first occur in the incus at 117 mm in the malleus at 126 mm and in the stapes at 146 mm. Endochondral ossification proceeds rapidly in the malleus and incus with none of the remoulding of contour observed so dramatically in the stapes.

The ossicles form without epiphyseal areas of growth, and therefore do not increase in size after bone becomes continuous around their peripheries. During ossification the stapes becomes hollowed at the capital and basal extremities, and channelled throughout the entire length of each crus. Vascular marrow gradually retreats before the advance of the tympanic mucous membrane. Endochondral bone persists only on the internal aspect of the head and base, forming a thin plate lining the 'articular' cartilages. The ossicles attain full dimensions near the middle of intrauterine life and possess adult form by the thirty-second week or 190-mm. stage.

EARL W. CAULDWELL, M.D.

An Experimental Study of the Toxic Effects of Streptomycin on the Vestibular Apparatus of the Cat. The Central Nervous System. JULES WINSTON F. H. LEWIS AND P. A. PARENTAU. *Philipp A. Marden, and Faith B. Cramer. Ann. Otol Rhinol.*, 1948, 57, 738.

A destructive effect upon the vestibular function is the most important toxic reaction of prolonged therapy with streptomycin. Various authorities mentioned in this article disagree as to whether the lesion causing this effect is located in the central vestibular nuclei in the brain stem, in the peripheral vestibular end-organ, or in both of these places. The author has carried out three entirely different methods of investigation on cats whose vestibular apparatus had been destroyed by toxic doses of streptomycin and each of these methods has disclosed evidence of central damage. He is now engaged in investigating whether there is concomitant damage to the peripheral end organ. All of the experiments appear to be adequately controlled.

The first experiment is based upon the fact that damaged but not normal brain cells have an affinity for a stain (trypan blue) when injected intravitaly into the carotid artery. In this experiment the control cats showed no staining of any of the tissues of the central nervous system. The cats whose vestibular apparatus had been destroyed by streptomycin showed staining Purkinje cells of the cerebellar cortex dentate, and fastigial nuclei and the medial and lateral vestibular nuclei. A slight amount of dye was found in the ventral cochlear nuclei.

The second experiment is founded upon the fact that surgical destruction of the right vestibular nuclei will result in an uncompensated nystagmus to the left. Additional surgical destruction of the right vestibular nuclei but not of the right vestibular peripheral apparatus will completely and permanently eliminate this nystagmus. After surgical de-

struction of the right vestibular nuclei all control cats developed nystagmus to the left but all cats that had been treated with streptomycin did not develop nystagmus. This experiment definitely limits the destructive effect of streptomycin to a solitary destruction in the vestibular nuclei or possibly destruction to both the vestibular nuclei and the vestibular end-organs.

The third method of investigation consists of the examination of brain sections stained with phosphotungstic acid and cresyl violet. The controls showed no pathologic changes. Animals treated with streptomycin showed pyknosis and increase of glial fibers around the dendrites of the Purkinje cells of the cerebellum in 4 out of 6 animals. There was no destruction in the other 2. The temporal bones of these animals are now being examined to determine the presence of lesions in the peripheral end-organs.

NOSE AND SINUSES

Rhinocleroma Apparently Cured with Streptomycin. GORDON B. NEW, LYLE A. WELZ, DONALD R. NICHOLS, and KENNETH D. DEVINE. *Ann. Otol Rhinol.* 1948, 57, 412.

Rhinocleroma is a chronic granulomatous process involving the nose, upper lip, mouth, and upper air passages. It is believed by many to be an infection but it is only slightly if at all, contagious. An organism of the genus *Klebsiella* may usually be isolated from such patients. The chronic progressive clinical disease of rhinocleroma has not been reproduced in animals but the organisms are always present in the tissue of patients with this clinical manifestation. The organisms are usually seen in the large phagocytes and are easily grown in an artificial culture medium. Organisms with similar cultural features are frequently isolated from the respiratory tract of normal persons.

The disease was once thought to exist only in central and southeastern Europe, but it now occurs anywhere, and its incidence in South and Central America seems to be increasing. According to Cunningham and Guerry a total of 102 cases had been reported in the United States and Canada by 1942; 16 of the patients were native born.

Clinically there is at first an insidious growth of hard smooth nodules in the anterior nares. This growth spreads gradually until in many cases protruding, rounded smooth masses with intact skin surfaces close the nostrils. From the anterior part of the nose the lesion spreads backward into the pharynx, larynx, and trachea, and even into the bronchi. It may extend forward onto the upper lip or involve the cheeks, gums, antrum, lacrimal ducts, soft and hard palates and tonsils. Because of the presence of these masses function is impaired and such symptoms as foul nasal discharge, nasal obstruction, deafness, tinnitus, hoarseness and difficult breathing may ensue. Tracheotomy is often necessary. The disease is limited to the mucous

membrane and skin, ulceration is the exception and not the rule and constitutional symptoms are rare.

Up to the present no satisfactory method of treatment has been available. Therapy with roentgen rays or radium is, at best, palliative and must be repeated as recurrence of the disease dictates. Sulfanilamide and its derivatives seem to control the secondary infection, but have no effect on the scleromatous tissue.

Recently a patient with rhinoscleroma was treated at the Mayo Clinic with streptomycin.

This patient with rhinoscleroma is the first to be reported as probably cured with streptomycin, as far as the authors know. At the time of the original examination since the airway was partially obstructed it was thought that tracheotomy would be necessary as much of the granulomatous and scar tissue in the larynx and trachea as possible would then be removed and replaced with a skin graft, and later with an obturator in order to maintain an opening. The use of streptomycin cleared up the granulomas and also eliminated *Klebsiella* from tissue taken subsequently for biopsy. This evidence adds to the general impression that *Klebsiella* is an etiologic factor in the disease.

NECK

Clinical and Experimental Research on Thyro-Inhibitory Substances. The Employment of Sulfur Derivatives in the Continuous Medical Treatment of Hyperthyroidism (Ricerche cliniche sperimentali sulle sostanze tiroinibitrici. L'impiego dei solforidrivati nel trattamento medico continuativo dell'ipertiroidismo.) LUIGI PAMONI and MAXIO DE GRACIOSI. *Arch. Ital. Clin.* 94B, 70: 69.

The major portion of this article consists of a detailed review of the history, clinical application, influence on the symptoms of hyperthyroidism, contraindications, toxic manifestations, late results, and methods of action of thyroinhibitory drugs as gleaned from the literature.

The authors then present their own experiences with 3 patients who varied from 30 to 60 years in age and who were classified as follows: 23 with Flajani-Basedow's disease, 4 with hyperthyroidism and 5 with secondary thyrotoxicosis. The condition in 12 patients was considered grave and in 9 moderately grave when first seen. Most of the patients had received iodine therapy previously. Before treatment was begun the subjects had a complete blood count, basal metabolism test and blood chemistry tests for sugar, urea, and cholesterol. Aminothiazole was used in 5 cases and methylthiourea in the remainder. While therapeutic doses were being given, the complete blood count was repeated weekly and the other laboratory tests were made every 2 weeks; these determinations were made less frequently during the period of maintenance. Electrocardiograms were taken only of patients who presented thyrocardiac symptoms. Eleven of the patients were hospitalized. At the time of writing, 16 patients had

finished with a complete course of treatment and the medication had been stopped for from 2 to 12 months. The results were considered to be very good in 5, good in 4, and mediocre in 3; 5 patients had a recurrence of hyperthyroidism. One third of the total number of patients developed toxic manifestations, including arthralgia, nausea and vomiting, exanthemas, fever and subicterus. There was only 1 instance, however, wherein the drug had to be stopped. This was for severe leucopenia. Three patients who did not respond well to medical therapy were also treated by irradiation of the hypophysis, with 600 roentgens divided into 6 weekly doses. All 3 responded well thereafter. The essential data for all 31 cases are clearly presented in table form.

In general, the authors conclude that:

1. Methylthiourea and aminothiazole have demonstrated a specific curative effect against a large portion of the morbid components of Basedow's disease, particularly in respect to neuropsychic and cardiovascular symptoms and weight loss.

2. These drugs have little or no effect on exophthalmos nor on the final size of the thyroid gland.

3. There are wide individual variations in the therapeutic response to these drugs, but there is no relation between these various responses and the type, duration, or gravity of the disease, or the age or sex of the subject.

4. Methylthiourea has a more potent therapeutic action and is more likely to result in toxic manifestations than aminothiazole.

5. Irradiation of the hypophysis is a valuable adjunct in some subjects who demonstrate a poor therapeutic response to the drug alone.

As a final definitive treatment for hyperthyroidism as compared to thyroidectomy, these drugs have been used in too few cases by the authors and the patients treated have not been followed up long enough to make a decision in favor of medical treatment. However, the authors state that this form of therapy is usually not indicated in toxic adenomas of the thyroid.

N. CHRISTIAN MEYER, M.D.

The Association of Carcinoma of the Thyroid Gland and Exophthalmic Goiter. JOHN DEJ. PAXTON, JR. and B. MARSH BLACK. *Surg. Clin. N. America*, 94B, 8: 935.

Carcinoma of the thyroid gland occurs occasionally in association with exophthalmic goiter. In a series of cases of carcinoma of the thyroid gland collected from the literature, 1.75 per cent of the malignant lesions were associated with exophthalmic goiter. At the Mayo Clinic, 0.4 per cent of thyroid glands removed because of exophthalmic goiter from 1916 through 1946 contained coincident carcinomas. A total of 8 such cases have been encountered at the clinic. In 15 of the cases the malignant lesions had evidently not originated in an adenoma while in 7 cases the carcinomas had developed in adenomas. The great preponderance of low grade, slowly growing carcinoma in the series, and the fact that in only 1 of the 22 patients had the carcinoma produced

symptoms suggests that the malignant lesions could well have developed before the onset of the exophthalmic goiter in most cases. At least this explanation of the preponderance of low grade lesions seems more acceptable than the belief that the hyperplastic or hypertrophic cells give origin almost exclusively to papillary malignant lesions. The finding of a carcinoma in the thyroid gland of a patient who has received goitrogenic drugs or radiolodine does not imply an etiologic relationship between the drug and the malignant lesion.

Hemorrhage in Deep Infections of the Neck: A Review with Report of 2 Cases. MAURICE D. GRANT and GOODLATTE B. GILMORE. *Arch. Otolaryng.* 1948 47 446

The authors review the etiology and the anatomy of deep infections of the neck. They call attention to the fact that the layers of deep cervical fascia define certain potential spaces which become actual pockets when they are distended with pus. One such area is in the floor of the mouth, a second is deep to the submaxillary and the parotid glands, a third is found in the retropharyngeal area and a fourth is seen along the carotid sheath. It is in the carotid sheath that the danger of hemorrhage is important. The vessel most commonly affected is the internal carotid artery. Although it was not proved in the authors' 2 cases that this vessel was the source of the fatal hemorrhage, it was presumed to be.

To avoid the possibility of hemorrhage, the authors feel that all of the infections in the neck should be incised early. The methods usually used for this drainage, as suggested by Mosher and by Beck, are briefly described. Should hemorrhage occur before the infection has been adequately drained, a ligation of the common carotid artery is advisable. If time permits a test of the effect of this ligation as suggested by Matas, may be worth while. This consists in the compression of the common carotid artery for 10 minutes and observation of the patient for any sensations and reactions of cerebral anemia. This is usually worthy of trial, as the first hemorrhage is rarely the fatal one, and some time elapses between the hemorrhages.

The 2 cases reported occurred in children aged 4 and 7½ years. The first child was admitted with a history of hemorrhage but without any evidence of active bleeding. He improved rapidly after transfusion but on the following day suffered a fatal hemorrhage. The second child was admitted with a similar history. A ligation of the external carotid artery was carried out. A ligature was placed around the common carotid artery but not tied. After 4 days the ligature was removed. A few hours later the child suffered a fatal hemorrhage.

WILLIAM C. BECK, M.D.

Traumatic Lesions of the Larynx. MEXCER G. LYNN. *Arch. Otolaryng.* 1948, 47: 413.

The traumatic lesions of the larynx, while not frequent, are the cause of a high rate of mortality and

long disability in both military and civilian injuries. The therapy resolves into three stages: the first aid and emergency treatment, the plastic repair stage and the stage of rehabilitation.

In the first stage, the control of hemorrhage, the establishment of a dry airway and the control of shock are the keynotes. In the control of hemorrhage and in the establishment of an airway the author points out two pitfalls. The wound should be debrided only of those structures whose vitality is unquestionably impaired and every effort should be made to preserve as much tissue as possible. The second pitfall is the avoidance of a high tracheotomy. The tracheotomy should be performed as low as possible.

In the stage of the plastic repair a careful analysis of the situation is imperative. The author feels that only by means of direct suspension laryngoscopy is he able to carefully study the structures and plan his procedure. A low tracheotomy should be performed if it has not already been done. Various procedures are described for the re-establishment of a wide patent larynx, as well as those which are indicated in concomitant esophageal injuries and fistulas. Dilatation with tantalum molds is recommended. Loss of part of the thyroid or cricoid cartilages will require grafts from the costal cage.

Rehabilitation, with speech training, is most important. Work of this nature is highly specialized and schools for this purpose have proved their value.

In the discussion, G. E. Martin (Edinburgh, Scotland) and Henry B. Orton (Newark, New Jersey) point out the relationship between the development of carcinoma of the larynx and old traumatic lesions of the larynx, and cite several cases which they have observed.

WILLIAM C. BECK, M.D.

Laryngeal Tuberculosis. Observations Based on an Experience of 28 Years with Laryngeal Tuberculosis. EDWARD ANDERSON LOOPER and I. B. LYON. *Ann. Otol. Rhinol.* 1948, 57 754.

Laryngeal tuberculosis is the most common chronic disease of the larynx. In the authors' experience, the occurrence of this complication of pulmonary tuberculosis is decreasing. Among 2770 patients examined, tuberculous involvement of the larynx was found in 214, or 7.7 per cent of the patients. A survey made by the authors (20 years ago) covering a 5 year period showed an incidence of 15.5 per cent.

The decreased incidence is attributed to improvement in the care of patients with pulmonary acid fast infections. Pulmonary collapse has decreased the chances of infected sputum being brought up and deposited on the laryngeal mucosa to cause contact invasion of the tubercle bacillus. Infected sputum is the most common cause of this illness but organisms may enter by way of the lymph and blood streams.

A thorough examination of the larynx should be made in all cases of tuberculosis as soon as the pulmonary lesion has been diagnosed. Slight congestion, dryness and tickling sensations of the larynx

should receive prompt attention as such symptoms often indicate early invasion of the larynx.

In the authors' experience, caution of the lesions, combined with general care of the patient and the removal of foci of chronic infection has given the best results. Vocal rest is considered most important and patients were given writing pads for their requests. Cauterization was done under local anesthesia by the indirect method at about monthly intervals.

Elevations of temperature to high degrees, marked asthenia and high blood pressure were contraindications for the use of electrocautery.

The article is accompanied by 5 informative tables summarizing the authors' experience with this illness.

EDMUND R. DOMOCROUX, M.D.

The Treatment of Laryngeal Papillomas in Childhood. H. ZALIN. *J. Lar. Otol. Lond.*, 94, 8, 6

Papillomatosis of the larynx occurring in infancy and childhood is uncommon. It is observed more frequently in boys between the ages of 18 months and 4 years. It is not familial, although 30 per cent of all cases are congenital. There is evidence that a filterable virus is the causative factor. Papillomas in children are not single and are not confined usually to the vocal cords as in adults, but are multiple, and may occur all over the periglottal zone and recur rapidly following removal, but become quiescent with the onset of puberty.

The presenting symptoms are hoarseness and laryngeal dyspnea, and treatment is difficult and tedious as there is a high mortality from respiratory complications. Treatment is aimed at clearance of the laryngeal thoroughfare with the avoidance of local injury and subsequent dysphonia or laryngeal stenosis. Tracheotomy may be a lifesaving measure.

New and Erich prefer to treat laryngeal papillomas with diathermy. Chevalier Jackson advises avulsion of the tumors by surgical means, to be repeated when necessary. H. feels that radiation injures the larynx unnecessarily.

The fact that gonococcal vaginitis, intractable in children, ceases at puberty, presented an obvious analogy to the problem of childhood papillomatosis of the larynx. Broyles described the treatment of 5 patients at the Johns Hopkins Hospital, Baltimore, with the weekly application of 0.5 c.c. of 10,000

units of estrogen per cubic centimeter of oil to the larynx. All 5 cases, 4 of which required previous tracheotomy cleared up within a period of 6 months.

The author describes success in swabbing the laryngeal area with 1 c.c. of dimenformon 10,000 units per cubic centimeter in oil, once weekly for 5 successive weeks or more in 3 different cases. The results were excellent. The rationale of this treatment is that estrogenic substance will produce a temporarily adult epithelium which is immune to infection in this disease, possibly a filterable virus.

ERNEST D. BLOOMENTHAL, M.D.

Report of Postoperative Course of Subperichondral Total Laryngectomy. EDWARD M. WALKER and EDWIN N. BROYLES. *Ann. Otol. Rhinol.*, 94, 3, 686

The authors' modification of the Crowe-Broyles technique for total laryngectomy for selected cases of cancer of the larynx is described. Their modification varies from the original operation, in that the base of the epiglottis is left attached to the tongue during most of the operation. They believe that this maneuver gives a better view of the pharynx, and the mucous membrane on the dorsal surface of the epiglottis can be utilized later in closing the pharyngeal defect. After the larynx has been removed the mucous membrane on the epiglottis is incised and elevated, and then the epiglottis is removed. The mucous membrane from the posterior cricoid is then sutured to the mucous membrane which was raised from the epiglottis and anchored to the connective tissue in the upper angle of the wound. The remaining defects in the pharynx are closed with inverting sutures.

The authors also report an absence of wound infection in all cases in which the wounds were irrigated with tyrothridin solution at the time of operation. With this and systemic penicillin, they feel there need be no fear of wound infection from the mouth, as none of their patients so treated became infected.

The periods of hospitalization were relatively short, ranging from 8 to 13 days.

The postoperative course of the last 27 consecutive cases is reported. No deaths occurred in this series.

EDMUND R. DOMOCROUX, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

The Surgical Pathology of Brain Abscess. GEORGE SWINBURNE. *Med J Australia* 1948, 2: 169.

The author presents a detailed and complete study of the formation development clinical types regional pathology bacteriology and histopathology of brain abscesses.

The majority of brain abscesses arise from an extension of some inflammatory focus in the ear or nasal accessory sinuses, a smaller percentage follow penetrating injuries to the skull. Metastatic abscesses from another localized abscess or a systemic infection such as endocarditis or furunculosis are less common. Rarer still are abscesses following orbital or buccal infections.

Infection may travel from an external focus out side the skull through the bone and meninges by direct extension or by natural anatomical channels. However it is anatomically impossible for infection to reach the brain by way of the general somatic lymphatic system. Infection by direct extension may result from erosion of the bone followed by necrosis of the dura. The dura itself is resistant to a spreading infection and progress of the infection is delayed temporarily. Usually an extradural abscess forms which produces an inflammatory reaction of the arachnoid and the pia mater and causes their adhesion to the dura sealing the process off. The underlying cortex may undergo an ulcerative process. A subdural abscess may form or a generalized leptomeningitis may occur.

In the case of direct trauma the infection may result from direct implantation in the cerebral tissue from osteomyelitis or from scalp infection.

Infection may penetrate the brain and the blood vessels by the intravascular or perivascular route. Perivascular spread usually occurs after the infection has reached the subarachnoid space. The perivascular infiltration of predominantly mononuclear cells into a sulcus is accompanied by cerebral edema and the formation of numerous new capillaries in the cortex. The cortex itself is invaded by inflammatory cells radiating from the vessels, and by large numbers of endothelial cells and phagocytes. The abscess begins in the relatively avascular zone in the subcortical white matter and tends to spread towards the ventricles. It may be stopped by the central mass of white matter with its relatively good blood supply. Intravascular infection may spread by way of the veins or arteries. In the veins it takes the form of a retrograde thrombophlebitis. After a short period perivasculitis also occurs and the area of the brain normally drained by the thrombosed veins undergoes degeneration first in the relatively avascular subcortical zone in which the abscess later develops. The arterial spread follows the

formation of an infected mural thrombus or a bacterial embolus. In this case the area of cerebral infarction becomes infected.

Nasal or aural infections may spread from the nasal or ear cavities to the subarachnoid spaces along the perineural sheaths around the olfactory auditory or facial nerves. Two vestibular channels may be differentiated the aqueduct of the cochlea and the aqueduct of the vestibule. The latter is probably the commonest route of infection—from the labyrinth to the cerebellum. Erosion of the bony wall of the aqueduct or empyema of the sacculus with spread along the endolymphatic duct may occur. Infection from the mouth through a persistent cranio-pharyngeal canal or from the ear through the hiatus subarcuatus or a persistent petrosquamous suture is of rare occurrence.

In the cerebrum the cortex offers considerable resistance to infection because of its good blood supply. Infection spreads from the relatively avascular subcortical white matter fairly rapidly in a direction parallel with the course of the blood vessels and is caused by tissue destruction which occurs as a result of thrombosis of the vessels around the edge of the abscess. The abscess may drain along its stalk and its pathway of entrance or it may perforate into the ventricles or leak into the subarachnoid space. In the cerebellum extension of the infection occurs in the white matter of one lobule and compresses the surrounding area. Edema and inflammation take place in the more resistant cortex.

Clinically the cerebral and cerebellar abscesses may be classified as adjacent if they occur in the immediate neighborhood of a focus of infection (otogenous rhinogenous osteomyelitic and traumatic) and nonadjacent, or metastatic. The former are usually single and are situated in the frontal or temporal lobes or in the cerebellum the latter often are multiple and occur in the course of an overwhelming generalized septic process or (more commonly) secondary to subacute pulmonary infection or infections of the urinary tract.

Temporal lobe abscesses are secondary to aural infections. The infection spreads from the roof of the attic or mastoid antrum into the middle fossa and the inferior surface of the temporal lobe. Frontal lobe abscesses are secondary to frontal or ethmoid sinus infections. They often grow to a large size with a thick wall before manifesting any symptoms. Abscesses of the parietal and occipital lobes are uncommon and usually of pyemic origin. They may follow a retrograde thrombophlebitis from a thrombosed lateral sinus or a local osteomyelitis. Adjacent abscesses of the cerebellum are usually of aural origin and are found in the posterior inferior or posterior superior lobules.

The cerebrospinal fluid in brain abscesses contains a large number of polymorphonuclear cells during

the period of meningitis, and a greater number of lymphocytes during the period of localized encephalitis and early abscess formation. A chloride content below 700 mgm. per cent indicates generalized leptomeningitis. When the abscess is encapsulated the fluid chloride content is normal. An increase in total protein and globulin, which is always present, is not diagnostic.

Streptococci are the most common organisms found in brain abscesses. Pneumococci, not infrequently mixed with staphylococci are less common. Occasionally *Bacillus proteus coli*, and anaerobic organisms may be found. *Streptococcus viridans* has also been observed. Anaerobic bacteria do not favor the formation of an abscess capsule.

The author also reviews the histopathological evolution of a brain abscess and describes the phases classified by Carmichael, Kernohan, and Adson as (1) focal necrosis and microglia, (2) primary delimitation and fibrosis (3) secondary delimitation and astroglia, and (4) repair and vascularization. These stages merge gradually into each other and have no particular relationship to the chronological and symptomatic progress of the abscess.

The whole problem of cerebral abscess: its prophylaxis, treatment, and cure has been profoundly modified by the introduction of modern methods of chemotherapy. Repeated aspiration of the abscess under chemotherapeutic control, followed by total removal when it has become stabilized seems to be the best method of treatment. The author is also in favor of dealing with temporal lobe abscesses through a separate clean approach and not through the mastoid and ear. However the problem of treatment of brain abscess is not as yet solved completely. GEORGE PERRET, M.D.

SPINAL CORD AND ITS COVERINGS

Cysts of the Sacral Roots. I. M. TAYLOR *J. Am. M. Ass.* 1948, 38: 740

Cysts of the posterior sacral nerve roots seem to constitute another cause of the sciatic syndrome which may be dealt with satisfactorily at operation.

A case report is noted in detail. The history was that of a typical disc syndrome. There was a traumatic incident followed by pain in the right sciatic distribution of the thigh and leg, with distinct periods of remission and exacerbations. There were, in addition, some paresthesias in the affected extremity. Neurological examination suggested motor sensory, and reflex changes consistent with a diagnosis of protruded nucleus pulposus at the lumbosacral joint. Routine x-ray examinations of the spine were normal and myelography was regarded as essential. The only equivocal finding on admission was no pain either on hyperextension or lateral flexion of the spine.

Hemilaminectomy was performed on the right at the lumbosacral joint with no evidence of any pathological finding. A similar result was obtained on exposing the fourth and fifth lumbar interspace. A

re-examination of the lumbosacral space led to the discovery of a piece of epidural fat which bulged upward. Upon tracing this further by removal of 3 cm. of sacrum on the right, a cystic tumor 1 cm. by 2 cm. was exposed on the posterior division of the second sacral nerve root. The lesion did not connect with the subarachnoid space, and was removed by excising a portion of the posterior nerve root. The patient recovered rapidly having only transient darting pains in her right thigh. The only positive neurological finding was the persistent absence of the right ankle jerk.

A group of cases of backache and sciatica exist, for which there is no adequate explanation. Operations for protruded intervertebral discs have been negative in 10 per cent of the cases which presented typical signs and symptoms requiring operation. In 1938, the author found 5 perineural cysts on extradural portions of the posterior sacral or coccygeal nerve roots in the course of dissecting the filum terminale in 30 cases. He believes that failure to explore the sacral region more fully may mean overlooking some of these lesions and may account for some of the negative explorations in the surgical treatment of sciatica. It is felt that myelography would not demonstrate such lesions because the cystic cavity does not communicate with the subarachnoid space, and therefore diagnosis can be made only by exploration. RICHARD C. SCHMIDT, M.D.

Discussion on Rupture of the Intervertebral Disc in the Cervical Region. W. RUSSELL BRAIN, G. C. KNIGHT and J. W. D. BULL. *Proc. R. Soc. M. Lond.*, 1948, 4: 509.

W. RUSSELL BRAIN. Although protrusions of the intervertebral disc are common in both the lumbar and cervical regions the comparative anatomy reveals that the disc is relatively larger in the cervical region and contributes more to the lordotic curve. In the cervical region the spinal cord is anchored firmly and the roots run a short course hence, producing greater fixation of the cord and more likelihood of direct pressure. The posterior longitudinal ligament does not reach the lateral margins of the disc and is weakest in the midline. Disc protrusions are likely to occur either in the midline and cause spinal cord compression, or at the lateral margin, producing root compression. This author discusses the possibility of many of the symptoms being produced by pressure upon the veins and arteries with the secondary changes of edema or ischemia.

The discussion is based largely upon 10 surgically verified cases. Eight patients exhibited signs of spinal cord compression while 2 had symptoms only of a radicular type. It is realized that the relative frequency of these two clinical pictures is not represented by the 10 cases. Trauma appeared to be a factor in only 2 of the patients. Osteoarthritis was present on x-ray examination in 7 of the 10 and in 1 patient there were osteoarthritic changes in the thoracic spine only. A traumatic origin was thought to be more likely in the younger patient whose con-

dition was possibly associated with a congenital weakness of the disc. Osteoarthritis was thought to be a very definite etiologic factor in the older age group. The etiology of osteoarthritis as a causative factor is obscure and may be associated with osteophytic changes. In 6 cases the disc protrusions occurred at the fifth cervical interspaces in 2 cases at the fourth cervical interspace and in 1 case each at the second, third and sixth cervical interspace.

The mode of onset may be acute with special involvement of the neck and one upper limb. This usually follows trauma which may often be very slight. An insidious onset, which may be remittent in type may be associated with symptoms of either radicular or spinal cord compression. The most common radicular symptom is pain which is described as shooting or burning in character and corresponds to the distribution of the nerve root involved. It is usually made worse by coughing or by movements of the neck. The area of pain may be more extensive than the actual distribution of the nerve root. Sensory loss is often slight and rather patchy. Although slight muscular weakness may be present a gross muscular wasting is unusual. Spinal cord compression usually resulted in greater damage to the pyramidal tract than to the sensory pathways. A Brown-Sequard syndrome was found in 4 cases however the laterality of the disc protrusion could not be made out on the clinical basis alone. Involvement of the posterior column was rare and only 1 patient showed much damage to the spinothalamic tracts.

Examination of the cerebrospinal fluid showed some abnormality in 8 cases which were investigated by this means. This consists of evidence of a subarachnoid block (in 4 cases) or an increase in the protein content of the spinal fluid. X-ray examination revealed osteoarthritic changes in 7 of the 10 cases and myelography yielded positive results in all 6 cases in which this procedure was carried out. Although movements of the neck are somewhat limited, particularly in cases of acute rupture examination may be surprisingly negative in chronic cases with osteoarthritis. The diagnosis can be verified by changes in the cerebrospinal fluid and associated x-ray changes, however in doubtful cases myelography may be necessary. Conservative treatment will often give good results particularly in patients with radicular symptoms; hence an operation would be necessary only in patients with persistent symptoms and with evidence of spinal cord compression.

G. C. KNIGHT. The author agrees with Stookey with regard to the three types of herniated cervical discs—root compression, hemi-cord compression or anterior midline compression of the spinal cord. However he points out that occasionally the symptomatology may be that of a progressive lesion changing from one phase to another. In a comparatively brief discussion he presents an excellent description of the symptomatology of the various types of compression.

Acute protrusions of the cervical disc may occur following comparatively mild injuries. These may be seen in elderly patients after a fall or even on a sudden movement of the neck. If the disc protrusion resulted only in a contusion of the spinal cord then a substantial degree of recovery might be expected. If however the anterior spinal artery is occluded by a disc, then there is great likelihood that the condition will be irrecoverable.

The earliest symptom of nerve irritation is characterized by exacerbations and remissions of severe pain usually in the lower portion of the neck radiating to the shoulder and down the upper extremity in the distribution of the nerve root involved. Protrusions at the fifth or sixth cervical interspaces cause pain in the shoulder, the supraclavicular fossa and lateral aspect of the upper arm, but rarely into the forearm or the hand. If the sixth cervical nerve is compressed the patient will usually complain of paresthesias on the radial side of the forearm and thumb. Irritation of the seventh root will produce paresthesias on the back of the index, middle and ring fingers and on the dorsum of the hand. In some, what larger protrusions, the nerve root may be fixed and compressed resulting in less pain but in more neurologic signs. A more severe compression will result in a greater degree of motor weakness and sensory loss. In rare cases the pain may radiate into the anterior pectoral region and may sometimes be diagnosed as pseudoganglia.

Compression of half of the spinal cord by a protruded disc may result in a typical Brown Sequard syndrome. In greater degrees of involvement of the spinal cord there are usually signs of damage to the pyramidal and spinothalamic tracts. The signs and symptoms however may be variable and occasionally a diagnosis of subacute combined degeneration may be made.

The treatment will depend upon the type of disc protrusion. In cases of root irritation especially in the early stages conservative treatment is definitely advocated. Knight treated 39 patients by conservative measures and complete relief was obtained in 24 cases. A partial hemilaminectomy was required in 5 cases. In all cases showing evidence of unilateral cord compression a laminectomy is required. In cases of bilateral cord compression there is some doubt as to the advisability of attempting to remove the disc, especially since attempts to do so may lead to an increase in neurologic signs. In such cases a decompression and section of the dentate ligaments may be all that should be done.

J. W. D. BULL. The author presents a careful qualitative study of the volume of both the lumbar and the cervical intervertebral discs. Considering that 15 per cent of the volume of the disc may be nucleus pulposus the greatest portion of the nucleus pulposus that could be extruded would have a diameter of 0.7 cm. Usually of course, they would be much smaller than this amount. It is pointed out that in the lower cervical region the cervical nerves extend out from the spinal canal between two joints.

The anterior joint is formed by a synovial lining between each vertebra. This small anterior joint is usually not mentioned in anatomical studies. Although the author presents diagrams revealing the various types of disc protrusions, particularly the midline posterior protrusion and the lateral protrusion, resulting in nerve root irritation, he appears to be quite skeptical that the actual protrusion would be sufficient to produce the neurologic signs presented by these patients. In verified cases of definite protrusion of the disc, the author feels that there must be some other degenerative or neoplastic process in addition.

The narrowing of the lower cervical interspaces is thought to produce irritation of the anterior synovial joint resulting in a small effusion with thickening of the tissues and compression of the nerve root. These changes may be detected by x ray examinations, especially by oblique views of the cervical spine.

The roentgenographic examination of the patient should consist of anteroposterior, true lateral, and right and left oblique views. The frontal roentgenograms should be taken last in order to determine the direction of the ray since there is often a tilt of the lower three cervical vertebrae.

JACK I. WOOLF, M.D.

Cordotomy and Leucotomy (Chordotomie und leucotomie) U. S. A. XXXI, *Des. med. Wochs.* 948, 73-39.

The relief of intractable pain by cordotomy and by leucotomy is discussed in this article. Special attention is paid to the anatomical and physiological concepts which are involved in both procedures. Routine cordotomy with section of the lateral spinothalamic tract in the cervical region is described in detail and particular emphasis is placed upon the fact that the fibers of the lower extremity tend to be more laterally in the tract than those of the upper extremity and sacral areas. The postoperative changes in various sensory modalities are listed, but no note is made of the complications associated with injury to fibers controlling the bladder or the motor power in the lower extremities.

The theory of leucotomy is reviewed. It is believed that interruption of the thalamocortical fibers eliminates the driving force of the thalamus acting upon the frontal lobe, and that section of corticofugal or frontothalamic fibers removes the rather rigid control which the frontal lobe exerts upon the thalamus. With the interruption of the tangentially lying associated fibers there is a loss of memory of previous painful experiences. The immediate postoperative state is one of stupor, depression and confusion but

the author believes that alleviation of most of these symptoms is to be expected along with little diminution of intelligence. The unfavorable sequelae of the procedure are discussed in more detail than those of cordotomy.

According to the author the problem of relief of intractable pain can be approached from two points of view "the sensory theory" with the associated treatment by cordotomy and "the emotional theory" with its corresponding procedure of leucotomy. Throughout the article the author cites various physiological experiments on animals as the bases for his concepts regarding the underlying principles of these operations.

RICHARD C. SCHOFER, M.D.

PERIPHERAL NERVES

The Bridging of Large Nerve Defects (Zur Frage der Überbrückung grosser Nervendefekte) B. HUNDELMANN, *Chirurg.* 944, 19: 253.

The author reviews the process of nerve degeneration and regeneration and discusses various types of nerve repair including the bridging of nerve defects with foreign material and autogenous and homogeneous nerve grafts.

He proposes the bridging of large nerve defects with a cable graft obtained from the phrenic nerve. The advantages of such a graft are numerous. It is an autogenous graft, it is a motor nerve, its length and caliber are greater than that of sensory nerves, and it can be obtained easily by a division through a small wound. The unilateral paralysis of the diaphragm does not produce complications or disturbances in the function of a normal lung.

The author presents 2 cases in which he has used a phrenic autograft. In 1 patient he bridged a defect 10 cm. long of the right ulnar nerve with a cable made of 20 cm. of the phrenic nerve. The nerve was repaired 5 years after the injury. Although the patient had a postoperative wound infection the author reports a complete return of function of the flexor pollicis brevis and adductor pollicis muscles and partial return of function of the interosseus 6 months after the operation.

In the second case he repaired (11 months after injury) a defect 8 cm. long in the right radial nerve with a cable graft obtained from 15 cm. of phrenic nerve. He drained the wound but there was also a postoperative hematoma. Beginning return of function was observed 34 days after operation, and after 3 months the patient could extend his fingers actively but he was not yet able to dorsiflex his hand.

GEORGE PERRET, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Reduction of Massive Breast Hypertrophy H O
BAMES. *Plast. Reconstr Surg* 1948 3 560.

The experience gained in 25 years of mamma plastics resulted in the production of a film in sound and color with the color cinematography intended to be so exact as to leave no doubt about any phase of the surgical technique each step being explained as encountered.

The film was well received but the desire of the author to answer more completely some of the questions asked about the operation inspired the publication of this article.

Massive breast hypertrophy is considered a condition which is frequently encountered and it is believed that the subject has a justified complaint and is entitled to relief and that by radical surgery

Two well defined procedures are in vogue. One seeks to avoid tissue necrosis by simple amputation enough tissue being left to suggest a reasonably normal sized breast, and upon this mass the separately

amputated areola and nipple are transplanted as a free graft.

The other method maintains the areola and nipple in undisturbed continuity with the glandular portion and at the same time creates a well shaped normal appearing breast.

The author discusses the physiology of the reconstructed breast from the aspect of lactogenesis. Such function exists in minimal degree or not at all in the very large breast, and surgery cannot destroy create, or recreate it.

The disturbance of the endocrine balance is discounted by the fact that these huge hypertrophies are of fibrous tissue and fat which replace normal glandular structure.

The blood supply is discussed and the all important point stressed is that the central core of the remaining breast tissue must be left attached to the chest wall on the broadest possible pedicle of undisturbed circulation. In this connection it is important to avoid trauma in handling the remainder of the blood supply excessive or rough handling or twisting

Fig 1. (BAMES) a and b, Front and profile views before operation. c and d, Front and profile views showing markings for incisions. e and f, Front and profile views after operation.

of the tissue may lead to thrombosis which can result in necrosis.

The author contends that mere reduction of size and relief of physical distress are not sufficient, but that the attempt should be made to correct psychological distress by creating a form, shape and position with fullness and firmness of bosom desirable in the female figure. To attain this desirable result, painstaking preoperative study and planning is fundamental.

The operative, planned procedures are outlined in advance. Photographs are made for the record.

Skin markings are made to establish the pattern of the proposed changes, and are checked with the patient in different positions. Modifications of the original design are made at this time if necessary.

The two patterns which must be applied to obtain a satisfactory correction are

The pattern of skin incisions which affect the shape that is to be created only from the skin fixation viewpoint.

The deep pattern for elimination of the excess breast tissue, the realignment of the remainder and its fixation on the chest wall.

The marking fluid preferred is 5 per cent brilliant green in 95 per cent alcohol, and a marker is made of an applicator wound with a small amount of cotton.

The tentative design is sketched in with ordinary green ink. These markings are studied, modified or changed until the design has been found acceptable in all positions when the permanent stain is applied.

Detailed descriptions are given of the development of the designs, illustrated by excellent explanatory drawings.

The operative procedures are discussed in detail, and the dangers inherent in careless technique and operative trauma resulting in interference with the circulation are emphasized.

The author presents the complete technique of a one-stage operation for the reduction of massive breast hypertrophy which has been found most effective and gratifying in 25 years of experience with mammoplasty. FREDERICK W. MERRIFIELD M.D.

31 Malignant Lesions of the Breast. Statistical Review with Results of Therapy (Lesões malignas da mama. Revisão estatística e resultados terapêuticos) MARIA CLAUDIOTINA MALLA. *Arg. Pat.*, 947 p. 1

This lengthy article represents a statistical study of breast cancer at the Oncological Institute of Portugal, including the cases seen between January 1939 and December 3, 1942. There were 946 cases in this report, 932 occurred in women and 14 in men.

The data are condensed in table form, giving the age of the patients and the incidence, location, duration, and initial symptoms of the disease. Eighteen of the 932 women noted a discharge from the nipple as the first symptom. Nine patients had bilateral lesions.

Concerning the results of treatment there were 186 patients who had undergone treatment prior to

admission to the Institute and on whom only incomplete data were available. These cases are tabulated separately. The remaining patients, treated exclusively at the Institute, are analyzed according to the method of treatment—irradiation or surgery. These cases are broken down into the clinical groups of Steinfeld and the results are tabulated accordingly. The cases treated surgically are still further broken down according to histologic type.

Three cases of Paget's disease, and the cases in males are analyzed separately. There are 46 major tables of statistics. HERMAN T. LARSON M.D.

Radical Mastectomy. HEDLEY ATKINS. *Brit. J. Surg.* 1948, 36: 87

Since the time of Halsted, radical mastectomy has been the treatment of choice in early carcinoma of the breast. To meet better the standard criteria laid down for an adequately executed radical mastectomy, the author describes certain modifications in technique.

The skin is infiltrated with a 1 to 500,000 solution of adrenaline in normal saline, both under the incision and deep to the skin flaps over a wide area, thus rendering the dissection of the flaps nearly bloodless and defining precisely the plane of skin reflection.

The second modification consists essentially in leaving the medial skin flap to the last stage of the operation, dissecting the axilla first and securing the trunks of intercostal vessels as they emerge, thus further controlling hemorrhage. A generous area of skin is usually removed and any raw areas are covered with "postage stamp" split skin grafts. Dead space is obliterated by means of the cotton-wool snowball, and arm movements are encouraged from the second postoperative day onward.

JESSE E. THOMPSON M.D.

TRACHEA, LUNGS, AND PLEURA

The Syndrome of Bronchial Obstruction with Perimembranous Stenosis; (Filtration of Air) (El síndrome de la obstrucción bronquial con filtración aérea). RAUL F. VACCAREZZA y ALBERTO SOBRINHO. *As. Méd.* *pat. clín. tuberc.* 947 p. 5.

Bronchial obstruction is generally considered to be of three types:

1. Partial—in which type there is a free passage of air through the stenosis, even though this is reduced in volume.

2. Valvular—in which the arrangement of the stenosis is such that air passes the stenotic area with relative ease in one direction only. The most common occurrence is for the inspiratory rush of air to be freer than the expiratory which leads to progressive distention of the lung distal to the point of obstruction. This condition is called obstructive emphysema.

3. Complete—in which there is no passage of air past the stenosis. The present article concerns itself with an attempt to describe a functional type of

bronchial obstruction which permits the passage of sufficient air to maintain aeration of the lung parenchyma yet does not provide for significant ventilatory function of the lung.

Nine case histories are given as illustrations of this syndrome. They were all cases of pulmonary tuberculosis of rather long standing which presented retraction of the affected hemithorax, cavernous lesions in the upper lung field, retraction of the mediastinum and decreased radiotranslucency of the base. They were predominantly unilateral lesions. Bronchial obstruction was not visualized in the majority of cases it being supposed that such obstructions were beyond the range of visibility.

Bronchosprometric studies revealed virtually no ventilatory or respiratory function on the affected side. The occurrence of an aerated lung (as shown by x rays) which however has no ventilatory or respiratory function (as determined by bronchosprometric or oxygen saturation studies on blood) is explained by postulating a type of bronchial obstruction through which air in small amounts only may filter.

HIRAM T. LANGSTON M.D.

Echinococcal Disease of the Lung. Surgical Treatment (*Equinococosis pulmonar Tratamiento quirúrgico*) JORGE A. TALANA, EDUARDO SCHIEPPATI, and RODOLFO BORACINA. *Rev. As. Méd. Argent.*, 1948 61: 441.

This well illustrated article reviews briefly the surgical management of echinococcal disease of lung indicating the various procedures that have been utilized in the evolutionary history of thoracic surgery. The management proposed includes:

1. General anesthesia (cyclopropane ether given endotracheally with pentothal induction)
2. Wide exposure by thoracotomy preferably posterolateral.
3. Adequate management of small cysts by incision and evacuation of the contained parasite, resection of the pericystic adventitial coat, suture of communicating bronchi and closure of the lung defect. The pleura should be drained.
4. For cysts of large size, multiple cysts or large cysts accompanied by complicating lung disease, resection of the involved lung is the treatment of choice. This is done by individual ligation technique. Whereas segmental resection may be feasible, the authors have preferred total lobectomy or pneumonectomy.

Of 29 cases of pulmonary echinococcal disease treated surgically 9 were managed by resection with entirely satisfactory results and without a fatality.

Numerous roentgenograms, photographs of specimens and 7 concise case histories amply document the article.

HIRAM T. LANGSTON M.D.

Solitary Pulmonary Abscess Treated by Primary Pulmonary Resection JENS L. HANSEN. *Acta chir. scand.* 1948, 97: 1.

The treatment of chronic pulmonary abscess by primary resection is advocated because of the tendency

toward the formation of bronchial fistulas and cavities and in an attempt to reduce the long postoperative period following simple pneumonectomy for chronic lung abscess.

Fourteen patients with solitary putrid pulmonary abscesses were submitted to radical operation: pneumonectomy (2), lobectomy (11) and partial lobectomy (1). Two had cavernous tuberculosis with severe putrid infection. In the remaining cases radical operation was indicated because of (1) duration of the disease (2) recurrence (3) bouts of severe pneumonitis or hemoptysis or of both and (4) a location which made pneumonectomy impractical (subcapular supra axillary, interlobar mediastinal).

One patient died in the immediate postoperative course of cor pulmonale. The condition in the 2 tuberculous patients improved considerably for the first several months after operation but death occurred 1 year later. The remaining 11 patients recovered and were able to return to work earlier than would have been possible following pneumonectomy.

Radical operation is considered inadvisable in acute stages of pulmonary abscess.

C. FREDERICK KITTLE, M.D.

Streptomycin in Surgical Infections. Lung Abscess and Empyema. EDWIN J. PULASKI and THOMAS T. WHITE. *Ann. Surg.* 1948 128: 312.

Seventeen cases of lung abscess, nontuberculous empyema, and tuberculous empyema were treated with streptomycin. In 2 of 3 cases of lung abscess improvement which could possibly be attributed to streptomycin was noted. Five patients with nontuberculous empyema were benefited by the use of streptomycin. However 1 patient presented no improvement until adequate surgery was combined with the antibiotic. Streptomycin was tested in 9 cases of tuberculous empyema. Three of the 9 patients were treated by medical measures only with no sign of improvement. It is clear that streptomycin is of no value in chronic productive tuberculous bronchopleural fistulas and empyema of tuberculous origin will not show improvement following streptomycin therapy if the parenchymal lesions show no improvement. In 1 of 2 patients treated by closed tube drainage and streptomycin, the condition became worse, while in the other it showed improvement only after penicillin was added to the therapy. Streptomycin was used as an adjuvant to extensive surgery in the treatment of 4 patients with definite benefit.

Streptomycin may suppress the pyogenic organisms in a mixed tuberculous empyema and permit the case to be managed as a purely tuberculous empyema. However it may be of advantage to add penicillin to the regimen to secure maximal benefits. Streptomycin appears to afford protection during extensive maneuvers in open mixed tuberculous empyema and is extending the scope of surgery by permitting a direct attack upon the visceral fibroplastic membrane.

JENNIS E. THOMPSON M.D.

Bronchial Adenoma. CARLTON R. SOUTHERS and J. W. KIRKLEY JR. *N. England J. M.* 1948, 39: 459.

This report from the Lahey Clinic in Boston, Massachusetts reviews the experience with bronchial adenoma over a period of 18 years. Of 217 histologically classified primary lung tumors, 15 were adenomas—an incidence of 6.9 per cent.

This tumor is usually accessible to bronchoscopic vision and its characteristic gross appearance in most cases will serve to differentiate it from carcinoma. It is a potentially malignant tumor but the malignancy is of a low grade.

Sixty per cent of these tumors occurred in patients under 40 years of age and a slightly greater percent age occurred in females than in males. Chronic cough, hemoptysis, repeated bouts of pulmonary infection or atelectasis, a localized wheeze or evidence of obstructive emphysema should arouse suspicion of the possible presence of an adenoma.

Since surgical resection eradicates the area of damaged lung as well as the entire tumor it constitutes the treatment of choice in most cases. Eleven patients in this series were so treated. There were no deaths. Local removal may suffice for pedunculated tumors without extrabronchial extensions (which are frequent) or irreparable lung damage but the possibility of recurrence requires continued observation.

The data on the 15 patients are summarized in table form and include age, sex, duration and character of symptoms, physical x-ray and bronchoscopic findings, treatment, essential pathology and follow-up. The latter runs from 5 months to 6.5 years in 13 of the cases. In 1 case the treatment has been too recent to justify comment and in another the patient has been lost to follow-up.

HIRSH T. LANGSTON, M.D.

Cytological Diagnosis of Pulmonary Cancer (Cito-diagnóstico del cáncer de pulmón.) GUTILLERMO TERZANO and JOSE MARIA E. MEZADRA. *Dis. med. B. Air.* 1948, 20: 68.

The authors present a review of the possibilities of diagnosis of bronchogenic carcinoma by examination of the sputum or bronchial secretion. The technique for fixing and staining the material as well as the general description of the cytological elements of normal secretions and secretions from tumor-bearing bronchi are briefly reviewed. The paper is based on a review of the literature and includes a bibliography of 23 references.

HIRSH T. LANGSTON, M.D.

HEART AND PERICARDIUM

Analysis of Malformations of the Heart Amenable to a Blalock Tausig Operation. HELEN B. TAUSIG. *Am. Heart J.* 1948, 35: 3.

The Blalock Tausig operation is designed to increase the circulation to the lungs therefore it is of benefit to patients suffering from lack of adequate pulmonary blood flow provided the heart can adjust itself to the altered circulation.

Patients with the tetralogy of Fallot can adjust to the altered circulation. Other types of malformation improved by operation are those with a cardiac contour similar to that of the tetralogy of Fallot with left axis deviation, those with partial rotation of the heart on its axis, possibly those with pure pulmonary stenosis and an auricular septal defect, and some with unusual arrhythmias. The operative risk, however, is considerably greater in persons who have atypical malformations with pulmonary stenosis or atresia than in those with the tetralogy of Fallot.

The six criteria essential for successful operation are: (1) the primary difficulty must be an inadequate pulmonary blood flow; (2) there must be a pulmonary artery suitable for the anastomosis; (3) a systemic artery must be available for the anastomosis; (4) the pressure difference between the systemic and pulmonary circulations must be great enough for the blood to flow from the aorta to the lungs; (5) the lung structure must be such that the patient can tolerate collapse of one lung and temporary occlusion of one pulmonary artery; and (6) the structure of the heart must be such that it can adjust to the altered circulation.

In an analysis of heart structure it is emphasized that: (1) venous blood must be directed to the systemic circulation; (2) the increased volume of oxygenated blood returned from the lungs must be able to reach the aorta; (3) the structure of the particular heart must allow continuous circulation of blood at an accelerated rate; and (4) the structure of the heart must also be such that operation does not cause progressive enlargement.

Less than 5 per cent of the patients have exhibited progressive cardiac enlargement or died of cardiac failure. Thirty per cent have shown no increase in heart size, 30 per cent have shown early increase in heart size with subsequent readjustment, 30 per cent have shown cardiac enlargement during the first 6 postoperative months but no further enlargement thereafter.

The results following use of the subclavian artery for the anastomosis have been as beneficial as when the innominate artery has been used. A patient with the tetralogy of Fallot has a 90 per cent chance of marked and sustained improvement by operation.

JAMES E. THOMPSON, M.D.

Chronic Constrictive Pericarditis. VACON MORTENSEN and ERIC WARBURG. *Acta med. scand.* 1948, 13: 203.

After presenting a brief review of the collected material dealing with the syndrome of chronic constrictive pericarditis, the authors give a rather detailed report of their own cases. This comprises 23 cases in all. Twenty-five of these were typical and form the main body of the material discussed. The 8 other cases were considered as probable examples of chronic constrictive pericarditis but the work-up on them was not conclusive. Four of them were found at autopsy but clinical data were lacking to prove physiological cardiac constriction. In 3 others the

diagnosis was not confirmed and the last 2 cases were complicated by a tuberculous empyema so that evaluation of the cardiac status was not accurate.

There were 18 men and 7 women all principally young people. Tuberculosis, trauma and rheumatic fever are discussed as the principal etiologic possibilities but no definite conclusions in this regard were drawn.

The clinical picture is briefly described along with the diagnostic features of various means of examination. Dyspnea, enlarged liver, distended neck veins and ascites were common. A protodiastolic gallop rhythm described as a pericardial click is given real diagnostic value. The roentgenologic, electrocardiographic, and kymographic findings are given. Venous pressure readings as high as 400 cm. of water are recorded.

Twenty of the 25 patients were treated by pericardiectomy. Of this number 11 have died. Two patients were not benefited but 7 had very gratifying results. Surgical treatment is strongly advocated for constrictive pericarditis, particularly in the younger age groups. Pericardial calcification is believed to greatly increase the risk of surgery and caution is advocated in its presence. When tuberculosis is known to be the cause, surgical intervention is undertaken if the process is believed to be in a quiescent state.

Finally cardiac insufficiency in young persons, the cause of which is obscure should call to mind the possibility of a chronic constrictive pericarditis.

HIRAM T. LANGSTON, M.D.

ESOPHAGUS AND MEDIASTINUM

The Injection Treatment of Esophageal Varices Due to Manson's Schistosomiasis. Preliminary Report. CARLOS E. MUÑOZ MACCORMICK. *Laryngoscope*, 1948, 58: 993

Schistosomiasis is a parasitic disease that in its late stages closely resembles the so-called Bantu syndrome, and frequently kills by exsanguinating hemorrhages from esophageal varices. The author describes the pathogenesis of schistosomiasis and the life cycle. The ova which are laid in the intestinal wall instigate a colitis. Those that are swept away by the blood accumulate in the portal spaces. After the embryo dies and is absorbed, the remaining shell which is very resistant instigates a fibrosis which after 10 years or longer produces the syndrome of hepatic cirrhosis. Since the fibrosis is mainly portal, it causes blockage, portal hypertension, and splenomegaly. Anastomoses then begin to form. The veins in the submucosa of the esophagus are one form of anastomosis.

Diagnosis is based upon a history of exposure to contaminated waters, progressive enlargement of the spleen and liver with contraction of the latter at a subsequent time, a clinical picture of cirrhosis of the liver, eosinophilia, and the finding of ova in the feces. Some special diagnostic procedures are biopsy of the rectal mucosa, skin testing with cercarial

antigen and liver biopsy. The administration of fusidin which contains 13.5 per cent antimony seems to be the treatment of choice. The treatment of bleeding esophageal varices has been by thermocoagulation, electrocoagulation, or cauterization through a gastrostomy opening. From a surgical standpoint, splenectomy, ligation of the coronary vein, portocaval shunt, and lienorenal anastomoses have been used.

The author presents a case of esophageal varices due to schistosomiasis, with recurrent bleeding after splenectomy. The patient was treated by four injections of the esophageal varices with 5 per cent sodium morrhuate. A satisfactory result was obtained. The author states that as far as he knows this is the first case of bleeding varices in schistosomiasis treated by this method. He suggests that splenectomy by relieving over 20 per cent of the load from the portal circulation, followed by injection of the varices may prove to be the treatment of choice in cases in which splenectomy is indicated. Recanalization or the formation of new varices is a complicating factor and presents a problem in the timing of injections.

ROBERT E. FLORES, M.D.

Spontaneous Rupture of the Esophagus. THOMAS J. KINSELLA, RUSSELL W. MOREE, and AMAROSE J. HERTZOG. *J. Thorac. Surg.*, 1948, 17: 613

Spontaneous rupture or perforation of the esophagus is more dramatic and tragic than smaller perforations. The condition is more lethal because it is not suspected and the patient's condition is so poor that surgery is not tolerated. On the other hand, smaller perforations usually present little difficulty because of the antecedent history.

The clinical picture is not generally recognized and the majority of cases reported in the literature (over 50) were not diagnosed before death. There is a rather characteristic history with only slightly variable physical findings. The patient is usually healthy, often addicted to alcohol, and frequently a heavy eater. Following vomiting usually with some blood, there is a sudden excruciating pain, frequently epigastric, which is followed by collapse, shock, dyspnea, and cyanosis. The pain is severe and responds little if at all, to narcotics. The findings are those of a patient in shock, frequently upper abdominal rigidity, pneumothorax or hydropneumothorax, and subcutaneous cervical emphysema. The differential diagnosis includes all upper abdominal and thoracic conditions. Only 25 per cent of cases have been correctly diagnosed before death because of unfamiliarity with the condition. The most frequent misdiagnosis has been ruptured peptic ulcer.

The authors report 5 cases of spontaneous rupture of the esophagus. In 3 the diagnosis was made before death, and in 2 of these the condition did not permit a surgical procedure. One patient was subjected to thoracotomy with suture of the rent in the esophagus with silk. The immediate postoperative course was favorable until the eighth day when death occurred on account of pulmonary embolism.

Following their experience, the authors have devised the following plan for treatment: (1) treat shock (2) decompress the pneumothorax by needle aspiration and follow by intercostal catheter drainage (3) discontinue oral food and fluids (4) administer adequate chemotherapy (5) perform a thoracotomy with cleansing of the tissues and suture of the esophagus when the patient's condition permits and (6) use postoperative suction on the gastric contents for several days and then feed through the nasal tube.

An extensive bibliography is included

W. HARRISON MERRY, M.D.

Primary Sarcoma of the Esophagus (*Sarcome primitif de l'œsophage*) J. HORACIO REBAÑO and ALFONSO ALBAÑEZ. *Rev. chir. Pat.*, 1948, 67, 57

Primary sarcoma of the esophagus is extremely rare, only 60 cases having been published in the literature up to 1944. The differentiation from carcinoma is nearly always impossible prior to surgery or autopsy. Esophagoscopy does not help in the diagnosis as to the kind of tumor and biopsy should be discouraged in cases in which the mucosa appears intact. Clinically dysphagia seems to be less severe than in carcinoma but more severe than in benign tumors.

The authors describe in great detail the case of a man 56 years old, who complained of dysphagia, retrosternal oppression, and hoarseness due to paresis of the left vocal cord. An extrinsic tumor of the superior third of the esophagus was removed by the cervical route after resection of the sternal portion of the sternocleidomastoid muscle. Histologic examination revealed a primary fibrosarcoma of the esophagus. The patient gained 9 kgm. postoperatively but died 3 months after surgery of metastases in the trachea.

WALTER M. SOLMITZ, M.D.

MISCELLANEOUS

Strangulated Diaphragmatic Hernia B. NOLAND CARTER and JEROME GIBBERT. *Ann. Surg.* 1948, 128, 38.

In a review of 39 cases from the literature together with 4 cases from the author's own hospital records the clinical picture of strangulated diaphragmatic hernia is presented. Emphasis is placed on the striking consistency of the history and physical findings, as follows: (1) history of a previous thoracic injury, (2) physical findings referable to the left chest, particularly displacement of the heart to the right, dullness or tympany in the lower portion

of the thorax, adventitious sounds, and aspiration of bloody fluid from the left pleural cavity. (3) roentgenologic findings suggestive of a high left diaphragm with displacement of the heart to the right and (4) signs of acute gastrointestinal obstruction with particular emphasis on the fact that where the stomach alone is strangulated there is absence of abdominal distention and a patent intestinal tract.

The use of a combined thoracoabdominal incision is recommended in the surgical treatment.

BENJAMIN GOLDMAN, M.D.

Anesthetic Block of the Vagus and Phrenic Nerve and of the Sympathetic Trunk at the Neck in Thoracic Surgery. Its Protective Effect on the Arterial Blood Pressure. Experimental Study. (Il blocco anestetico del vago del simpatico e del tronco al collo in chirurgia toracica. Sui azioni positive sulla pressione arteriosa. Ricerche sperimentali.) FRANCO SOAVE. *Chirurgia* 1948, 3, 193.

Nine dogs were used in the author's study. A Ludwig manometer connected up to the femoral artery was used to control the blood pressure. Under intra-venous anesthesia and artificial respiration by means of the Palmer apparatus, the pleural cavity on the right side was opened. With a long curved forceps a mild traction, compression or both, as exercised on the pulmonary hilus as a whole and on its constituent structures (bronchus, artery, vein) separately.

One of the animals died during the manipulations; however, the remaining 8 invariably exhibited a drop in blood pressure with the traction or compression as described. The pulmonary vein seemed to react to the manipulations with a greater and longer lasting drop in blood pressure than did the hilus as a whole, the bronchus or the pulmonary artery. This behavior on the part of the pulmonary vein leads the author to believe that he has substantiated the work of Morin and Del Pol (Arch. Sc. med. Tor. 1937, 48, 339) on the special sensory receptors in the wall of the pulmonary vein.

After the control tracings were recorded the large nerve trunks in the neck were then blocked in each of these animals with from 10 to 15 c.c. of 0.5 per cent novocain. The tracings were then repeated under the same conditions as before. The nerve block did not entirely prevent the drop in blood pressure; however, the drop was unimportant in fact, often imperceptible, and leads the author to regard the blocking of the three large nerve trunks in the neck as a valuable therapeutic adjunct in the surgery of the thoracic cavity.

JOHN W. BRECKMAN, M.D.

SURGERY OF THE ABDOMEN

GASTROINTESTINAL TRACT

Gastroscopic 'Cytodiagnosis' (Über gastrokopische 'Zytodiagnostik') HANS STOLLMEIER. *Deut. med. Wschr.*, 1948, 23 330.

Fifty-eight patients with gastric disturbances observed by the author at the Ludolf Krehl Medical Clinic of the University of Heidelberg were studied cytologically. The material for examination was obtained by means of a small alteration (Hartert) at the end of an ordinary flexible gastroscope. The method is without trauma to the mucosa. In the recognition of the eventually present cancer cells the atypical forms and especially the relation between the protoplasm and the nucleus of the individual cells were given the most important place in the diagnosis. Details of the cytologic studies will be given in a separate article by Doerr; the pathologic.

In 28 of these 58 cases there was a certain clinical diagnosis of inflammation (ulcus gastritis) and the cytologic findings corresponded perfectly. In the remaining 30 cases with a clinical diagnosis of carcinoma or the suspicion of carcinoma the cytodiagnosis gave valuable supplementary aid to the clinical, roentgenologic, and gastroscopic findings in 20 (66%) patients. In several instances in which the clinical examination did not give unequivocal certainty of cancer the cytologic study furnished evidence of such urgency as to justify operation. In these cases the surgeon was thus brought in contact with a cancerous process which was still at a stage in which resection could be attempted.

The majority of gastrologists have regarded the perfecting of the roentgenologic demonstration of the gastric mucosal pattern as the most promising means of bettering the early diagnosis of gastric carcinoma. Others have turned to gastroscopic photography as the best means of directly inspecting and recording (by repeated photography) the suspicious lesion for comparative purposes. In this sense gastric cytodiagnosis may also be regarded as a direct method of mucosal inspection. The method is particularly adapted to the study of conditions existing in the medial and proximal portions of the stomach and in this regard it may serve as a fortunate supplementation of the roentgenologic methods which are better adapted to the study of the medial and distal regions.

JOHN W. BRENNAN, M.D.

Vagotonic Gastric Colic Stimulating Perforated Gastric Ulcer (Vagotonische gastrische Koliken unter dem Bilde des Ulcus ventriculi perforatum) CARL BLUMENFELD. *Chirurg.*, 1948, 10 286.

Proper interpretation of severe colicky pain will require differentiation between organic and functional spasms as well as determination of their special organic relation (gastric, intestinal, biliary, pancre-

atic, or renal). Operation for apparently well defined perforated gastric ulcer frequently reveals normal conditions. Pseudoperforation symptoms have been attributed to a neurosis of the solar ganglion due to extension of inflammatory gastric conditions along the lymphatics to the solar plexus. Cases have been described, however, in which no gastritis or other symptoms of inflammation could be demonstrated. Darup has attributed such cases to intestinal and vascular spasms due to a disequilibrium between the vagus and sympathetic system.

In patients with ulcer secondary pancreatitis may give rise to perforation symptoms. In 5 of 39 patients presenting the picture of perforated ulcer of the stomach with peritonitis diagnosis could not be confirmed, that is 12.6 per cent of the series. These 5 cases are described in detail and the symptoms are tabulated; they reveal a striking similarity to those observed in perforated gastric or duodenal ulcer.

Two types of cases were distinguished in this group: (1) a type characterized by acute onset, more or less marked bradycardia, no rise in temperature, and an extremely short course (12 to 24 hours); and (2) a type in which symptoms developed over a course of 3 or 4 days followed by sudden severe exacerbation with violent pain and a picture resembling perforation peritonitis. Even in this type, however, there was no typical gastric anamnesis. The temperature was elevated and there was no bradycardia in this group while the duration of symptoms varied from 4 to 6 days.

The picture in the first group would not justify the conclusion that the condition was of gastric or inflammatory origin. In the second group the chief etiologic factor would seem to have been gastroduodenitis without demonstrable pathologic-anatomic gastric lesions. In the former group the condition was probably one of vagotonic gastric colic. Adrenalin and atropin were injected into these patients for diagnostic and therapeutic purposes. Adrenalin was thus probably used for this purpose in cases of this kind for the first time.

Acute nonmechanical gastric dilatation has also been interpreted as a pathologic-sympathetic control of the stomach or sympathetic stigma. The same holds true for acute gastric dilatation following contusion of the abdomen. Whether these vagotonic gastric colics simulating perforated ulcer are caused by central peripheral or intramural influences on the parasympathetic system cannot be definitely determined. Probably some local organic sensitivity of the receptive apparatus of the vagus nerve is involved. Bradycardia is a known symptom of vagotonia.

Differential diagnosis must include, besides exclusion of the various organic colics mentioned, elimination of tabes and thyrotoxicosis. Adrenalin and

pilocarpin may be of value in excluding tabes, since their administration in tabes will release fresh attacks. In the gastric crises of thyrotoxicosis the uncontrollable vomiting is a distinguishing feature. In order to exclude perforated ulcer in these cases with bradycardia, but without fever or other signs pointing definitely to perforation the surgeon should await the results of the atropin and adrenalin tests. If the symptoms then subside within 0.5 or 1.0 hour further postponement of the operation is justified at least for 4 to 6 hours after the onset of symptoms. In some cases an exploratory laparotomy will be imperative in order to exclude perforation. If the symptoms subside following the administration of these drugs atropin should be given in fair-sized doses for a period of several days in the vagotonic cases and appropriate conservative therapy should be administered in the gastritic cases.

EDITH SCHAMBER MOORE.

Gastrojejunal Ulcer: Clinical Features and Late Results. JAMES T. PRESTLEY and ROBERT H. GIBSON. *Arch. Surg.* 94:5, 56-65

In order to have a basis for comparison of the relative value of partial gastrectomy and vagotomy in the management of jejunal ulcer it appeared worth while to review the results that were obtained in the treatment of jejunal ulcer prior to the use of vagotomy. By this means one can derive some opinion regarding how effective vagotomy must be in order to supplant partial gastrectomy. Data on 83 patients with jejunal ulcer who were operated on in the Mayo Clinic from 1937 to 1942 have been reviewed and as many of the patients as possible have been followed up to determine the late result.

The case of jejunal ulcer is similar to that of duodenal ulcer. The routine use of gastroenterostomy in the treatment of duodenal ulcer is followed by a relatively high incidence of jejunal ulcer. Similar use of moderately high gastric resection with complete removal of the pyloric antrum is followed by a low incidence of jejunal ulcer. The ultimate frequency of jejunal ulcer after vagotomy and gastroenterostomy remains to be determined. Prevention is of paramount importance in any consideration of jejunal ulcer. Diagnosis of this lesion usually is not difficult. The complications are hemorrhage, perforation, and gastrojejunochole fistula.

Treatment of jejunal ulcer is primarily surgical. To date the best results have been obtained by disconnection of the gastroenteric antrum, excision of the jejunal ulcer, and adequate gastric resection of the posterior Polya type. With this type of treatment results are satisfactory over a period of from 5 to 10 years in approximately 85 per cent of the patients who have undergone previous gastroenterostomy. Results are less satisfactory if the original operation is partial gastrectomy. From a physiologic point of view vagotomy would seem to be a sound procedure if the original operation is partial gastrectomy. Late results of vagotomy in the treatment of jejunal ulcer remain to be determined. Of 44 cases

in which this procedure was performed, the immediate results have been good in 19 of 24 cases in which vagotomy was performed for jejunal ulcer that developed after partial gastrectomy, and in 19 of 20 cases in which jejunal ulcer developed after gastroenterostomy.

The Surgical Treatment of Peptic Ulcer. GROSS, CHUTE, JR. *Surg. Clin. N. America*, 91:5 25, 1173.

The treatment of gastric ulcer is primarily a surgical problem involving excision of a potential cancer, whereas the treatment of duodenal ulcer is essentially a medical problem and operation is required only when the symptoms are rendered intractable by complications.

In the treatment of gastric ulcer gastric resection is the treatment of choice. Since there is almost no tendency for marginal ulcers to develop after operations for gastric ulcer there is no need to perform a vagotomy unless the values of free acid are unusually high. When the ulcer is located so high that it can not be resected without removing all of the stomach, satisfactory results can be obtained by vagotomy provided a biopsy is made to rule out malignancy. Small gastric ulcers can be treated by excision of the ulcer with vagotomy and gastroenterostomy. Vagotomy alone of a gastric ulcer without resection, excision, or biopsy should not be employed because of the danger that carcinoma might be present.

The surgical treatment of duodenal ulcer is still controversial. Some still believe that radical gastric resection is the treatment of choice whereas others prefer the more conservative procedure of vagotomy combined with pyloroplasty or gastroenterostomy.

About 85 per cent of the patients with duodenal ulcer seen at the Cleveland Clinic made satisfactory progress on medical management. In the surgical management, the author prefers transabdominal vagotomy coupled with a conservative operation to afford drainage of the denervated stomach. This preference is based on an experience of bet 2½ years but justification for this form of treatment is the result of "superior results" to those obtained by any other method of treatment. Two hundred and twenty-eight transabdominal vagotomy operations have been performed at this Clinic with 4 deaths, a mortality rate of 1.5 per cent. This is slightly less than the mortality rate for gastric resection at the same Clinic in the past 10 years (2.8 per cent).

In the treatment of jejunal ulcer the author prefers transabdominal vagotomy if no obstruction is demonstrable in the roentgenogram. If obstruction is present, a vagotomy is performed, the old gastroenterostomy taken down, and a new one made. The results in 17 patients who were treated in this manner have been excellent and there has been no recurrence of symptoms. These patients have been followed from 1 month to 28 months after operation.

The technique of vagotomy and gastroenterostomy is reviewed as well as that of pyloroplasty.

The author believes that the transabdominal vagotomy coupled with pyloroplasty or gastroenter

ostomy is (a) safer than gastric resection, (b) more effective than gastric resection in controlling the tendency to recurrent ulceration and (c) attended by lesser morbidity and disability than is gastric resection.

HAROLD LAUFMAN M.D.

The Surgical Treatment of Ulcer (Chirurgische Ulkusbehandlung) A. PLENK and A. ZECKMANN
Wien med Wschr 1948 98 238.

One hundred thirty-eight cases of stomach ulcer were diagnosed clinically and roentgenologically. However in 24 of these it was proved that the diagnosis was incorrect. Four patients did not have a callous ulcer; they were treated by pyloromyotomy. 15 per cent of the patients had carcinoma which was recognizable macroscopically and these were subjected to resection. The remainder of the patients had callous ulcer which failed to respond to medical treatment, 56 were subjected to the Billroth I operation, 57 to the Billroth II operation and one was subjected to the Madlener operation. The mortality was zero and today at the Allgemeinen Oeffentlichen Krankenhaus in Linz Austria, gastric ulcer is treated surgically with the exception of only a few cases (patients under 40 with serious complicating disease, or with permanent cure after one period of internal management).

Vagotomy is not done in ulcers of the cardia in which internal management is not successful carcinoma is suspected and a Madlener resection is done. In 200 of these the Billroth II operation was done and in 15 resection by exclusion of the duodenum was done. The latter method has been pretty well abandoned with credit to Finsterer. One patient died on the sixth postoperative day of cardiac insufficiency. Vagotomy was added in only 18 per cent of the cases. This procedure did not lower the mortality; the author fears disturbance of the motor of the stomach with this operation.

There were 35 patients with gastric ulcer combined with duodenal ulcer. One of these patients was operated upon by the Billroth I operation, 30 were operated upon by the Billroth II operation and 14 patients were subjected to resection with exclusion of the duodenum. The total mortality was 5.7 per cent (2 of the esophagus). In these 2 patients the ulcer had involved

The author's material for jejunal peptic ulcer comprised 12 patients. Five of the ulcers followed retrocolic gastroenterostomy, 4 followed antecolic gastroenterostomy with a Braun anastomosis, 1 followed pyloric exclusion, 1 an antecolic Billroth II operation with a Braun anastomosis and 1 a retrocolic Billroth II operation with a Braun anastomosis. Eleven of the patients with jejunal ulcers were subjected to a Billroth II operation and 1 was subjected to resection with exclusion. In this group of 12 patients there was 1 death from bilateral pneumonia 3 days after operation. The results of resection with retrocolic gastrojejunostomy in the jejunal ulcer cases especially those developing after antecolic

gastroenterostomy with Braun anastomosis are regarded so favorable that this procedure will be continued. The author is inclined to regard the jejunal ulcer following the two-thirds resection with retrocolic anastomosis as "surgically incurable" and believes that vagotomy with or without subsequent resection is justified in these cases.

Of the 18 patients with massive hemorrhages 3 were treated conservatively and both died; the remaining 16 were subjected to resection and 1 of these died. In these cases mistaken diagnoses of esophageal varices will occur. When the hemorrhage did not seem to threaten life it was managed expectantly always with good results. However success in these cases was ascribed to careful selection of the cases for such treatment rather than to the hemostatic treatment instituted. In these cases Meulengracht's diet was not started until 3 to 5 days following the hemorrhage.

Not to be included in this group of conservatively managed patients are those with a history of previous hemorrhages but without anemia or with only a moderate degree of anemia when they come to operation. In these the indication for operation is practically without restriction. However the authors' faith in this absolute rule has been shaken by a recent experience. The patient was 50 years old with hypertension and a long history of ulcer hemorrhages. At the time of admission however the hemoglobin was 95 and the erythrocyte count 4,980,000. Two internists did not place any contraindications to the resection and the patient had every sign of that type of bleeding ulcer which Allen and Benedict and Thompson declare to be an absolute indication for early operation nevertheless 14 days after the operation the patient developed bronchopneumonia and died.

There were 67 patients with perforated ulcer of which 2 had a jejunal peptic ulcer. Of these 14 were subjected to resection and 53 to invagination and suture. All the resections were done in cases of duodenal ulcer. In 13 of the 52 patients in whom only closure by suture was done gastric ulcer was present and in 39 duodenal ulcer. There were 2 cases of jejunal ulcers in this group. There were three deaths among the total of 67 patients (4.5 per cent). Suture is regarded as the normal method of managing these cases of perforated ulcer when possible with brief history of illness. However these patients subjected to suture are re-examined every 3 months and when possible the resection is put off until later. Primary resection is carried out when the condition is exceptionally opportune for resection when the suture technique is impracticable (e.g., in a niche of a gastric ulcer) and when resection is practicable. The authors do not favor the recently recommended method of treating the freshly perforated ulcer conservatively (gastric drainage with conservative treatment of peritonitis) as the method is too dangerous because of the difficulty of choosing the patients for such treatment.

JOHN W. BRENNAN M.D.

Gastric Polyadenoma (1 polliadenom gastrici) AMERICO BRILL *Chirurgia*, 948, 3, 63.

The author presents 2 case reports of polyadenoma occurring in women, one of them aged 60 years and the other 73. Gastric resection was resorted to in both cases with uneventful recovery.

The history and physical findings are not characteristic and the diagnosis is usually made by means of x rays. The use of the gastroscope permits a more accurate diagnosis. The symptoms are usually of two main types: those caused by pyloric stenosis and those caused by invagination into the duodenum. The complications are ulceration or malignant degeneration. Some authors report that from 50 to 60 per cent of the tumors become malignant. If there is one tumor or a few closely placed tumors, local excision may be used. However if the adenoma is sessile or there are multiple tumors present, wide excision is advised. JUDAH J. FROEDUITE, M.D.

Esophagojejunostomy and Esophagogastrostomy in Inoperable Carcinoma of the Esophagus and Gastric Cardia (Oesophagojejunostomie u oesophagogastronomie u neoperovatelných nádorů Jícnu kardie) VLADIMÍR RAPANT and JAN KUČERA *Lék listy* 948, 3, 507.

Twenty four patients with carcinoma of the cardiac portion of the stomach and of the lower two-thirds of the esophagus were treated surgically at the surgical section of the Palacky University in Olomouc, Czechoslovakia, during the period from August 1, 1946 to May 1, 1948. Of these 13 patients were operated upon by radical resection of the tumor and 5 died. Of the 3 with carcinoma of the intrathoracic portion of the esophagus, 2 died of the 10 with carcinoma of the cardia (in 6 of these the intra-abdominal portion of the esophagus was also involved) 3 (30%) died. Of the remaining patients 3 came to operation. Of these 2 were operated upon palliatively with use of the esophagojejunostomy as recommended by Allison (*Thorax* 1946, 239) there was 1 death. This patient died of cardiac syncope. The operation revealed a huge carcinoma of the gastric cardia penetrating into the esophagus and diaphragm, with secondary growths in the liver. The authors raise the question as to whether even this palliative procedure is indicated in the presence of ascites. In the remaining esophagojejunostomy on the other hand the difficulty in swallowing was removed, the patient feels well, has gained weight, and is free of the troublesome nocturnal regurgitation.

F. d. Allaines and Ch. Dubost (*Ann. Acad. Chir.* 1948, 7415-6, 151) have been doing an esophagogastrostomy as the palliative procedure of choice and seem to want to reduce the operation to the status of an exceptional procedure. The authors do not sympathize with this attitude; they believe that such an attitude would be a step backward in surgical progress and that the newer surgical procedures demand a revision of the surgeon's attitude towards operability in these cases. However they do think that even the palliative operation is contraindicated

in the presence of constant pain in the interscapular region, palpable metastases in the lesser peritoneal sack (fewer advanced cachexia, ascites (interference with the blood current in the vena cava), metastases in the supraclavicular fossa, paralysis of the nerves recurrentes, and invasion of the bronchus by the malignant process. JOHN W. BRIDGMAN, M.D.

A Combined Abdominothoracic Incision Particularly Adapted for Use in Total Gastrectomy and Esophagogastrostomy. ARTHUR J. KERNET, *Surgery* 1948, 24, 605.

The author presents a detailed description of his technique for an abdominothoracic approach adaptable for use in total gastrectomy and esophagogastrostomy as well as in the repair of large paraesophageal hernias. Although several similar incisions have been described previously—notably those of Marwedel in 1903, Kirschner in 1920, Ohsawa in 1933, Humphreys in 1946, Garlock in 1946, Harper in 1947 and Carter in 1947—none of these incisions provide principally for an abdominal dissection with the idea of extending the horizon of total gastrectomy to include removal of additional segments of the lower esophagus.

The patient is placed in a supine position on the operating table with a sandbag under the left side, which produces about a 10 degree elevation from the horizontal. A kidney brace is fastened on the right side of the table to hold the patient in position while the table is rotated later in the operation. The skin incision begins near the lateral edge of the right rectus muscle slightly above the umbilicus and extends horizontally and upward to the left costal margin where the eighth costal cartilage crosses the seventh interspace. The incision is carried through the abdominal wall into the peritoneal cavity. Abdominal exploration is carried out at this time and operability of the lesion is determined. If a decision to proceed with resection is made at this point, the operating table is rotated elevating further the left side of the patient to 30 to 35 degrees from the horizontal. The eighth costal cartilage is cut and the incision is extended into the pleural cavity through the seventh interspace as far as the midaxillary or posterior axillary line. If total gastrectomy alone with infradiaphragmatic esophagojejunostomy is to be performed, incision of the diaphragm about half way from the costal margin to the esophageal hiatus is carried out. If an additional segment of the esophagus is to be resected, the diaphragmatic incision is continued to the esophageal hiatus. The left phrenic nerve as it passes along the lateral surface of the pericardium, is crushed early in the operation. This reduces the motion of the diaphragm and aids in its subsequent repair and healing.

Dissection of the stomach particularly around the cardia and high along the lesser curvature in the area of the left gastric artery is markedly facilitated by removing the barrier of the costal margin. The abdominal portion of the operation (dissection of the lower stomach, transection of the duodenum, and

duodenal closure are readily accomplished. Mobilization of a jejunal loop for esophageal anastomosis is facilitated and if necessary one can readily section one or more of the mesenteric vessels near their origin to gain added mobility of the jejunal loop as recommended by Sweet. All portions of the operation are performed without limitation of exposure. Because of the added exposure, a wider and more complete excision of lymphatic bearing tissue can be accomplished. Although the incision opens two serous cavities it is believed that the added exposure gained allows for a more careful dissection, preparation and anastomosis so that leakage and infection which has been the principal cause of a fatal outcome in most reported cases are less likely to result. Resection of an added segment of esophagus in doing a total gastrectomy is readily accomplished with the exposure obtained whereas in doing a transabdominal total gastrectomy one cannot with ease sacrifice more than small segments.

Closure of the intercostal incision is as follows:

The diaphragm is circumferentially sutured to the anastomotic jejunal loop to prevent any herniation of abdominal viscera into the thoracic cavity. The last few anterior sutures in the diaphragm are placed from the peritoneal surface and tied later from below after the intercostal incision has been closed. In two areas the rib above and below the incision is bared of periosteum and perichondral sutures of No. 0 chromic catgut are passed around the ribs care being taken to avoid catching the intercostal nerves. Tying of these sutures closes the intercostal space. Further closure is obtained by interrupted No. 000 or No. 0000 silk sutures uniting the cut intercostal muscle bundles. Closure is reinforced by suturing the serratus anterior muscle.

The abdominal component of the incision is closed in the usual fashion with interrupted No. 000 silk in the peritoneal layer and in the anterior rectus sheath. Because of the length of the incision the closure takes considerable time. The time can be shortened by having two closure teams working from either end toward the center.

Two potential disadvantages are pointed out by the author. First unless the patient is rotated somewhat laterally there is a tendency for the heart to interfere with exposure in making a high esophago-jejunal anastomosis above the diaphragm. Second with this exposure one is limited to dissection of the esophagus below the hilus of the lung and the inferior pulmonary vein. An anastomosis must therefore be done below the hilus. Consequently, the incision is not useful in lesions of the midesophagus or above the diaphragm.

HAROLD LAUFMAN M.D.

End-to-End Anastomoses after Gastrectomy Technique of Suture Following Hemilection (Anastomoses termino-terminales après gastrectomie; procédé de suture après hémiectomie) J. HUGUEN and C. L. CHATELAIN *Rev. chir.*, Par. 1948, 67, 211

The authors' technique of subtotal and total gastrectomy with end-to-end anastomosis is given

End-to-end anastomosis seems to be the procedure of choice after gastrectomy because it allows a more extensive resection thus eliminating the possibility of marginal ulcer and because it is a more physiological procedure re-establishing the normal continuity of the digestive tract. However this procedure is not without contraindications. It should not be used first in the presence of deperitonealized duodenum second, in cancer of the fundus requiring extirpation of the retropyloric lymph nodes and third when mobilization of the duodenum is insufficient. The procedure is indicated in (1) benign gastric or pyloric ulcer (2) perforated ulcers, if the condition of the patient justifies gastrectomy and (3) bleeding ulcer. Moreover the authors advocate its use after total gastrectomy for carcinoma of the cardia and advise an esophagoduodenal anastomosis.

GERARD GAIGNON M.D.

Intussusception in Children Diagnosis and Therapy with Barium Enema HANS HELLMER. *Acta radiol.* Stockh., 1948, Supp. 65

In an extensive treatise including diagrams and roentgenograms the author describes the picture of intussusception in children, and the technique and results of reduction by barium enema under continuous roentgenologic control. The study is based on 162 cases of intussusception occurring in 137 patients who were diagnosed by means of roentgenograms at the University of Lund, Sweden, during the past 14 years. Forty per cent of the patients were less than 1 year of age.

As a preliminary to reduction plain roentgenograms were taken in the upright and supine positions primarily to exclude other pathologic states—some times located above the diaphragm. The combined diagnostic-therapeutic enema is given by introducing barium through a soft rubber rectal catheter under hydrostatic pressure which is controlled by elevation of the barium reservoir. Fluoroscopic and roentgenologic observation is maintained during the entire time. The importance of the assistant *ad anum* in tightly compressing the buttocks to prevent leakage along the catheter is stressed. Also it is essential that an adequate supply of contrast medium is available at every stage of the procedure. Hellmer uses a 10 liter enema container which is fitted with a thermostat and a stirring device. During the diagnostic portion of the procedure the hydrostatic pressure is kept low (from 50 to 60 cm.) in order that short intussusceptions will not be inadvertently reduced before they can be studied. When the invagination has been located and studied the pressure is increased ordinarily a pressure higher than 15 meters is not used. Hydrostatic pressure alone is used chiefly for the reduction and taxis is avoided unless it is required in forcing the intussusceptum back through the ileocecal valve.

No anesthesia whatsoever is used.

As a criterion of successful reduction it is necessary that the entire colon and cecum be completely filled with the contrast medium. When the reduction

Gastric Polyadenoma (1 polidennomu gastrick) *Ann into Brit. Chir. Soc.* 948, 3 63

The author presents a case report of polyadenoma occurring in women, one of them aged 60 years and the other 73. Gastric resection was resorted to in both cases with uneventful recovery.

The history and physical findings are not characteristic and the diagnosis is usually made by means of x-rays. The use of the gastroscope permits a more accurate diagnosis. The symptoms are usually of two main types: those caused by pyloric stenosis and those caused by intussusception into the duodenum. The complications are ulceration or malignant degeneration. Some authors report that from 50 to 60 per cent of the tumors become malignant. If there is one tumor or a few closely placed tumors, local excision may be used. However if the adenoma is sessile or there are multiple tumors present, wide excision is advised. *LOUIS J. FROSTEN MD*

Esophagojejunostomy and Esophagogastrostomy in Inoperable Carcinoma of the Esophagus and Gastric Cardia (Oesophagojejunostomie a oesophagogastronomie a neoperovatelných nádorů jícnu a kardie) *VLADISLAV RAFAŇ and JAM KUČERA. Lék. listy* 948, 3 307

Twenty-four patients with carcinoma of the cardiac portion of the stomach and of the lower two-thirds of the esophagus were treated surgically at the surgical section of the Palacky University in Olomouc, Czechoslovakia, during the period from August 1, 1946 to May 1, 1948. Of these 13 patients were operated upon by radical resection of the tumor and 5 died. Of the 3 with carcinoma of the intrathoracic portion of the esophagus 1 died of the 10 with carcinoma of the cardia (in 6 of these the intra-abdominal portion of the esophagus was also involved) 3 (30%) died. Of the remaining patients, 5 came to operation. Of these 3 were operated upon palliatively with use of the esophagojejunostomy as recommended by Allison (*Thorax* 946, 1 359) there was 1 death. This patient died of cardiac syncope. The operation revealed a huge carcinoma of the gastric cardia penetrating into the esophagus and diaphragm, with secondary growths in the liver. The authors raise the question as to whether even this palliative procedure is indicated in the presence of ascites. In the remaining esophagojejunostomy on the other hand the difficulty in swallowing was removed, the patient feels well, has gained weight, and is free of the troublesome nocturnal regurgitation.

F. d. Allaines and Ch. Dubost (*Mém. Acad. Chir.*, 1948, 7415-6 151) have been doing an esophagogastrostomy as the palliative procedure of choice and seem to want to reduce the operation to the status of an exceptional procedure. The authors do not sympathize with this attitude; they believe that such an attitude would be a step backward in surgical progress and that the newer surgical procedures demand a revision of the surgeon's attitude towards operability in these cases. However they do think that even the palliative operation is contraindicated

in the presence of constant pain in the intercostal region, palpable metastases in the lesser peritoneal sack, fever, advanced cachexia, ascites (interference with the blood current in the vena cava), metastases in the supraclavicular fossa, paralysis of the nerves recurrentes and invasion of the bronchi by the malignant process. *JOHN W. BRENNAN M.D.*

A Combined Abdominothoracic Incision Particularly Adapted for Use in Total Gastrectomy and Esophagogastrostomy *ANNALS J. KANAKA. Surg.* 1948, 4 605

The author presents a detailed description of his technique for an abdominothoracic approach adaptable for use in total gastrectomy and esophagogastrostomy as well as in the repair of large paraesophageal hernias. Although several similar incisions have been described previously—notably those of Marwedel in 1903, Kirschner in 1920, Okawa in 1933, Humphreys in 1946, Garlock in 1946, Harper in 1944 and Carter in 1947—none of these incisions provide principally for an abdominal dissection with the idea of extending the horizon of total gastrectomy to include removal of additional segments of the lower esophagus.

The patient is placed in a supine position on the operating table with a sandbag under the left side, which produces about a 10 degree elevation from the horizontal. A kidney brace is fastened on the right side of the table to hold the patient in position when the table is rotated later in the operation. The skin incision begins near the lateral edge of the right rectus muscle slightly above the umbilicus and extends horizontally and upward to the left costal margin where the eighth costal cartilage crosses the seventh interspace. The incision is carried through the abdominal wall into the peritoneal cavity. Abdominal exploration is carried out at this time and operability of the lesion is determined. If a decision to proceed with resection is made at this point, the operating table is rotated, elevating further the left side of the patient to 30 to 35 degrees from the horizontal. The eighth costal cartilage is cut and the incision is extended into the pleural cavity through the seventh interspace as far as the midaxillary or posterior axillary line. If total gastrectomy alone with intradiaphragmatic esophagojejunostomy is to be performed incision of the diaphragm about halfway from the costal margin to the esophageal hiatus is carried out. If an additional segment of the esophagus is to be resected the diaphragmatic incision is continued to the esophageal hiatus. The left phrenic nerve as it passes along the lateral surface of the pericardium is crushed early in the operation. This reduces the motion of the diaphragm and aids in its subsequent repair and healing.

Dissection of the stomach particularly around the cardia and high along the lesser curvature in the area of the left gastric artery is markedly facilitated by removing the barrier of the costal margin. The abdominal portion of the operation, dissection of the lower stomach, transection of the duodenum, and

duodenal closure are readily accomplished. Mobilization of a jejunal loop for esophageal anastomosis is facilitated and if necessary one can readily section one or more of the mesenteric vessels near their origin to gain added mobility of the jejunal loop as recommended by Sweet. All portions of the operation are performed without limitation of exposure. Because of the added exposure, a wider and more complete excision of lymphatic bearing tissue can be accomplished. Although the incision opens two serous cavities it is believed that the added exposure gained allows for a more careful dissection, preparation, and anastomosis, so that leakage and infection which has been the principal cause of a fatal outcome in most reported cases are less likely to result. Resection of an added segment of esophagus in doing a total gastrectomy is readily accomplished with the exposure obtained whereas in doing a transabdominal total gastrectomy one cannot with ease sacrifice more than small segments.

Closure of the intercostal incision is as follows:

The diaphragm is circumferentially sutured to the anastomotic jejunal loop to prevent any herniation of abdominal viscera into the thoracic cavity. The last few anterior sutures in the diaphragm are placed from the peritoneal surface and tied later from below after the intercostal incision has been closed. In two areas the rib above and below the incision is bared of periosteum and perichondral sutures of No. 0 chromic catgut are passed around the ribs care being taken to avoid catching the intercostal nerves. Tying of these sutures closes the intercostal space. Further closure is obtained by interrupted No. 000 or No. 0000 silk sutures uniting the cut intercostal muscle bundles. Closure is reinforced by suturing the serratus anterior muscle.

The abdominal component of the incision is closed in the usual fashion with interrupted No. 000 silk in the peritoneal layer and in the anterior rectus sheath. Because of the length of the incision the closure takes considerable time. The time can be shortened by having two closure teams working from either end toward the center.

Two potential disadvantages are pointed out by the author. First unless the patient is rotated somewhat laterally there is a tendency for the heart to interfere with exposure in making a high esophago-jejunal anastomosis above the diaphragm. Second with this exposure one is limited to dissection of the esophagus below the hilus of the lung and the inferior pulmonary vein. An anastomosis must therefore be done below the hilus. Consequently the incision is not useful in lesions of the midesophagus or above the diaphragm.

HAROLD LAUFMAN M.D.

End-to-End Anastomoses after Gastrectomy Technique of Suture Following Hemisection (Anastomoses termino-terminales après gastrectomie; procédé de suture après hémisection). J. HUGUENIN and C. L. CHATELIER *Rev. chir. Par.* 1948, 67, 211.

The authors technique of subtotal and total gastrectomy with end-to-end anastomosis is given

End-to-end anastomosis seems to be the procedure of choice after gastrectomy because it allows a more extensive resection thus eliminating the possibility of marginal ulcer and because it is a more physiological procedure re-establishing the normal continuity of the digestive tract. However this procedure is not without contraindications. It should not be used first, in the presence of deperitonealized duodenum second in cancer of the fundus requiring extirpation of the retropyloric lymph nodes and third when mobilization of the duodenum is insufficient. The procedure is indicated in (1) benign gastric or pyloric ulcer (2) perforated ulcers. If the condition of the patient justifies gastrectomy and (3) bleeding ulcer. Moreover the authors advocate its use after total gastrectomy for carcinoma of the cardia and advise an esophagoduodenal anastomosis.

GERARD GAONON M.D.

Intussusception in Children. Diagnosis and Therapy with Barium Enema. HANS HELLMER. *Acta radiol. Stockh.* 1948 Supp. 65.

In an extensive treatise including diagrams and roentgenograms the author describes the picture of intussusception in children and the technique and results of reduction by barium enema under continuous roentgenologic control. The study is based on 162 cases of intussusception occurring in 137 patients who were diagnosed by means of roentgenograms at the University of Lund, Sweden, during the past 14 years. Forty per cent of the patients were less than 1 year of age.

As a preliminary to reduction plain roentgenograms were taken in the upright and supine positions primarily to exclude other pathologic states—some times located above the diaphragm. The combined diagnostic-therapeutic enema is given by introducing barium through a soft rubber rectal catheter under hydrostatic pressure which is controlled by elevation of the barium reservoir. Fluoroscopic and roentgenologic observation is maintained during the entire time. The importance of the assistant *ad manus* in tightly compressing the buttocks to prevent leakage along the catheter is stressed. Also it is essential that an adequate supply of contrast medium is available at every stage of the procedure. Hellmer uses a 10 liter enema container which is fitted with a thermostat and a stirring device. During the diagnostic portion of the procedure the hydrostatic pressure is kept low (from 50 to 60 cm.) in order that short intussusceptions will not be inadvertently reduced before they can be studied. When the invagination has been located and studied the pressure is increased ordinarily a pressure higher than 15 meters is not used. Hydrostatic pressure alone is used chiefly for the reduction and taxis is avoided unless it is required in forcing the intussusceptum back through the ileocecal valve.

No anesthesia whatsoever is used.

As a criterion of successful reduction it is necessary that the entire colon and cecum be completely filled with the contrast medium. When the reduction

is complete the barium will pass unimpeded to a point fairly high in the small intestine.

Reduction with a barium enema was successful in 130 of the total 162 cases (80.3%). In these 130 cases the point of origin of the intussusception was found to be in the small intestine in 60 cases and in the colon in 9 cases. It could not be definitely ascertained in 61 cases. In 30 cases the reduction had to be completed by surgical intervention and among these cases 9 deaths occurred. In 3 cases in which reduction by means of a barium enema failed spontaneous reduction occurred. There were no deaths in the cases reduced by the barium enema alone. There was a recurrence rate of 16.5 per cent among the cases reduced by enema, which is somewhat higher than the recurrence rate following surgical treatment. WATKES FIELD CAMERON, M.D.

A Case of Anthrax Intestinalis (Shichal or anthrax intestinalis) R. STORCKENY, Chir. arthrop. Soda, 948, No. 2-3 1937

A 17 year old girl suffered chills, fever, and generalized abdominal pains following a meal. The attack lasted until 8 o'clock in the evening when the fever dropped and the patient slept the whole night. The next day there were 3 similar attacks of chills and pain which became steadily worse. Nose bleed lasted the whole day and she vomited all of the food she had eaten. During the following 3 days the condition became worse and there were 3 more attacks of chills. Convulsions occurred and the mind became clouded. On entrance to the hospital a diagnosis of ruptured appendix was made and the patient was operated upon as an emergency.

Upon opening of the abdomen there issued from the peritoneal cavity considerable hemorrhagic exudate. The appendix was removed although it was not obviously pathological and as the patient suddenly changed for the worse the abdomen was hurriedly closed. She died some time later.

Autopsy disclosed discolored portion of the small intestine, from 10 to 12 cm. in length, immediately above the ileocecal valve, as well as portions of the large intestine covered with a dark colored exudate. The mesenteric and retroperitoneal lymph glands were enlarged. On section the wall of the affected portion of the intestine was found to be edematous throughout with a diameter of from 2 to 2.5 cm. Involving the mucosa was a carbunclelike discolored mass. In the mucosa of the stomach, also, immediately below the cardia, was a carbunclelike lesion, clearly delimited, of irregular form and irregularly necrotic, which protruded into the gastric lumen. In both carbuncles were great quantities of anthrax bacilli.

The author recalls a similar case in 1940 in which anthrax bacilli were found in the spinal fluid sediment, but were at that time considered to be a contamination.

Although the diagnosis during life of intestinal anthrax is exceedingly difficult, nevertheless in all cases presenting a severe abdominal septic picture

the possibility must be considered and the anthrax bacillus should be sought in the blood, spinal fluid, and feces. Once the bacillus is demonstrated, which should not be too hard to do, treatment should be initiated immediately with large doses (300 to 500 cm.) of antitetanic serum, given intramuscularly or intravenously for 2 or 3 days (Andreev).

Recently penicillin has been highly recommended for anthrax infection but even this type of treatment must be started early.

JOHN W. BRENNAN, M.D.

Duodenal Ulcer—A Follow Up Study of 343 Veterans Discharged Because of Ulcer Allied to HUSAR. Gastroenterology 948, 1:183.

Duodenal ulcer among military personnel was a much discussed problem in the medical literature during World War II because of its incidence and the difficulties encountered in establishing the diagnosis and in finding the proper policy for the disposition of the soldiers. Because veterans are receiving disability compensation if their ulcer was initiated or aggravated by military service, a postwar problem arose. What is the fate of duodenal ulcer in patients who are being compensated for their illness? Three hundred and five veterans were interviewed and re-examined in order to adjust their compensation received from the government according to the status of their ulcer and the degree of disability. The average length of time elapsed since their separation from military service was 34 months. Only 5 patients had undergone surgery. 300 had medical management.

X ray examination revealed ulcer crater in 22 per cent, irritable bulb in 21 per cent, deformed bulb in 41 per cent, and negative findings in 26 per cent of the cases. Clinical activity as determined from the patient's symptoms was found in 60 per cent. From x ray examination and symptoms, the ulcer was diagnosed as active in 63 per cent and inactive in 37 per cent of the cases. From the patients' histories it was learned that since their separation from service 6 per cent had no recurrences, 9 per cent had no symptoms so long as they adhered to the diet, 23 per cent had rare recurrences, 30 per cent had frequent recurrences, and 43 per cent had almost continuous symptoms. Thirty-eight per cent of the patients who had followed an adequate or fairly adequate ulcer regimen had frequent recurrences or continuous symptoms and were therefore classified as intractable to medical management. The figures obtained from both sources—case histories and x-ray findings, were higher than could be expected from noncompensation experience.

The unusual figures were explained by the presence of the compensation factor which caused the patients to exaggerate their symptoms and interfered, through a psychosomatic way with the healing of the ulcer. Evidence of improper ulcer management existed. There were also good reasons to believe that these patients had more emotional conflicts than noncompensation patients. Suggestions

were made to eliminate the compensation factor to educate the patients, and to make psychotherapy available to them.

BENJAMIN GOLDMAN M.D.

Use of the Defunctionalized Loop of Jejunum in Biliary and Pancreatic Surgery L. W. PETERSON and WARREN H. COLE. *Arch. Surg.* 1943, 56 445

The authors present both roentgenographic and clinical evidence of reflux of the jejunal contents into the biliary tract following anastomosis of a jejunal loop to the hilar bile ducts for stricture and absence of the common bile duct. Reflux occurred even though enteroanastomosis between the ascending and descending loops of jejunum had been performed. In 2 patients subsequent severing and turning in of the ends of the proximal or ascending limb of jejunum resulted in immediate cessation of chills and fever and an asymptomatic course thereafter. This observation led the authors to adopt the principle of the jejunal loop leading to an anastomosis between a cyst and the gall bladder even though an anastomosis was made between the two arms of the jejunum. At no time has roentgen examination showed reflux of barium up the proximal limb of jejunum past such folds or valves through the stoma connecting the intestine with cysts.

Animal experiments showed that the flap type of valves atrophied to such an extent that the valve function would appear impossible. On the other hand valves made by infolding the jejunal wall showed no evidence of atrophy or other significant change for at least 8 months.

The authors found that use of the Roux Y principle in anastomosing the jejunum to the common duct for head of the pancreas was satisfactory. Originally they constructed valves or folds in the jejunal limb but no longer do so because reflux of food or secretion would have to take place against the peristaltic mechanism. They recommend that the arm of the jejunum above the 16" enteroanastomosis be at least 16 inches (41 cm.) long.

When cholecystenterostomy is performed for inoperable carcinoma of the pancreas they do not modify or lengthen the operation by the construction of folds or valves since the patient will probably die before symptoms of suppurative cholangitis develop. However when the small intestine is anastomosed to the gall bladder or other structures for benign lesions they recommend construction of two or three folds in the proximal arm of the jejunum even with an enteroanastomosis.

JOHN L. LINDQUIST M.D.

Ectopic Appendix (Appendice ectopica) A. R. ALBARRAZ and S. CUBANY ACUTER. *Cirugía* 1948, 1 235

The authors report 2 cases of ectopic appendix vermiformis. In the first the entire large bowel was isolated left of the abdominal midline. Unable to find the colon or appendix through a McBurney's in-

cision, closure was performed and roentgen studies revealed the position of the bowel. At a second left iliac incision and removed. Recovery was without incident.

In the second case, 2 years later when neither the cecum nor omentum was found in their normal position through a McBurney's incision, a dressing forceps inserted into the left iliac fossa produced the omentum and a second forceps delivered the cecum with the appendix. The latter was removed. The patient's recovery was uneventful.

The location of the appendix depends upon the partial or complete rotation of the bowel, which presents the following possibilities: (1) normal, in right iliac fossa; (2) oblique colon, with partial rotation of the bowel the appendix lies high under the liver in the superior right quadrant of the abdomen; (3) in complete rotation with the small intestine in the right hemiabdomen and the entire colon in the left iliac fossa; (4) situs inversus, in which there is transposition of all the organs of the abdomen the sigmoid will be in the right and the appendix in the left iliac fossa. This condition the authors believe should be designated complete appendicular ectopia. When the appendix and cecum alone are displaced the term cecoappendicular ectopia should be employed.

STEPHEN A. ZIEGLER M.D.

Volvulus of the Transverse Colon (Le volvulus du colon transverse) CL. OLIVIER and H. LEBLAUD. *Presse med.*, 1948 56 541

The authors discuss the problem of volvulus of the transverse colon and state that only 16 case reports appear in the literature.

Volvulus of the transverse colon occurs almost always in females past 50 years of age who have had a long history of chronic constipation. The presence of a megacolon can often be demonstrated. The abdominal pain is usually colicky in nature, sometimes similar to that experienced in the passage of a urinary calculus. Even though the obstruction from the volvulus is almost complete vomiting is a late sign and the general well being of the patient is preserved for quite a long period.

The evolution of the illness is slow. Most of the patients whose cases are reported in the literature were operated upon not less than 3 days after the onset of symptoms. The abdominal distention which is predominantly perumbilical is asymmetric in that it crosses the midline on an oblique axis from one or the other hypochondrium to the opposite iliac fossa. The roentgen study of the colon by barium enema usually shows complete arrest of the barium column at the most distal portion of the volvulus.

Volvulus of the transverse colon frequently is caused or accompanied by other local lesions such as polyps or neoplasms of various sorts or inflammatory conditions of the immediate area. Early recognition and operative correction of the condition involved is mandatory in order to reduce the significant mortality of the disease.

ORVILLE F. GRIMES M.D.

The Response to Vagotomy in Idiopathic Ulcerative Colitis and Regional Enteritis. CLARENCE DIXON, FRANK D. EDDY, HOWARD H. FRYDMAN, AUSTIN M. MCCARTHY and DARRELL WESTOVER. *Ann Surg* 1948, 128: 470.

A study of the experience with idiopathic ulcerative colitis at the University of Minnesota Hospitals, Minneapolis during the 10 year period ending January 1, 1944 revealed that 57 patients were treated expectantly and nonsurgically throughout, or until the situation had deteriorated to a desperate point, with a 28 per cent hospital mortality and that more than one-half of the group so treated from 1934 to 1936 were dead by the time the study was undertaken. Furthermore, cancer of the colon took a high toll in all cases in which the colon was allowed to remain.

Twenty-five patients were subjected to elective ileostomy at a time when there was a reasonable choice with a resulting mortality of only 8 per cent—a decided improvement. However this method of treatment failed to salvage the diseased colon and subjected the patient to a radical and deforming surgical procedure as well as to the complications of skin erosion and ascending ileitis.

A case is presented of a 20 year old girl who had had five-sixths of the ileum and the colon removed for ulcerative colitis and who continued to suffer from ascending ileitis. Vagotomy was proposed as a possible corrective measure, and was carried out with astounding relief of the patient's symptoms. This was followed by similar treatment in 4 cases selected early in the course of their disease. These patients were followed for a period of 6 months and likewise responded very well. In view of the results, a more extensive clinical study was planned.

Twenty-eight patients who had undergone vagotomy for ulcerative colitis were studied. These patients presented many phases of the disease, and 4 died. In one case death occurred before surgery could be attempted, and this case is not included in the study. The 3 remaining deaths were caused by (1) apparent auricular fibrillation (2) intra-abdominal abscess and fistula between the ileum and sigmoid presumably present before vagotomy, and (3) recurrent intestinal obstruction apparently related to previous abdominal surgery. Twenty-five patients remained for follow up study. Vagotomy alone was done in 16 of these, 4 of whom were not completely asymptomatic after surgery. 5 patients are unimproved and the remaining 6 showed marked improvement, as did many of the patients who had already undergone an ileostomy or an ileostomy concomitantly with the vagotomy.

Certain of the special studies of these vagotomized cases reveal interesting facts. The average weight gain was 15 per cent. Proctoscopy revealed improvement in the rectal mucosa in 7 cases, and complete healing in 4 cases. In 3 there was no improvement and in 3 the mucosa appeared worse.

Roentgen changes were striking and showed improvement in all but one case. The response was

best in those cases in which preoperative study did not reveal complete loss of distensibility and haustral markings of the colon.

Stool examination revealed less frequent blood, pus, and mucus after vagotomy but none of the patients was entirely free of all three constituents.

An attempt was made to evaluate the transit time of food through the various segments of the gastrointestinal tract. Gastric delay in emptying after vagotomy is well known. The mean small bowel passage time increased from 3.5 hours to 7.5 hours, and the colon passage time from 3.1 hour to 11.5 hours.

The mechanism of improvement in ulcerative colitis following vagotomy is unknown. That the vagal effect and fibers, thought to end in the mid-colon, probably extend to the anus is very likely.

The patients with ulcerative colitis who showed the greatest improvement following vagotomy are those with the earliest signs of the disease and the least permanent changes in the colon.

FREDERICK C. HOKERT, M.D.

Volvulus of the Cecum. CLAUDE F. DIXON and ALFRED C. MITTER. *Surg Clin. N. America*, 1948, 8: 933.

Twelve cases in which volvulus of the cecum was encountered at the Mayo Clinic were analyzed. In all cases failure of normal fixation of the cecum was manifested. Eleven of the 12 patients had had previous operations. 10 of them abdominal, and in 2 cases volvulus occurred in the immediate postoperative period.

The signs and symptoms of volvulus of the cecum are those of a low intestinal obstruction, but absence of vomiting and passage of gas and fecal material by rectum do not preclude diagnosis early in the disease.

Occasionally diagnosis of volvulus of the cecum may be made on roentgenographic examination. A hugely distended loop of large bowel is apparent and the presence of gas in the small intestine is evident but the colon is not distended.

Simple detorsion and fixation if possible are the best treatment in the absence of gangrene. Resection over a three-bladed clamp is the safest procedure when gangrene is present.

Intermittent volvulus of the cecum does occur. A new operative procedure is suggested for its correction.

Certain Considerations of Acute Volvulus of the Cecum (Quelques considérations sur les volvulus aigus du caecum). JEAN SÉCHOUX and MAURICE COUDRE. *J. chir. Par.* 1948, 64: 409.

A review of 4 cases of acute volvulus of the cecum, collected from the literature, is supplemented by 6 case histories from the authors' material.

In some instances the cecum may be rotated as much as 720 degrees. In 4 of 6 cases the distended cecum formed a right angle with the ascending colon. The author states that the length of the mesocolon represents the radius of the arc described by the cecum in its migration; that distention of the right

colon always provokes a certain degree of rotation, and that gaseous distention is not the only cause of volvulus excessive peristalsis being an important factor.

Volvulus of the cecum occurs with approximately equal frequency in men and in women and the majority of patients are over 30 years of age. Usually the general condition of the patient remains good for a relatively long period of time.

Two roentgenologic signs are of great diagnostic importance:

1. Empty space in the right iliac fossa and the presence of incisurae characteristic for the colon, namely coarser, farther apart and more shallow than those in the ileum.

2. If scout pictures of the abdomen do not furnish sufficient information, pneumoperitoneum has not occurred and the general condition of the patient is satisfactory, a barium enema may be employed. No barium is allowed to pass the obstacle in the ascending or transverse colon.

Operative relief of torsion must be supplemented either by a cecostomy or if this is impossible a cecostomy or hemicolectomy. Cecostomy permits immobilization of the cecum and better drainage than that which is obtained through a colon tube introduced through the rectum. Cecostomy is indicated especially in advanced cases of volvulus; it should be done through a special incision. As a rule the cecostomy closes spontaneously. Hemicolectomy is indicated when an abnormally long gut is implicated or when the vitality of the affected cecum is greatly impaired. Exteriorization is condemned.

The authors believe that prophylactic treatment is of great value. An ectopic cecum which is recognized clinically, roentgenologically or in course of appendectomy should be properly immobilized. Repair of a sliding hernia should be supplemented by immobilization of the cecum and the adjoining portion of the colon.

Of 44 patients in whom the evolution of the condition could be followed 12 or 27 per cent died from volvulus. JOSEPH K. NARAT, M.D.

Surgical Management of Carcinoma of the Colon and Rectum. T. E. JONES, *Surg. Clin. A. America* 1948 23: 1159

Improvements in the surgical management of carcinoma of the colon and rectum during the past 25 years are attributed to improvements in surgical technique and the application of physiologic principles to the preoperative and postoperative care. Early diagnosis by virtue of improvements in roentgenology and in the allied fields of medicine also has been a contributing factor.

A further plea is made for early diagnosis on the part of the practicing physician, since many patients who reach the surgeon in an inoperable condition have been examined previously.

As to the choice of operation, the one fundamental prerequisite is an extensive and as radical an operation as possible. Whether this is done by the closed

or open method, by the one-stage or two-stage method or by any other technique makes little difference provided the surgeon can show that his results from the standpoint of mortality and morbidity are equal to those of other techniques. Perfecting one technique is considered by the author as more desirable than trying every new procedure that is introduced. The type of procedure must fit the needs of the patient. Obstruction, subacute perforation or fixation must alter the course of even the strongest advocate of the one-stage procedure. Eventually less depends on the method used than on the manner of its execution. The mortality figures in recent years show a range of 10 to 25 per cent for the same operation. The author feels that this disparity is probably due to the manner of execution.

One of the greatest difficulties of resection of the right colon, particularly in the very obese patient, is peritonealization of the right gutter. Improperly completed, it will lead to adhesions and obstruction, a definite factor in mortality. For several years the author has obviated this complication by the use of the modified Mikulicz pack. This pack prevents the small intestine from becoming adherent to the area and the postoperative convalescence is therefore much smoother. The technique for the use of the pack is reviewed. With careful postoperative attention the cavity created by the pack assumes the shape of a vertical sinus within a week, and the wound is entirely healed in 6 to 10 weeks. In selected cases the omentum can often be employed to cover denuded surfaces. When its use is favorable, no problem exists. In resection of the right colon for growths in that area, the author does not employ a two-stage procedure unless there is obstruction or perforation of the growth.

In the operative treatment of lesions of the transverse colon it is important to carry out a complete temporary tube cecostomy in conjunction with a one-stage procedure. Resection is performed in the manner best suited to the case. If the cecostomy tube is removed on the fifth or sixth day the stoma will be closed by the time the patient is discharged from the hospital. In cases of marked obstruction, which is generally not the rule, the tube cecostomy should be performed first under local anesthesia, followed in a week by resection.

In regions of the splenic flexure mobilization may be difficult because of adhesions to the spleen and it may be necessary to remove the spleen with the lesion.

In the treatment of lesions of the descending colon and sigmoid, the author has come to prefer the Rankin modification of the Mikulicz procedure. Since this modification has been employed, the mortality for resection of lesions in this area has dropped from 14 per cent to 5 per cent.

The author reiterates his firm conviction that the treatment of carcinoma of the rectum and rectosigmoid is the one-stage abdominoperineal resection (Miles). In a series of over 1,000 cases, the mortality was 7.2 per cent. One hundred and thirty-seven

consecutive patients were operated upon without a single fatality.

"None alone will tell whether the mortality morbidity and curability justify" the employment of sphincter-saving operations.

HAROLD LAUTMAN, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

On Surgically Treated Hepatitis. STEN BRATTENRÖM
Acta chir. scand., 945, 97-53.

The author cites earlier reports in the literature of acute hepatitis with a prolonged course in patients who were treated by means of perfusion of the biliary passages with good results. The beneficial effect has been ascribed to the washing away of an assumed mucus plug in the choledochus which constituted a relative obstruction to the biliary flow when secretion pressure was lowered by primary hepatitis. In this connection a brief account is given of recent French studies on the physiology and pathophysiology of the biliary passages by means of cholangiography and manometric measurements during operation. The authors of these studies stated they were able to show that a condition of dystonia within the biliary passages, or disturbances of the neuromuscular co-ordination in the sphincter system play an important role in the origin and course of certain out prolonged hepatic conditions.

Experience suggests that a closer analysis of the dystonias, by means of cholangiography and manometric measurements of pressure conditions during operation, would facilitate a rational surgical therapy in certain conditions of hepatitis by indicating vagotomy, splanchicotomy or epiphi terotomy. Experience already gained in this field affords further clarification of the beneficial effect of external drainage of the choledochus, long recognized in several quarters.

From the surgical department of Helsingborg's County and Municipal Hospital the author reports 4 cases in which the clinical diagnosis was acute hepatitis and the surgical procedure consisted of drainage of the choledochus. In all of the cases, biopsy of the liver was done at operation, and the 13 surviving patients were re-examined. In 13 cases intervention resulted in immediate improvement, although in several instances there were serious microscopic changes and the biopsies revealed parenchymal lesions. Two patients subsequently developed cirrhosis, and after a lapse of 6 months one had a reactivation of the hepatitis.

The author stresses the importance of the dystonias of the biliary passages in certain prolonged cases of hepatitis and points out that in many instances these are amenable to surgical treatment, and that conservative therapy should not be pursued unduly long as disastrous effects on the liver parenchyma may ensue.

Cholangiographic and manometric studies during operation may on careful analysis, afford indica-

tions for intervention involving the vagus, the splanchnicus, or the sphincter of Oddi. Pending further experience of these measures, external drainage of the choledochus provides a fairly safe procedure which undoubtedly has a beneficial effect on the hepatic process. BENJAMIN GOLDMAN, M.D.

Gangrenous Cholecystitis: A Clinical and Pathologic Study of 100 Cases. LEONARD C. HALLIDAY, MALCOLM B. DOCKERTY and JOHN M. WAGNER. *Surg. Clin. N. America*, 945, 28-979.

The series of 100 cases studied by the authors represented about a 5 per cent of all cases of cholecystic disease in which operation was performed, and constituted about 33 per cent of all cases of acute cholecystitis in which surgical exploration was performed at the Mayo Clinic. Males and females were affected about equally while 57 per cent of the patients were more than 50 years of age. The symptoms were severe when the patients were seen early; in delayed cases the symptoms were often minimal.

A palpable gall bladder was present in 39 per cent of the cases. Obstruction of the cystic duct was present in 93 per cent of cases, while in 59 per cent this obstruction was due to a gallstone impacted in the duct. Perforation of the gall bladder was present in 24 per cent of the cases (there were no free perforations in this series).

Histologically there were massive necrosis, congestion, edema, hemorrhage, thrombosis, fibrosis and subintimal arterial edema and proliferation. Infiltration of polymorphonuclear cells, indicating infection, was present in 41 per cent of the cases.

Cholecystectomy although difficult in some cases, was done in these 100 cases with 3 deaths.

It was concluded by the authors that most cases of gangrenous cholecystitis are primarily obstructive in nature, because of a stone in the cystic duct. Infection is commonly present, but seems to play a secondary role. Circulatory lesions are predominant, and perforation is frequent. Generalized peritonitis is rare presumably because of the walling-off influence of the surrounding structures. The treatment of choice in gangrenous cholecystitis is early operation: the operation of choice is cholecystectomy although in selected cases cholecystostomy is advisable. The results of cholecystectomy in cases of gangrenous cholecystitis are generally good. The best treatment for gangrenous cholecystitis lies in prophylaxis, which consists in cholecystectomy early in the course of the disease. Eighty-eight per cent of this series of patients had had previous attacks.

External Choledochoduodenostomy (Die Choledochoduodenostomia externa) P. E. SCHMIDT. *Chirurg.*, 1945, 19-257.

Following a brief review of the frequently clashing opinions as to the proper indications for external choledochoduodenostomy, the author defines his purpose to be that of extending the indications for this operation beyond that of an emergency procedure, especially as a primary as opposed to a secondary

intervention. The latter often comes too late to be of benefit to the patient.

The author presents 13 cases of external choledochoduodenostomy, the postoperative duration of treatment of which averaged 25.9 days. There were no deaths. In 1 case the choledochoduodenostomy was performed as a second operation and in another case as the third operation on the biliary tract. In 11 of the 13 cases clinical and operative findings were most serious. There was no case of bile peritonitis.

The author believes that this operation is indicated in patients in poor general condition rather than for drainage of the choledochus. Prolonged bile deficiency leads to digestive disturbances as well as disturbances in blood regeneration and calcium metabolism. Laterolateral anastomosis to the posterior wall of the duodenum will help to prevent constriction of the site of anastomosis. Also tension must be avoided. The author did not mobilize the duodenum, always employing a supraduodenal anastomosis. A transverse incision of the choledochus was made. Suture was performed in two layers, one with catgut (the internal layer) and the other with silk. Neither a biliary fistula nor peritonitis was observed. The internal suture with catgut is the surest guard against fistula stricture, or recurrence of stenosis.

Three of the patients suffered from cholangitis and 3 others had symptoms of damage to the parenchyma of the liver. In all of these cases choledochoduodenostomy brought prompt recovery. The same was true of patients operated on during jaundice. Also cholangitis responds to this procedure, if it is done promptly before the walls of the bile ducts become rigid with cicatricial changes. No cases of ascending postoperative cholangitis were observed. The anastomoses in this series were performed for cholangitis, parenchymal damage to the liver and abscesses as well as perforations into the intestine and liver and for massive displacements of the biliary and hepatic ducts due to calculi and cicatricial changes in the papilla of Vater. Not a single biliary fistula was observed and not a single case of hepatobiliary dysfunction. There was no bile peritonitis and no abscess of the abdominal wall or cicatrice. There was 1 wound fistula at the site of drainage. The advantages of suture in 2 layers with the inner layer of catgut, are stressed.

EDITH SCHANZEE MOORE.

The Quantitative and Qualitative Control of Bile Flow and Its Relation to Biliary Tract Surgery R. RUSSELL BEST. *Ann Surg.*, 1948, 128 348.

This study is based upon the premise that many of the recurrent or remaining symptoms following gall bladder and common duct surgery are caused by small retained stones and debris or the recurrence of such stones and debris because of slow flow of viscous bile low in quality and high in total bile solids. The rate of flow is also affected by spastic or atonic conditions of the sphincter of Oddi and of stricture or narrowing of the common duct.

It is assumed that if the flow of bile could be qualitatively controlled it would be possible to prevent development of biliary tract stones. This has never been accomplished to date, but a bile can be produced which is thin and watery and less conducive to stone formations by the choleretic effect of bile and bile fractions. Likewise, the quantity of bile and thus the rate of flow through the bile ducts can also be controlled.

The physiology and chemistry of bile and bile fractions is reviewed in relation to the quantity of bile and the quality of the bile produced when these fractions are taken by mouth. Experimentally ox bile salts (this is unoxidized conjugated glycocholic and taurocholic acid) given orally increases the volume of bile 36 per cent, increases the total solids 22 per cent and increases bile viscosity. Dechad (oxidized conjugated bile acids) increases bile volume 39 per cent and total solids 2 per cent, but does not change the viscosity.

Ketochol increased the bile volume 99 per cent, reduced the total bile solids 8 per cent and reduced the viscosity of the bile. Decholin increased the bile volume 106 per cent reduced the solids 22 per cent reduced the bile viscosity and was the only one tested that reduced the cholesterol content of the bile.

The last two products are recommended for use in "flushing" the bile ducts and for reduction of the incidence of stone and sludge formation. The author outlines his method of using either of these two products in combination with atropine and nitroglycerin to "flush" the biliary system, and indicates that he uses it routinely following biliary tract surgery. It is used preoperatively in some cases and periodically in cases in which the common duct has been reconstructed over a vitallium tube or other foreign material likely to become encrusted with precipitation of bile contents. The results as illustrated are good.

FREDERICK C. HOGART, M.D.

Reconstruction of the Bile Ducts (Beitrag zur Problem des Gallengangesnates) GERHARD KREIER. *Chirurg* 1948, 19: 161.

On the basis of 3 personally observed cases the author discusses the reconstruction of extensive defects of the biliary tract reaching almost to the portals of the liver or directly to them. Two methods of bridging these defects are available: (1) direct anastomosis of the remaining extrahepatic or intrahepatic duct with the gastrointestinal tract, or (2) the use of prosthetic material. These two methods have been combined in the Voelcker operation. Attempts to utilize prosthetic or autoplasmic materials for such repair have yielded questionable results and involve difficult technical problems.

Any method of repair of defects in the bile ducts involving danger of stenosis with its fatal consequences should be eschewed. Methods in which the use of proper technique will obviate this risk include:

1. Anastomosis of the stump of the hepatic duct to the duodenum, employing if necessary a transi-

tory interpolation of a rubber tube according to Voelcker and thus favoring direct union. The Voelcker operation is frequently not feasible, however. The necessary mobilization of the duodenum for this purpose is frequently impossible because of adhesions.

2. Goetze's operation. Here, too, adhesions interfering with mobilization of the duodenum may prohibit this operation.

3. Anastomosis between the stump of the hepatic duct and the jejunum, i.e. hepaticojejunostomy.

4. So-called hepatogastricojejunostomy which has little chance of success.

Good results have been obtained, however, both with Goetze's operation and with hepaticojejunostomy.

The author describes a case of artillery wound in which laparotomy revealed injury of the bile ducts (th. common duct, th. cystic duct and the inferior hepatic duct). The duodenum had been torn also, although the lumen had not been injured. The gall bladder, the cystic duct, and the remnants of the other ducts were removed. The very short stump of the choledochus was closed and the duodenal wall was sutured and later covered with omentum. The hepatic stump was about 1 cm. long. Hepaticojejunostomy was followed by speedy recovery. Three months later the patient reported that he was in splendid health. Exclusion of the jejunal loop renders access of the intestinal contents to the bile ducts almost impossible. This constitutes a great advantage over other biliary-intestinal anastomoses. Because of the absence of tension between the biliary stump and the highly movable loop of the small intestine, exactly approximated sutures and supplementary overcasting are possible which diminishes the danger of fistulization.

Another case in which the Goetze plastic procedure was employed is likewise described in detail. The result was successful in spite of preoperative jaundice of 6 1/2 weeks duration fever and debility. No signs of biliary stasis were observed following the operation nor of stasis of food in the bile ducts of the liver which conditions have frequently been complained of as results of this operation. The Goetze operation is very rapid as compared with hepaticojejunostomy. The two procedures have their special indications.

In certain cases the use of prosthetic or autoplasmic material for the repair of defects cannot be avoided. A case is described in which severe jaundice and gallstones demanded intervention 3 months following thyroidectomy. The technique used was employed because very rapid intervention was indicated on account of the very poor condition of the patient. In liberating the neck of the gall bladder the hepatic duct and a portion of the choledochus were resected. A T-drain was inserted to replace the resected portion, one limb being inserted into the intrahepatic orifice of the hepatic duct and the other limb into the choledochus. The drain was covered with omentum in the hope of forming a sort of canal through the

tissue. After a stormy postoperative session, the patient recovered. The drain was removed and the fistula closed. Further observation will be needed to evaluate the end results of this procedure in this case. This operation should be done only as a last resort.

In the absence of an extrahepatic bile duct rest, the Goetze operation with duodenal anastomosis, or if the duodenum is immovable, a jejunal anastomosis is indicated. When ample extrahepatic duct rests are present, hepaticojejunostomy is indicated.

EDITH SCHMIDTKE MOORE.

Four Years after the Reconstruction of the Common Duct with a Rubber Tube (Quattro anni dopo la ricostruzione del coledoco con protesi di tubo di gomma). ANTONINO CIRMATA. *Chirurgia*, 1943, 3: 83.

The author illustrates a case of reconstruction of the common duct with a rubber tube prosthesis. At operation an anomaly was found in which the gall bladder was interposed between the hepatic duct and the common duct, no cystic duct being present. The gall bladder was contracted, thickened, and contained stones. There were stones in the common duct also. After cholecystectomy there was a gap of 4 cm. between the hepatic and common ducts. This was bridged by means of a rubber tube measuring about 6 cm. which fitted into either end so well that no sutures were used to anchor it. The area was packed with a gauze pack and rubber drain. The postoperative course was uneventful and the gauze packs were left in for 3 weeks after which they were gradually removed in 1 week. There was very little bile drainage.

A roentgenogram taken after 5 months showed the tube to be still in place. The patient was not seen for 4 years because of the war. After 4 years, when roentgenograms were taken, the tube was no longer seen. Since the patient did not have any attack of pain which would suggest the passage of the tube the author is inclined to believe that the tube became macerated and was passed in small pieces. He postulates that the common duct regenerated over the rubber tube, the latter acting as a guide. The method of inserting the tube snugly into either end without the use of sutures and thereby avoiding necrosis of the mucosa, is considered to have played a great part in permitting the epithelial lining to regenerate and bridge the defect. The epithelial lining, in turn, was covered by connective tissue.

LUIGI J. FRODUTI, M.D.

Late Results Following Biliary Surgery (Esiti distanti degli interventi sulle vie biliari). ANTONINO RUFFO. *Arch. Ital. chir.* 1943, 70: 313.

The author analyzes 600 cases of biliary surgery performed at the Surgical Clinic of the University of Turin in the period from 1923 to 1946. Cholecystectomy was performed upon 530 and cholecystostomy on 86 of the patients. The others had lysis of adhesions or other procedures. The over-all mortality

was 10 per cent. However, this has been decreasing and for the last 10 years alone was 6.9 per cent.

Of the 660 patients, 350 were recalled and of these 95 reported to the clinic. They had been operated upon from 1 to 23 years previously and 54.8 per cent were completely cured, 34.7 per cent were benefited and 10.5 per cent had not been affected for better or worse by the treatment.

Among the causes for recurrent colic are the functional causes of biliary dyskinesia, which have been well determined only in the last years. By determining whether there is a hypertonicity or hypotonicity according to the studies of Mallet Guy who resorted to radiomanometry during surgery, one may attribute the cause to excessive vagal or sympathetic stimulation. These cases may then be treated by sphincterotomy or right splanchnicectomy. These methods may also become efficacious in the treatment of recurrent symptoms following biliary surgery. However, the author believes that the test itself may stimulate the complicated biliary nervous system and therefore, the diagnostic value may not be as accurate as the originator of the test would claim it to be. The author thinks that observations should be continued for some time before the test is used to determine the definite operative procedure.

LUCIAN J. FROMDUTT, M.D.

Chronic Relapsing Pancreatitis: An Analysis of 27 Cases Associated with Disease of the Biliary Tract. EARL E. GAMMILL, MANDRELL W. COMFORT and ARCHIE H. BAGGERSTOSS. *Gastroenterology* 1948 11: 1

Comparison of the clinical, clinicopathologic, and pathologic features of chronic relapsing pancreatitis with associated cholecystic disease as exhibited in the 27 cases of this series with those of chronic relapsing pancreatitis not associated with disease of the biliary tract as exhibited in the 29 cases of a series recently analyzed and reported, discloses many similarities and remarkably few dissimilarities.

First, the anatomic and histopathologic features of the disease in the pancreas are essentially the same in the two series of cases. Interstitial fibrosis and residual necrosis are rather constant findings. Cyst and abscess formation and the deposition of calcium occur in both. In each series the pancreatitis most often involves the entire organ but it may be largely localized to the head, body or tail and shows no distinct tendency toward involvement of that part of the pancreas in close proximity to the disease of the biliary tract, that is the head when disease of the biliary tract is present.

Second, chronic relapsing pancreatitis regardless of the presence or absence of disease of the biliary tract, involves males more frequently than females and begins at all ages.

Third, the clinical features of chronic relapsing pancreatitis are essentially the same in the two series.

Fourth, the same sequelae due to involvement of the pancreas appear regardless of the presence or absence of cholecystic disease.

Fifth, the most frequent sequela due to pressure of the enlarged pancreas on the neighboring structures is dilatation of the common bile duct both in the series with and in the series without disease of the biliary tract.

Sixth, in cases in which painful seizures occur, the diagnosis of both pancreatitis and cholecystitis in the same patient is made difficult by the similarity of the clinical syndromes of each disease. The most frequently made diagnosis will be cholecystic disease because (if for no other reason) cholecystic disease occurs many times more frequently than does pancreatitis. However, it seems clear that pancreatitis as well as complications of cholecystic disease should be strongly suspected when the painful seizures last days, not hours and especially so when the pain starts in the left upper quadrant of the abdomen and when the pain extends to the left upper quadrant, left anterior part of the chest, left side of the back or left shoulder even if cholecystitis also is present. It also is clear that pancreatitis is definitely present in cases of disease of the biliary tract when disturbance of acinar and islet function accompanies and follows acute seizures and the deposition of calcium can be demonstrated. The appearance of a rounded, cystic mass in the pancreatic region during the painful seizure or soon thereafter may have the same significance as does diabetes, steatorrhea and calcification. Finally, it may be said that a high index of suspicion of pancreatitis, more careful analysis of the features of painful abdominal seizures, and careful investigation of pancreatic function in every instance of acute abdominal seizures will increase greatly the frequency with which the diagnosis of pancreatitis is made. Once the diagnosis has been made, the clinician should investigate for evidences of past pancreatitis and be on the lookout for recurring attacks and sequelae of pancreatitis because pancreatitis is often a recurring and progressive disease.

Exclusion of disease of the stomach, duodenum, small and large bowel, kidneys and heart, and even of retroperitoneal disease may prove a necessary step in the diagnosis of pancreatitis, especially when the patient is seen in the intervals between attacks and in the absence of diabetes, steatorrhea, and calcification. Careful notation of clinical features and appropriate laboratory data will accomplish this.

Seventh, three possible relationships between cholecystitis and chronic pancreatitis have been considered: (1) chronic pancreatitis is secondary to cholecystitis, (2) the cholecystitis may be secondary to the pancreatitis and (3) cholecystitis and pancreatitis may occur simultaneously and could well be due to the same etiologic agent.

Eighth, removal of the diseased gall bladder is clearly indicated. Chronic duodenal obstruction requires some type of side-tracking operation as does obstruction of the common bile duct. Pancreatic cyst requires either internal or external drainage and abscess external drainage. Pancreatolithotomy may be feasible.

The acute exacerbation should be treated medically. Ephedrine sulfate and papaverine hydrochloride should be used for the relief of pain whenever possible. In the event such drugs do not control the distress the usual opiates must be resorted to. The intravenous administration of fluids to combat dehydration, hypochloremia, alkalosis and acidosis as the case may be decomposition of the gastrointestinal tract, and accepted measures for combating shock also are used as indicated. During the acute attack operation to drain an abscess or pseudocyst rarely is advisable. Between the acute seizures, a bland diet is given and alcohol is forbidden. Diabetes is controlled. Insufficiency of external pancreatic secretion with resulting steatorrhea and azotemia is treated by a high caloric, high protein, high carbohydrate low fat diet by substitution therapy in the form of enteric-coated pancreatic tablets, or by both measures.

The clinical picture, the pathologic physiology and the course or the pathologic alterations in the pancreas in cases of chronic relapsing pancreatitis are very constant regardless of the presence or absence of disease of the biliary tract.

The problems of diagnosis of chronic relapsing pancreatitis are increased by the presence of associated disease of the biliary tract. Awareness of the possibility of pancreatitis and familiarity with its clinical features, roentgenologic findings and tests of pancreatic function should lead to a correct diagnosis in a high percentage of cases.

Treatment of chronic relapsing pancreatitis associated or unassociated with disease of the biliary tract is the same except that there is need for surgical removal of the diseased gall bladder.

Evidence has been cited supporting the thesis that in chronic relapsing pancreatitis, disease of the biliary tract may be secondary to that of the pancreas.

Splenic Panhematopenia. S. VAN CREEVELD. *Arch. Dis. Child.*, Lond., 1943, 23, 163.

Primary splenic panhematopenia may be congenital or acquired. If acquired, it may arise acutely or it may be secondary to pre-existing enlargement of the spleen. Proof that the dysfunction of the spleen is primary is provided by the favorable effect of the removal of the spleen and any accessory spleens. The condition is characterized by a striking decrease in erythrocytes, leucocytes, and platelets, and can be differentiated from aplastic or hypoplastic anemia by the finding of hyperplastic bone marrow.

In splenic panhematopenia which is secondary to splenic enlargement, removal of the spleen does not remove the original cause of the enlargement of the spleen, but it may improve the clinical state and prolong life.

Two cases are reported—one of primary splenic panhematopenia (secondary to splenic enlargement) and the other of secondary splenic panhematopenia due to hemolytic jaundice. In both cases, splenectomy gave excellent results.

SAMUEL KATZ, M. D.

Splenectomy: When Is It Indicated? FRANK H. LARRY and JOHN W. NORCROSS. *Ann. Surg.* 1943, 118, 363.

The authors' discussion of indications for splenectomy is divided into three groups. Group 1 includes splenectomy for trauma, primary tumors and cysts in the spleen, wandering spleen, and to add to the completeness of radical gastric surgery for malignancy or to facilitate surgical exposure in the left upper quadrant of the abdomen.

Splenectomy for trauma may be accomplished more quickly and bleeding may be controlled with less difficulty if the spleen is approached directly by separating the lateral peritoneal reflection and swinging the spleen and its pedicle medially into the operative field. The pedicle may then be ligated directly. This exposes the renal pedicle which, in direct force injuries, is frequently injured simultaneously and must therefore be examined during surgery.

Group 2 includes those cases in which abnormal splenic physiology affects the peripheral blood cells or the bone marrow and the production of red and white blood corpuscles and the platelets. This group which once included only congenital hemolytic anemia and idiopathic thrombocytopenic purpura must now be expanded to include certain other types of hypersplenism. It is essential in all cases in this group that other factors possibly responsible for the disease be carefully scrutinized, and that careful peripheral blood studies, and particularly bone marrow studies, be made. The co-operation of the surgeon and the physician is imperative.

Congenital hemolytic anemia, an hereditary abnormality in which the blood cells are spheroid and smaller than normal, is accompanied by jaundice and increased urobilinogen output in the urine and by perbilirubinemia, due to increased hemolysis. The bone marrow shows normaloblastic hyperactivity. Splenectomy in these cases resulted in 90 per cent cure and improvement in the other 10 per cent of patients.

Acquired hemolytic anemia acute or chronic, will rarely respond well to splenectomy if the cases are carefully selected. It should not be done in malignancy, infection, or in parasitic diseases producing hemolytic anemia.

Idiopathic thrombocytopenic purpura is a hemorrhagic disease of unknown origin. If the bone marrow reveals plentiful megakaryocytes with little platelet formation at the periphery and no evidence of infiltrating disease in the bone marrow if the eosinophils are not increased and all studies reveal the condition to be idiopathic, it will respond well to splenectomy. The response is usually prompt following surgery is rarely delayed and relapses may occur even years following surgery.

Idiopathic neutropenia, when other causes of neutropenia are carefully ruled out and the bone marrow is normal or shows hyperplasia of granulocytic cells, is included in the group for surgical consideration. Response to splenectomy is prompt and results appear to be lasting.

MISCELLANEOUS

In primary splenic panhematocytopenia all of the main cellular elements of bone marrow are depressed in the peripheral blood. The etiology is unknown. Congenital and acquired types are described. In either type the bone marrow demonstrates hyperplasia of all three elements. Response to splenectomy is prompt.

Secondary splenic panhematocytopenia may rarely (in selected cases) respond well to splenectomy.

Group 3 includes the congestive splenomegalies and splenomegalies of unknown origin. In the congestive group there is portal hypertension, gastric and esophageal varices likely to hemorrhage and occasionally panhematocytopenia. Splenectomy is generally recommended to control the panhematocytopenia and may be indicated for other reasons in selected cases. The decision is a difficult one and the mortality of 8 per cent, which is higher than in the other groups, makes the decision a more serious one. The results obtained in selected cases have been fairly good.

Splenomegalies of unknown origin must be studied thoroughly and observed for at least 6 months and none of the contraindications for surgery must be present if the patient is to be submitted to splenectomy. However operation is helpful in selected cases and frequently may result in the removal of an early localized malignant tumor or give early treatment to a congestive splenomegaly.

Agnogenic myeloid metaplasia is a contraindication to splenectomy because the spleen has taken over the function of the bone marrow. Leucemia, lymphoblastoma, polycythemia vera, splenomegalies in infection, Mediterranean and sickle cell anemia and paroxysmal nocturnal hematuria usually are serious contraindications to splenectomy. One must also weigh operative hazards against the problematical benefit of splenectomy in each case.

The complications which have proved most common to splenectomy are hemorrhage, thrombosis and infection.

Three operative variants are described: (1) ligation of the lienal artery close to its origin; (2) ligation of the lienal artery by deliberate exposure of the artery at the tail of the pancreas; and (3) the rapid approach herein described.

FREDERICK C. HORNEL, M.D.

Operative Treatment of Abdominal Obesity Especially Pendulous Abdomen. *JAMA* *FOGDO. Aca med sci.*, 1948 131 Supp 213 p 130.

Operative treatment for pendulous abdomen or for diffuse venter propendens was carried out on 35 patients. All of the patients were women. The indications for operation depend upon the severity of symptoms and the operative risk. The risk is comparable to that of operative treatment of any large hernia, including umbilical hernia, and the same contraindications hold for both lesions—advanced age, cardiovascular disease and chronic bronchitis being the most frequent contraindications. Intertrigo should be corrected before operation.

The various operative methods are all based on the same principle, namely, excision of the superfluous subcutaneous adipose tissue and skin, and vary merely in the way of incision and its localization. The technique varies according to whether the umbilicus is left untouched, is transposed or eradicated. The two most important principles are thorough asepsis and minute hemostasis. The outlines of incision are made preoperatively with the patient in an erect posture. In the majority of these patients the technique described by Jolly was used. Compressing bandages were used and the patients were permitted out of bed the day after operation.

A survey of results in 38 operations on 35 patients revealed that the weight of removed tissue varied from 600 to 6,500 gm., averaging about 2,500 gm. None of the patients died and in 31 cases the postoperative course was uncomplicated with primary healing of the wound. There was 1 case of shock and 1 case of multiple pulmonary infarcts. There were 2 cases of marginal necrosis of the skin, 2 cases of hematoma formation and 1 case of suppuration. In only 1 case was there a complication of a serious character. The immediate result was satisfactory to both the patient and the surgeon in 33 cases, the result being classified as unsatisfactory in the case of wound suppuration and the 2 cases of marginal necrosis, respectively. A follow-up of 17 patients for a period of from 6 months to 6 years revealed no recurrence and the result was considered good in 16 patients.

JOHN L. LORQUIST, M.D.

GYNECOLOGY

UTERUS

A Correlative Study of Adenomyosis and Pelvic Endometriosis, with Special Reference to the Hormonal Reaction of Ectopic Endometrium.
EVEL NOVAK and O. ADAMS. *Lancet*. **1938**, 50 654

This study is based on the analysis of the ectopic endometrium of adenomyosis and pelvic endometriosis as compared to the surface uterine endometrium of 243 patients who were operated upon in the private service of the senior author in Bon Secours Hospital, Baltimore, Maryland in the 8 year period extending from 1938 to 1946.

This analysis reveals that the endometrium located within these endometrial implants (both adenomyosis and pelvic endometriosis) is usually of an immature variety. Its immaturity is evidenced by the fact that it is physiologically responsive only to the growth stimulus of estrogen, and not to the differentiating influence of progesterone.

In this present series the ectopic endometrium showed no histologic evidence of secretory activity in any case regardless of whether or not the surface mucosa was of a secretory type.

JOHN R. WOLFE, M.D.

Fibromyoma of the Uterus During Pregnancy and in the Puerperium (Fibromioma uterini in gravidanza ed in puerperio). G. TARICO. *Ginecologia*. **1943**, 4 57

Nine women, all over 3 years of age presented themselves at the Ospedale S. Spirito at Casale Monferrato, Italy. All had uterine fibromyomas and had become pregnant. Four were treated by subtotal hysterectomy and 1 was treated by total hysterectomy. In 3 a myomectomy was done and in 1 of these the pregnancy then went on to term with birth of a living child, while in the third of these cases abortion occurred 20 days later.

The ninth case reported was especially interesting from the therapeutic standpoint. Following an amenorrheal period of 6 months the pregnant woman presented herself with nearly continuous pains in the lower and midabdominal cavity. Clinical and roentgenological examination disclosed in addition to the pregnancy the presence of a double fist-sized mass in the region of the fundus of the uterus. The advanced age (43 years) in this instance made continuation of the pregnancy seem desirable. Sedatives were given and the patient was counseled to report periodically. Instead the patient did not appear until well advanced in labor with a history of more than a month of diffuse abdominal pains and irregular elevations of the temperature. Forceps were applied at the outlet. That same day symptoms of intestinal occlusion developed and the following day a laparotomy was carried out. The peritoneal cavity

was found to contain turbid fluid, the small intestines were markedly congested and dilated and the entire abdominal cavity was involved in adhesions. An ileostomy was all that could be accomplished, the patient dying 5 hours later. Autopsy disclosed a subserous fibroid on the posterior wall of the uterus. This mass was twisted 90 degrees. The capsule had broken through giving vent to reddish-gray colloidal masses with stubborn adhesions to the greater omentum, descending colon, and sigmoid.

The author believes that in special cases a waiting period may be advisable until the period of viability of the fetus, the patient always being under constant supervision followed by a cesarean section with myomectomy or hysterectomy as indicated. In most instances, however, the patient should be operated upon early in pregnancy and if possible a myomectomy should be done. In the cases in which the number or location of the fibroids make the birth of a living child improbable an immediate hysterectomy is the only recourse.

JOHN W. BRENNAN, M.D.

The Relations Between Development of Carcinoma and Colposcopically Demonstrated Atypical Epithelium of the Portio (Ueber die Beziehungen zwischen Karzinomentwicklung und dem kolposkopisch gefundenen atypischen Epithel an der Portio). G. MEYERHOFFER and A. MEYERHOFFER. *Geburtsh. & Frauenk.*, 1947, 7 56.

Opinions regarding the benign or malignant nature of clinically and histologically demonstrated changes in the epithelium of the portio are frequently widely divergent. In practice doubtful findings are usually interpreted as carcinomatous. Any confirmation of

such a conclusion from the further clinical course appears problematic, since, whereas a 5 year survival is usually considered a cure, the malignant transformation of the portio lesions may require a longer time. On account of discrepancies in the interpretation of histologic findings in the diagnosis of portio carcinoma other diagnostic aids are recommended. Macroscopic speculum examination of the os uteri and its vicinity with a colposcope will permit a finer diagnosis in the living. By this method a suspicion may be confirmed or rejected. For this reason, a colposcopic examination should be made before a biopsy specimen is taken for histologic study and removal of the colposcopically demonstrated suspicious area should be done under colposcopic control. If colposcopic findings require histologic interpretation, the mucosa can be examined in serial sections, which will clarify many problems concerning the histogenesis of carcinoma of the portio. No superficial scraping of the epithelium or tiny excision from the portio will suffice. The entire epithelium of the surface of the portio including its substrate and transition to the cervix must be included. The

studies of Hinselmann, Franqué, Leip and Otto are reviewed. Survival in untreated cases of carcinoma of the portio averages from 15 to 2 years. The interval between the first stages of malignancy and the first clinical symptoms of the disease is not known. Leucoplakia may be present for years before undergoing malignant transformation. Whether early stages of leucoplakia can be considered as benign is uncertain. In the present authors' opinion the potency of the epithelium cannot be determined from the momentary status of the histological section. Histologic pictures of leucoplakia in its early stages, later developing into carcinoma, are extremely rare. Hinselmann has demonstrated histologically the development of a carcinoma from matrix areas and has, probably for the first time in the literature, followed a case histologically over a period of several years. He emphasizes the importance of following up histologically examined matrix cases. By means of histologic control examinations Schmidt repeatedly demonstrated development of carcinoma on the basis of vulvar leucoplakia.

The authors describe in detail 2 cases histologically controlled since 1937. In these cases the stages of atypical portio epithelium were followed up histologically progressively in their relation to pavement cell carcinoma of the portio. Variations in growth tempo seem possible. The present study would not seem to justify a distinction between the different stages of atypical epithelium. In many cases the matrix areas have been present simultaneously and adjacent to each other. The authors believe that there is no justification for designating atypical epithelial changes as benign, harmless or malignant.

They should preferably be considered as a whole as matrix areas of pavement cell carcinoma of the portio as a unit with gradual variations of malignant potency.

It is emphasized that if all colposcopically visible atypical epithelium be removed for histologic examination, it would be impossible to demonstrate any developing potency of the atypical epithelium. If only partial segments are removed at various intervals it will be impossible to determine the stage of development of the areas left in situ.

Biopsy must be performed only on the strictest indications. The associated dangers have often been stressed. Obligatory preliminary examination and colposcopic control should determine when and how a biopsy should be done. In this way many superfluous biopsies could be avoided and an epidemic of portio amputations prevented.

In the first of the 2 cases here reported, the development of carcinoma of the portio from colposcopically demonstrated matrix areas was followed colposcopically and histologically for nearly 6 years. In the second case, colposcopic and histologic control permitted detection of a microcarcinoma 8 months after surgical removal of a colposcopically demonstrated microcarcinoma. The first operation consisted in abrasion and amputation of the portio. Following detection of the last tumor a total vaginal

extirpation was done and followed by postoperative radium and x-ray therapy. In all, 2,422 serial sections of this portio were studied.

EDITH SCHANCHE MOORE.

The Problem of Early Diagnosis of Cancer of the Uterine Body and Cervix (Problema do diagnóstico precoce do câncer do corpo e do colo uterino). ARNALDO DE MORAES. *Am. Brasil. gín.*, 1948 13 1

By early diagnosis the author does not mean early clinical but early histologic diagnosis during the asymptomatic phase of cancer. This object can be attained by periodic examination of all women over 35 years of age by colposcopy, colposcopy and biopsy if indicated.

Colposcopy introduced by Hinselmann in 1924 is generally accepted in Europe but has met with little enthusiasm in the United States. It is regarded as a valuable aid in South America.

Colposcopy introduced by Stockard and Panicolaou in 1917 offers a simple method of studying the cells desquamated from the initial cancer lesions and found in the material which collects in the vaginal cul-de-sac. A small quantity of this material is spread thinly on a slide fixed with equal parts of alcohol and ether and treated with Panicolaou's trichromic stain or any of its modifications. The cancerous cells mixed with the normal ones, stand out because of their great difference in aspect and staining. They may assume the most bizarre forms, elongated like rods or muscular fibers and triangular resembling tadpoles. Intense vacuolization of the cytoplasm is frequent. However the most striking aspect is that of the nuclei which are always larger and more deeply stained than those of normal cells, their contour is irregular assuming monstrous arrangements, the chromatin is disposed irregularly in large granules or there may be just a dense spot that is strongly stained. Atypical mitoses result in deformed pictures, the abnormal fragmentations or the amitotic divisions give rise to inter-nucleated cells with the nuclei differing one from the other. To complete the picture there are large amounts of pus cells and there are always red blood cells. De Moraes also collects material from the cervical canal by means of a probe wrapped with cotton wool and from the uterine cavity with a non-cutting fine curet similar to that of Cary. From his own experience and study of that of United States authors he is able to stress the real value of colposcopy in the diagnosis of early cancer. Because of its great simplicity this examination should be the first to be made and should be used generally in women over 35 years of age even if they do not have any gynecologic symptoms. Positive or suspicious findings should be verified by colposcopy and biopsy. In the follow-up of patients irradiated or operated upon for cancer the method is of value for the control of the cure or the investigation of recurrence.

Histologic examination of a biopsy specimen is indispensable to establish the diagnosis of cancer. The present tendency is to regard as incipient cancer

even the intraepithelial lesions called carcinoma *in situ* intraepithelial cancer preinvasive cancer by pertrophy of the basal layer and the cervical disease of B. wen. The histologic study of these lesions reveals that near or in the zone of transition from the normal orifice of the cervix there is a definite abrupt change in the stratified epithelium to the epithelial type that indicates probable malignancy.

A gynecologic consultation service for the prevention of cancer should be equipped for complete careful examination of the patients including an amniotic gynecologic examination, colposcopy, colposcopy and biopsy. RICHARD KIMMEL, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Concerning the Symptom of Hydrops Tubae Profundus and its Significance in the Recognition of Primary Carcinoma of the Tubes (Über das Symptom des Hydrops tubae profundus und seine Bedeutung für die Erkennung des primären Tubenkarzinoms). GERHARD BEASLER, *Geburtsh. & Frauenh.* 1943, 8, 6.

Ten cases of carcinoma of the tubes were observed during the years from 1938 to 1947. In 3 of the women, bleeding occurred after the menopause; neither the clinical study nor curettement offered an adequate explanation. In 2 of the 3 patients the correct diagnosis of tubal carcinoma was made from the symptoms alone. These patients had no typical history of pains and no palpable demonstration of adnexal tumor was observed. In 4 other patients of this group the characteristic hydrops tubae profundus, which the author prefers to designate "hydrosalpinx tubae profundus" occurred. In the remaining 3 women the diagnosis was apparently not made prior to operation. The chief symptoms in all cases were one or more of the triad: pain, fluor, tumor.

The 4 patients with hydrosalpinx are given special consideration. In one patient curettement was done twice with negative results because no tumor was palpable. It was only later with the development of the typical profusions, that the tumor was palpable and the correct diagnosis was made (a loss of 7 months to the patient). In a second patient, a diagnosis of urinary incontinence due to cystocele was made and a plastic repair was performed. When the hydrosalpinx did not cease, a vesicovaginal fistula was suspected and the patient was referred to the author. However the fluid could be seen gushing from the vaginal cervical orifice and with descending pyelography the fluid from the vagina did not become colored. Operation disclosed a bilateral hydrosalpinx and bilateral carcinoma. In a third instance the apparent urinary incontinence from cystocele was correctly recognized however even the passing of bloody shreds did not lead to the diagnosis of tubal carcinoma. It was only the operation which led to the correct interpretation of the symptom. In the fourth patient the hydrops tubae profundus recognizable by the typical flooding resulted in the correct preoperative diagnosis. In none of these patients were tumor cells found in the discharged fluid and shreds in

none was the diagnosis made roentgenologically. In the second case cited, a hysterosalpingography showed both tubes to be normally permeable.

From these experiences, the author does not think that roentgenology is of aid in the diagnosis of tubal carcinoma; however he believes that it is of value in correctly interpreting and explaining the mechanism of hydrops tubae profundus, or hydrosalpinx.

In 6 of the 10 cases, carcinoma of the tubes was diagnosed with certainty or with great probability. The author states that an absolutely certain diagnosis of carcinoma in these cases cannot be made without the finding of cancer cells; however, in the presence of bleeding without corresponding findings by curettement, or in the presence of hydrops and of hydrosalpinx tubae profundus carcinoma of the tubes must be suspected and treatment must be the same as though the diagnosis was absolutely certain. This treatment consists in the removal of the uterus and of both adnexa. JOHN W. BRIDGES, M.D.

The Treatment of Blocked Fallopian Tubes by Pressure Injections of Gas and Iodized Oil. ALAN GRANT and ROBERT MACCART. *Med. J. Australia*, 1943, 2: 99.

One of the most exasperating situations encountered in sterility is that of the married couple in whom the major infertility factor operating is occlusion of the wife's fallopian tubes. An apparently simple solution to this pathological state of the tubes is some form of surgery which establishes an artificial ostium or resects the damaged segment of a tube, by the performance of salpingostomy or by tubal implantations. In practice such a procedure yields a very disappointing harvest of patent tubes and pregnancies.

It is a clinical impression that salpingostomy is a more successful operation when the tubes have been blocked by some extratubal pathological process, such as acute appendicitis, than when they are occluded as the result of a septic miscarriage or puerperal sepsis, in which the normal function of the tube has been badly impaired.

In a survey of 247 cases of tubal block, tuberculosis was reported in 2 cases, placental polypus in 1 case, previous cesarean section in 3 cases, peritonitis in 3 cases, previous normal confinements in 4 cases, pelvic operations in 8 cases, ectopic pregnancy in 10 cases, puerperal sepsis in 14 cases, genital hypoplasia in 14 cases, salpingitis in 21 cases, a previous history of appendectomy in 27 cases, no known cause in 69 cases, and a previous history of miscarriage in 73 cases.

The largest group of cases published is the collected series of cases consisting of 818 plastic operations on the tubes. 54 pregnancies took place, an incidence of 6.6 per cent, or one pregnancy for every 5 operations. Complications occurred in many of these pregnancies and the ultimate successful result was one baby for every 22.5 operations.

Treatment with gas injections was carried out. The gas used was carbon dioxide and it was admin-

lated with Sharman's modification of Bonnet's kymograph. The gas was regulated to flow at 65 millimeters per minute and the pressure was taken up to the maximum of 250 millimeters of mercury. Two such insufflations were given in 10 to 12 days after the conclusion of menstruation in separate months.

The third injection was made with iodized oil, 1 month later. The injection of oil was given at a pressure of 250 to 300 millimeters of mercury in the x ray department. An x ray film was taken at the time and another plain x ray film was taken 2 days later.

HARRY W. FINE, M.D.

On Female Sterility Due to the Congenital Obliteration of the Abdominal Aperture of the Tube. Surgical Intervention. Subsequent Pregnancy (Sur la stérilité féminine par obliteration congénitale de l'ostium abdominale de la trompe. Intervention chirurgicale. Grossesse consécutive) R. JOYEUX. *C. rend. Soc. fr. gyn.*, 1948, 18, 95

The frequency of sterility due to tubal obstruction according to recent reports is marked as this cause is found in from 45 to 50 per cent of all the cases.

Among all the tubal lesions which prevent conception inflammatory lesions predominate. Congenital malformations on the other hand are comparatively rare.

An unusual case treated by the author and a case he has not recorded in the literature is reported. This case is one in which there was a bilateral congenital obstruction of the normal openings of normal tubes due to an abnormal continuation of the mesosalpinx which formed a peritoneal hood around the abdominal opening of the tubes.

This occurred in the case of a woman of 22 years, who sought relief from pain in the right iliac fossa of more than a year's duration. Married at the age of 18 she never became pregnant. Her menstrual history was normal. As physical examination revealed her genital organs to be apparently normal an original diagnosis of chronic appendicitis was made.

Hystero-graphy was performed with the finding of a normal uterine cavity and obliteration of the tubes in the vicinity of the abdominal openings of the tubes. The deformity was identical on the two sides.

Laparotomy was performed and the abdominal extremities of the tubes were found to lie in a cul-de-sac which was formed by a continuation of the mesosalpinx. There were no adhesions, no signs of inflammation, and no abnormality of the tubes or uterus. The appendix was normal. The cul-de-sacs were dissected out with evacuation of the lipiodol used in the hystero-graphy. The tubes were readily catheterized. Incidental appendectomy was performed. Postoperative recovery was normal and 3 months after the operation the patient became pregnant.

The theory that the deformity found at operation was a congenital abnormality is supported by the

following facts: at operation there were no signs of pelvic or genital inflammation. There were no adhesions or cicatrices of the tubes or of the mesosalpinges. The tubes were easily catheterized. There was no hydrosalpinx. The lipiodol was in the cul-de-sac and not in the tubes. The deformity was bilateral.

The congenital deformity found at operation led the author to find an explanation of the condition. He studied the development of the hysterotubo-ovarian ligaments in a 10 cm. human embryo. At the second month of development of the human embryo the abdominal extremity of the Muellerian duct is intimately united to the superior pole of the ovary and the Wolffian body. These organs later diverge from one another. Then the diaphragmatic ligament divides into two small ligaments, one extending from the posterior abdominal wall to the mesovarium and to the abdominal end of the tube, the other extending from the abdominal end of the Muellerian duct to the superior pole of the ovary. The diaphragmatic ligament normally diminishes rapidly. An abnormal persistence of the diaphragmatic ligament attached to the abdominal end of the tube can form a veritable hood over the tubal pelvis. It was not surprising to find that this hood was purely serous.

In this case hysterosalpingography was instrumental in disclosing the congenital deformity causing sterility.

Tubal sterility, proved by hysterosalpingography justifies surgical intervention.

BLACKWELL MAREKIAN, M.D.

EXTERNAL GENITALIA

The Treatment of Chronic Bartholinitis; New Treatment Procedures; Their Superiority Over Classical Therapy; Question of Recurrences (A propos du traitement des bartholinites chroniques, nouveaux procédés de traitement, leur supériorité sur la thérapeutique classique; question des récidives) MARCEL GAUDEROT. *C. rend. Soc. fr. gyn.* 1948, 18, 189.

Acute bartholinitis is essentially of gonorrheal nature at least in the beginning, and requires immediate local treatment. It should be incised widely (3 cm.) as soon as pus has gathered. Usually the wound does not close completely and suppuration continues and results in fistula formation if it closes. Recurrence is practically the rule. In chronic fistulized bartholinitis two methods of treatment are available: disinfection of the cavity followed by obliteration through sclerosis and saucerization with the electric knife followed by electrocoagulation of the fundus of the gland.

The first method is indicated in all small cavities (about the size of an almond) in which probing reveals tracts that are narrow and not too deep. Disinfection is obtained by three instillations at 1 or 2 day intervals of penicillin G 5,000 units per c.c. or of soludagenan 33 per cent, which causes bleeding and sclerosis, or of sulfonamide which is less expensive than penicillin and less caustic than soludagen.

nan. If the latter is used, the disinfected cavity may be partially or completely sclerosed, but in most cases a solution of quinine and urethane 3 per cent each will have to be instilled three times at intervals of 3 days. It is essential that the entire cavity be sclerosed to avoid recurrence which occurs in 40 per cent of the cases mostly because a glandular crypt has escaped disinfection.

The second method is used for conditions which fail to respond to the first method, and is used immediately for large pockets or multiple and large infected tracts. It is also useful as the second stage in acute infections about 8 days after the first incision. The operation is performed under intravenous or epidural anesthesia.

In chronic Bartholin'sitis in which incision has been made during the acute stage the previous incision is reopened and enlarged if necessary and the gland is marsupialized at the vulvar opening with the electric knife.

In cystic Bartholin'sitis the internal aspect of the cyst is incised along its greatest length with the electric knife. The internal wall of the cavity is removed exposing the bottom of the gland which is then electrocoagulated, with destruction of all infected glandular crypts and abnormal tracts. A dressing with a saturated solution of antipyrine is applied to prevent postoperative bleeding. This operation is benign, easy, rapid and radical; the patient may get up on the evening of the intervention and attend to her occupation the following day. Healing requires from 4 to 6 weeks. The result is excellent; the deformity of the vulva decreases in 2 or 3 months and the region assumes a nearly normal aspect. Three of 12 recent patients have needed a slight intervention after the operation—one on the third day for local bleeding the other—on the sixth day to destroy a tract that had been overlooked.

MISCELLANEOUS

Histologic Studies in Cases of Amenorrhea Treated with Progesterone and with Parasympathicomimetic Substances (Histologische Untersuchungen bei mit Progesteron und parasympathikomimetischen Stoffen behandeltem Amenorrhoeen). K. BRODER and V. DUBRAUTZKY. *Geburtsh. & Frauenh.* 94, 8, 2, 576.

Thirty-six treatments were administered to secondary amenorrheics with histologic examination of the curetted endometrial specimens before and after each treatment. Five patients were given doryl, which is the German preparation corresponding to moryl (carbamino-cholin-chloride) for 5 days in doses of 2 mgm. thrice daily per os. In this group there was 1 instance of bleeding by diapedesis (not true menstruation). Five patients were given doryl for 5 days in daily subcutaneous doses of 25 mgm., with again 1 instance of bleeding by diapedesis. Six patients were given prostigmine for 5 days in daily injections of 0.5, 0.5, 0.75, 1.0 and 1.0 mgm. subcutaneously. Two bleedings were produced in this

group. In the one there was some proliferation produced by the injections, but the bleeding was by diapedesis. In the other there was already an endometrium in the secretory phase when the treatments were instituted and in this case a true menstrual type of bleeding developed. The author does not claim this as an instance of menstruation produced by prostigmine, as it might have occurred anyhow.

Finally there were 15 patients treated with progesterone for 5 days in daily injections of 10.0 mgm. In this group there developed 3 instances of true menstrual bleeding and 7 of bleeding by diapedesis.

From these experiences the authors conclude that both the progesterone and the sympathicomimetic substances will produce a certain amount of proliferation and even some evidence of the secretory phase in secondary amenorrhea, and will on occasion produce bleeding by diapedesis—probably as a result of vascular dilatation. However they will not produce true menstrual bleeding unless the endometrium is already in an advanced stage of secretory transformation. No attempt is made to assess the psychic effects on the patient of the false bleeding. It is admitted that these substances, through their stimulative action on the parasympathetic nervous system are able to produce some stimulation of the ovarian follicle; nevertheless they are not to be regarded as suitable for the treatment of secondary amenorrhea.

JOHN W. BRENNAN, M.D.

Report of 8 Cases Operated Upon for Vesicovaginal Fistulas, Complicated in 1 Case by a Functional Incontinence (Comunicación a propósito de ocho casos de fistulas vesico-vaginales operadas y en uno de los cuales existía una incontinencia funcional de orina). JAUN WOOD Y RAMON DAVAZO A. *Rev. Soc. Chilena Med.* 94, 3, 16.

The procedure employed in 4 cases of vesicovaginal fistula consisted in a modified Fueth operation whereby the vaginal mucosa is separated at the fistulous orifice and the mucosa of the fistulous tract is folded into the bladder by means of an inverting suture through the basal connective tissue. No suture is put in the vesical mucosa and the vaginal margins are approximated with interrupted No. 1 chromic catgut sutures.

This method sacrifices no tissue but permits good approximation without tension or serious alteration of the blood supply.

Vesicocystostomy complemented by posterior colopocineorrhaphy succeeded in correcting the remaining case in which urinary incontinence coexisted. The fistula was repaired by means of the modified Fueth procedure.

STEPHEN A. ZIEGLER, M.D.

Treatment of Inflammatory Tumors of the Adnexa by Douglas Puncture and Colpotomy (Die Behandlung der entzündlichen Adnexitumoren mittels Douglaspunktion und Kolpotomie). HERM. CORTESEN. *Geburtsh. & F. wch.*, 1943, 8, 165.

The therapeutic value of Douglas puncture in inflammatory tumors of the adnexa is even today a

sharply disputed question. Heynemann has recently clarified the indications for this method of treatment. Although he condemns a categorical rejection of this procedure for the cases in question, he emphasizes the fact that its injudicious application may diminish the chances of recovery. The conservative method remains the standard therapeutic procedure. Any other method including puncture of the Douglas pouch and colpotomy must be classified as general expectant and supplementary treatment. If these fail there remains the last resort of laparotomy and extirpation of the inflamed organs.

Douglas puncture is indicated when ordinary conservative measures have failed and conditions permit a technically perfect, and therefore safe puncture. The intervention must be made carefully so that it can be followed by physical therapy under medical supervision. In cases filling these requirements puncture is indicated in the presence of persisting fever and chills in patients in poor general condition or with cachexia, in the presence of intolerable pain not responding to other measures in patients with threatening perforation into the intestine, and in cases of failure of the inflammatory tumors and exudate to retrogress.

If possible, puncture should be done only in the chronic or subacute stages. The most meticulous antiseptic and aseptic precautions are imperative. Preoperative preparation of the patient is of the utmost importance in preventing complications. The safest site for puncture is through the posterior vault of the vagina, in the midline, about 3 cm. in back of the vaginal insertion of the portio. The cannula should be inserted to a depth of 1 cm. Blind puncture is recommended by some writers, who believe that pulsating vessels furnish a better guide and can be avoided more easily by palpatory location than by direct observation. Schultz has described the technique of the operation in detail. In the presence of multilocular processes puncture may be repeated. In some cases as many as 5 punctures have been required to locate the tumor. No undesirable reactions have been recorded. If puncture proves inadequate because of the extent of the process or the viscosity of the pus or if conditions indicate probable rapid recurrence the puncture may be followed by colpotomy and by drainage if necessary.

The incision is made from 1 to 2 cm. in length and from 0.5 to 1.0 cm. in width so that there is little danger of injury to the ureters or vessels. The packing is removed after 24 hours to prevent infection of the wound. Because of the danger of pressure necrosis, the drain should not be left *in situ* for more than 10 days. The feared complications of puncture, namely, general peritonitis or pelvic peritonitis, may

be largely prevented by aseptic technique. It is also possible that puncture may lead to the release of pus from a pyosalpinx or pyovarum into the abdominal cavity. Sudden body movements, exertion, external palpation or vaginal examination may be responsible. Usually severe peritoneal reactions do not result since the pus is encapsulated in the pouch of Douglas producing a relatively harmless Douglas abscess. Nevertheless immediate laparotomy is indicated. This possibility must be kept in mind so that perforation can be recognized immediately. With proper instruments and technique there is little danger of injury to the ureters or vessels. Perforation of the intestine may be recognized from the aspiration of feces. In this event, the operation must be discontinued and the patient put to bed with ice applications. The site of perforation is usually rapidly closed with peritoneum. Fistulization rarely results. The puncture orifice is usually closed within 24 hours. Fistulization is more apt to follow colpotomy, which should therefore be used only in cases in which puncture does not suffice. As a rule, colpotomy involves the same risks as puncture, but with the more extensive incision more severe hemorrhage may result and obliterate the operative field. Whereas Heynemann has strictly limited the indications for puncture, Conrad punctures every adnexal tumor having attained a given size and showing fluctuation. The more conservative attitude of Heynemann seems preferable.

In the author's series of 537 patients with acute inflammatory adnexitis, 65 or 12.3 per cent, were treated by puncture of the Douglas pouch or colpotomy. Ovarian insufficiency was demonstrated in 28.9 per cent of this series. It is believed that this condition impairs the powers of resistance and thus predisposes to infection. Treatment by puncture requires 31 days conservative treatment requires 29 days. Puncture yielded successful results in 65 per cent, or 41 of the cases. Transitory favorable results were obtained in 15.8 per cent. Thus good results were noted in 81 per cent of the cases. The results were doubtful in 11.1 per cent, and failures were recorded in 7.9 per cent of the cases.

Unfortunately conditions did not permit any extended follow up study of this series so that no conclusions as to late results are available. Usually the patients were advised to continue short wave therapy, mud packs, and sitz baths for a certain period of time.

Since puncture yields satisfactory results in 80 per cent of the cases and shortens the duration of treatment, it would seem a valuable procedure in the face of the rapidly increasing incidence of gonorrhea and the prevalent diminished resistance to infection.

EDITH SCHANCKE MOORE.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

The Diagnosis of Sex During Pregnancy (A propos du diagnostic du sexe pendant la grossesse) A. GRANTIN *Presse med.*, 948, No. 57 685.

A hormonal test for determination of the sex of the fetus has been published. The injection of 10 c.c. of urine of the pregnant woman is supposed to cause histologic changes and enlargement of the testicle in a rabbit if the embryo is male. This test however has proved unreliable in many cases.

The author believes it possible to visualize the scrotum and in some cases the penis of the fetus by roentgenography with appropriate technique. At least two or three pictures from different angles are necessary. **WILHELM M. SOLMITS, M.D.**

Eclampsia Control. T. F. CORRIE. *N. Zealand M. J.* 1948, 47 300.

The author presents a résumé of an earlier survey of eclampsia in the Wellington urban area from 1928 to 1939 inclusive which showed encouraging figures for incidence, maternal mortality and infant mortality. A later analysis, covering the 8 years from 1940 to 1947 inclusive, indicates still further improvement. Among 29,645 live births, the incidence of eclampsia was 2.8 per 1,000 live births (83 cases). The maternal mortality was 4.8 per cent and the infant mortality was 20.5 per cent. The important points in eclampsia control through antenatal supervision and treatment are discussed.

Even a minor rise in blood pressure or a trace of albumin calls for rest and closer watching. Anything more demands hospitalization if possible. In cases in which 36 or 37 weeks have passed there is little advantage in delay and there should be no hesitation about termination of the pregnancy. At the present time induction of labor is the most important measure in our treatment of pre-eclampsia. In cases in which the patient is in the last month of pregnancy, termination by simple induction of labor is almost always the correct procedure although very occasionally particularly in a primigravida in whom the symptoms and signs are of great urgency and in whom the unripe condition of the cervix causes a fear of delayed response, cesarean section has a proper place.

In the treatment of actual eclampsia, the conservative method continued to be used in the great majority of cases. The only obstetrical measures sometimes used in these cases were the early rupture of membranes to relieve pressure and instrumental termination of the labor if the second stage was delayed.

There was an increase in the number of cases in which cesarean section was necessary. Whereas cesarean section was performed only once among 153 cases of eclampsia observed during the period of 1928

to 1939 it was performed in 15 of the 83 cases which occurred in the last 8 year period. In 3 cases, the cesarean sections were performed late, as a desperate measure in patients who had not responded to conservative treatment. All 3 mothers died which accounted for 3 of the 4 maternal deaths in this period. The postmortem findings make it abundantly clear that such last resort operations are doomed to failure. **GEORGE BLONCK, M.D.**

Cervical Myoma and Pregnancy (*Mioma do colo gravidico*) CELSO ALMEIDA DE GODOY *Rev. hosp. clin.*, 948, 3 83.

Among the neoplasms of the female genital tract, 75 per cent are myomas of the uterus and these constitute 20 per cent of the gynecologic processes. The incidence of cervical myomas reported by modern authors varies from 1.3 to 16 per cent, and this lower incidence as compared to that of myomas of the uterine body is due to the difference in histologic structure of the two regions and in their vascular conditions and to the more intimate interrelationship between the ovaries and the uterine body than that between the ovaries and the cervix.

Macroscopically cervical myomas may be classified into (a) supravaginal (subserosal, submucosal, intramural, and interstitial) (b) intravaginal (submucosal, intramural, and interstitial) and (c) mixed. The myomas may consist of a single nodule, which is the most frequent form, or of several nodules which form is much rarer.

Microscopically these tumors consist initially of smooth muscle fibers, easily differentiated from those of the normal myometrium and arranged in disorderly fashion. As the tumor develops, there is marked proliferation of the connective tissue so that by the time the tumor has reached a certain degree of development it consists nearly exclusively of fibrous tissue; hence, the name of fibroma.

The etiology of cervical myoma is still unknown. Even when small, the tumor always produces symptoms which become serious in most cases. They are symptoms of compression on the urethra or on the bladder depending on the volume, the variety and the location of the tumor. The most frequent and important symptoms are dysuria, pollakiuria, hematuria, and retention. Retention may be paroxysmal or chronic. In the first, the capacity and the wall of the bladder are not altered. In the second, the capacity of the bladder is increased and the wall is thickened. Retention is progressive and is overcome only by extirpation of the tumor. Hemorrhage is rare and occurs only in submucosal tumors which cause repeated contractions of the uterus in an effort to expel them. Discharge is more frequent than hemorrhage because the myoma mechanically produces a constant state of chronic inflammation of the cervical glands.

Submucosal myomas and those assuming the form of a polyp may undergo secondary changes because of circulatory disturbances (necrosis), direct mechanical action on the polyp (ulceration) and malignant degeneration (carcinoma). In addition, they may undergo calcification. In adhyaline mucoid or sarcomatous degeneration, or they may become infected as infection occurs more frequently in these tumors than in myomas of the uterine body because of the highly pathogenic flora of the vagina and the constant traumatizations to which the cervical myomas are exposed. The influence of pregnancy is exposed. compared to the

The influence of pregnancy on the tumor is slight compared to that on myoma of the uterine body because it is exerted especially on the muscle fibers which are much less abundant than those in the myometrium. The influence of cervical myoma on pregnancy does not depend principally on its localization and volume. Submucosal and intravaginal tumors of small size generally do not interfere with pregnancy and labor but submucosal and supravaginal tumors compromise the active segment and may cause an interruption of pregnancy by acting as foreign bodies which cause uterine contractions to expel them. If small they may not interfere with labor if larger they may not interfere intrauterine by obstruction or by preventing dilatation. Intramural tumors may disturb dilatation and be a more frequent factor of dystocia. Interstitial tumors involving the entire cervix usually require intervention which in most cases is dangerous. Treatment varies from case to case and depends on the symptoms.

Treatment varies from case to case according to the symptoms, form, volume and localization of the myoma. If there is no pregnancy the tendency is toward surgery by the vaginal route for submucosal polypoid small intramural, necrosed and infected tumors, the abdominal route being reserved for all other forms. During pregnancy some authors prefer watchful waiting while others insist on removal at any time even during labor. For removal after the puerperium is best, with surgical involving the entire circumference for interstitial forms. Cesarean section should be used for submucosal and subserosal forms.

The author reports 2 cases. One patient presented a submucosal pedunculated polypoid myoma in which polypactomy did not interfere with the normal course of pregnancy. The other patient showed a myoma of the entire anterior half of the cervix and invading the posterior half, associated with a molar degeneration which was followed by chorioepithelioma in this case total abdominal hysterectomy was performed.

RICHARD KEMEL, M.D.

LABOR AND ITS COMPLICATIONS

Rare Injury of the Soft Tissues in Spontaneous Delivery (Ueber eine seltene Form von Weichteilverletzung bei Spontangeburt) J. E. Ott. *Geburtsh. & Frauenk.* 1948, 8: 874.

In a primipara of 22 years

In a primipara of 32 years spontaneous delivery was associated with development of a traumatic

rectovaginal perforation. No prior diseases, including syphilis or earlier operations were recorded. Perineal lacerations are known to occur in from 11 to 25 per cent of normal deliveries. They have been classified as the first, second and third degree lacerations. The most severe type is extremely rare and includes laceration not only of the perineum and vagina but also of the sphincteric musculature. The infant in the case here described was in the vertex position. The pelvis here described

The infant in the case here described was in left vertex position. The pelvic measurements were normal. The blood pressure was slightly raised and urinary albumin and marked edema pointed to pre-eclamptic toxosis. However the blood pressure responded to rectal suppositories and the subjective symptoms subsided. No further toxic symptoms developed during labor or in the puerperium. Delivery was complete within 8 hours. Dilatation and head were after routine.

Shortly after rupture of the membranes the head appeared. The perineum seemed adequately stretched. Before the greatest circumference of the head had emerged, the elbow and a portion of the upper and forearm appeared emerging from the anus. As the posterior shoulder progressed, the protruding elbow receded and finally disappeared completely being finally delivered through the vagina smeared with feces. The placenta was delivered without difficulty.

Inspection showed the perineum and anal sphincter intact, but with a communication measuring two finger breadths in width between the posterior vaginal wall and the rectum about 3 to 4 cm above the vaginal introitus. The fistula was repaired after a third degree perineal laceration was made by splitting the sphincteric musculature. The tissues seemed extremely friable. Healing occurred by primary intention.

A review of the literature revealed a almost identical cases, with the difference that in 1 case not the elbow but the entire forearm protruded from the rectum. Analogous cases have been reported in breech presentations. In some cases syphilitic strictures have been held responsible. Pressure erosion has also been incriminated, but would be plausible only in cases of greatly protracted labor. Hyperextension of the posterior vaginal wall has also been considered as playing a part. However in the present instance the infant was of normal weight and the delivery spontaneous so that such a factor could hardly have been involved. Among contributing factors mentioned by various writers are a narrow vagina, edema of the labia and septum, overdistended infants with very hard skulls, and simultaneous presentation of the head with some smaller part. EDITH SCHAEFER MOORE.

Changing Trends in Cesspool Section. ABRAHAM
B TAMIS and JACOB CLARK. Am J Oph., 1948, 56
700

In a study of cesarean section at the Morrisania City Hospital, New York, New York, it was noted that while the incidence of this operation had doubled in the last 10 years, the mortality when compared with the previous 10 years, had decreased from

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Adrenal Cortical Carcinoma ZACHARY R. COTTLER.
J Urol, Balt, 1948 60 363.

The nonhormonal type of adrenal malignancy is usually discovered in its late stages when it becomes manifest by the presence of a mass, vague pain malaise, and by signs and symptoms of metastasis in other organs. The diagnosis has been greatly aided by the technique of percutaneous air injection as described by Cahill and Mencher.

The treatment of the nonhormonal type of malignancies has been surgical extirpation when possible, followed by high voltage irradiation to the operative site and to metastases as they develop. The prognosis is poor because the lesions often attain large size and metastasize before presenting any symptoms.

The author presents the case of a 50 year old woman who entered the Jewish Hospital of Brooklyn New York, complaining of falling of the womb. There was no history of urinary disturbance. A large hard mass filled the entire right side and flank. The blood pressure ranged around 250/140 during the preoperative period. X-ray studies including intravenous urography and a barium enema, showed evidence of extrinsic pressure. Upon operation the tumor was found to reach from the diaphragm to the loin with adherence to the kidney. It was removed. Microscopic study revealed an adenocarcinoma of the adrenal gland.

The patient received 10,000 roentgens of radiation therapy. When she was found to have a recurrent mass in the abdomen another course of 4,000 roentgens was given. Metastasis to the para-aortic region of the chest was discovered 39 months after operation. At the date of the report the patient had attained 5 years of postoperative observation and is considered in fairly good general condition with a blood pressure which averages 120/80. The metastases have remained unchanged.

The author believes that renal ischemia was the cause of a Goldblatt phenomenon which accounted for the hypertension. JOSEPH E. MAURER, M.D.

Congenital Absence of One Kidney K. M. BOWDEN.
Med J Australia, 1948 2 303.

The author calls attention to the incorrect statement that the corresponding suprarenal gland is always absent in congenital absence of one kidney. This statement is believed to be challengeable on several grounds.

The kidney embryologically has a double origin. From the wolffian duct an outgrowth occurs which eventually gives rise to the ureter renal pelvis calyces and the straight collecting tubules. As the ureteric bud is developing the metanephros appears and covers the growing end of this bud. This even-

tually gives rise to the remainder of the kidney. The suprarenal gland likewise has a double origin but one that is quite independent of the developing kidney. The medulla is intimately related to the sympathetic nervous system. The cortex is of mesodermal origin and appears as a ridge close to the wolffian body. On embryological grounds therefore, there is no reason why the corresponding suprarenal gland should be absent when there is congenital absence of one kidney.

Congenital absence of one kidney is usually due to complete arrested development of the ureteric bud from the wolffian duct. There is usually no trace of the ureter and the portion of the trigone on that side is undeveloped. The reports of the incidence of this condition vary widely from 1 case in 1,000 to 1 in 2,500 individuals.

The author presents 2 case histories of patients with a congenital absence of one kidney and in whom both suprarenal glands were present.

ROBERT O. BEADLES, M.D.

Aneurysm of Renal Artery CHARLES PIERRE MATHER.
J Urol, Balt, 1948, 60, 543.

Aneurysm of the renal artery is rare. The present report of 5 cases brings the grand total to 86 cases. In 1933 the author reported a case of aneurysm of the renal artery and reviewed the literature. Since that time he has treated 5 additional patients. The author reports these 5 cases in detail.

The first case was especially interesting inasmuch as he found, on exposing the pedicle that the renal artery had divided into inferior middle and superior branches. On the superior branch a saccular aneurysm measuring 1.5 cm. in diameter was encountered. The posterior surface of the aneurysm was densely adherent to a large renal vein. This was carefully dissected free, and the superior branch of the renal artery was doubly ligated below and above the aneurysm with No. 3 catgut. The aneurysm was then extirpated without sacrificing the kidney. The author's case is the second one of its kind in the history of kidney surgery.

Four other cases were also reviewed. In 2 of these the aneurysms were treated by nephrectomy. In the third case the aneurysm occurred in a ptotic kidney and sclerosis resulting from the healing process after fixation of the kidney apparently reinforced the defect in the arterial wall inasmuch as the patient has had no further trouble during the 8 years which have elapsed since operation.

For a detailed description of this condition reference is made to a communication by the author published in 1932. Articles which have subsequently appeared reveal many pertinent facts. Trauma is no longer considered to be important as a factor in the etiology of aneurysm. It is believed that most aneurysms are due to the same degenerative changes

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Adrenal Cortical Carcinoma. ZACHARY R. COTTLER.
J Urol., Balt., 1948, 60: 303.

The nonhormonal type of adrenal malignancy is usually discovered in its late stages when it becomes manifest by the presence of a mass, vague pain malaise, and by signs and symptoms of metastasis in other organs. The diagnosis has been greatly aided by the technique of perirenal air injection as described by Cahill and Mencher.

The treatment of the nonhormonal type of malignancies has been surgical extirpation when possible, followed by high voltage irradiation to the operative site and to metastases as they develop. The prognosis is poor because the lesions often attain large size and metastasize before presenting any symptoms.

The author presents the case of a 50 year old woman who entered the Jewish Hospital of Brooklyn, New York, complaining of falling of the womb. There was no history of urinary disturbance. A large hard mass filled the entire right side and flank. The blood pressure ranged around 250/140 during the preoperative period. A ray studies including intravenous urography and a barium enema, showed evidence of extrinsic pressure. Upon operation, the tumor was found to reach from the diaphragm to the loin with adherence to the kidney. It was removed. Microscopic study revealed an adenocarcinoma of the adrenal gland.

The patient received 10,000 roentgens of radiation therapy. When she was found to have a recurrent mass in the abdomen, another course of 4,000 roentgens was given. Metastasis to the para-aortic region of the chest was discovered 39 months after operation. At the date of the report the patient had attained 5 years of postoperative observation and is considered in fairly good general condition with a blood pressure which averages 120/80. The metastases have remained unchanged.

The author believes that renal ischemia was the cause of a Goldblatt phenomenon which accounted for the hypertension.

JOSEPH E. MAUTNER, M.D.

Congenital Absence of One Kidney. A. M. BOWDEN.
Med J Australia, 1948 2: 203.

The author calls attention to the incorrect statement that the corresponding suprarenal gland is always absent in congenital absence of one kidney. This statement is believed to be challengeable on several grounds.

The kidney embryologically has a double origin. From the wolffian duct an outgrowth occurs which eventually gives rise to the ureter renal pelvis calyces and the straight collecting tubules. As the ureteric bud is developing the metanephros appears and covers the growing end of this bud this eventually gives rise to the remainder of the kidney. The suprarenal gland likewise has a double origin, but one that is quite independent of the developing kidney. The medulla is intimately related to the sympathetic nervous system. The cortex is of mesodermal origin and appears as a ridge close to the wolffian body. On embryological grounds therefore, there is no reason why the corresponding suprarenal gland should be absent when there is congenital absence of one kidney.

Congenital absence of one kidney is usually due to complete arrested development of the ureteric bud from the wolffian duct. There is usually no trace of the ureter and the portion of the trigone on that side is undeveloped. The reports of the incidence of this condition vary widely from 1 case in 1,000 to 1 in 500 individuals.

The author presents 2 case histories of patients with a congenital absence of one kidney and in whom both suprarenal glands were present.

Aneurysm of Renal Artery. CHARLES PIERRE MATHÉ.

Aneurysm of the renal artery is rare. The present report of 5 cases brings the grand total to 86 cases. In 1932 the author reported a case of aneurysm of the renal artery and reviewed the literature. Since that time he has treated 5 additional patients. The author reports these 5 cases in detail.

The first case was especially interesting inasmuch as he found, on exposing the pedicle that the renal artery had divided into inferior middle and superior branches. On the superior branch a sacular aneurysm measuring 1.5 cm. in diameter was encountered. The posterior surface of the aneurysm was densely adherent to a large renal vein. This was carefully dissected free, and the superior branch of the renal artery was doubly ligated below and above the aneurysm with No. 2 catgut. The aneurysm was then extirpated without sacrificing the kidney. The author's case is the second one of its kind in the history of kidney surgery.

Four other cases were also reviewed. In 2 of these the third case the aneurysm occurred in a ptotic kidney and sclerosis resulting from the healing process after fixation of the kidney apparently reinforced the defect in the arterial wall, inasmuch as the patient has had no further trouble during the 8 years which have elapsed since operation.

For a detailed description of this condition reference is made to a communication by the author published in 1932. Articles which have subsequently appeared reveal many pertinent facts. Trauma is no longer considered to be important as a factor in the etiology of aneurysm. It is believed that most aneurysms are due to the same degenerative changes

noted in the walls of the blood vessels that give rise to aneurysms elsewhere in the body among which arteriosclerosis and syphilis play a dominant role.

Most authors state that this lesion is asymptomatic. However a review of the symptoms recorded in published cases reveals that pain is more or less constant. In the author's 5 cases pain was a dominant factor. He believes that when a patient suffers from intractable pain in the kidney area one should not hesitate to carry out operation for the purpose of performing renal sympathectomy and at the same time the renal artery and its branches should be exposed for the presence of aneurysm.

The broken wreathlike shadow which is denser at its periphery is considered diagnostic. Brady and Hanten believe that when there is a defect in the calcified annular ring due to the connection between the aneurysm and the artery the differential diagnosis between aneurysm of the renal artery and other calcifications in and about the kidney can be positively made. Furthermore, laminograms taken in conjunction with an excretory urogram will reveal the shadow to be delineated in the same plane as the kidney. Unfortunately many aneurysms are not calcified and cast no shadow. Arteriography should be more commonly employed as a diagnostic method, particularly in patients presenting persistent renal pain in whom renal sympathectomy is contemplated. It gives valuable information concerning the distribution of the renal artery and its branches, and also may reveal the presence of aneurysm.

All authors agree that nephrectomy is the treatment of choice. Mathé emphasizes, however, that when the aneurysm involves one of the branches of the renal artery and the main branch is devoid of thrombotic changes, the aneurysmal sac can be resected without sacrificing the kidney. In the occasional case presenting a small fusiform aneurysm associated with other renal disease such as ptosis or hydronephrosis the kidney lesion can be corrected without sacrificing the organ. The fibrosis that has taken place during healing can be relied on to reinforce the defect in the arterial wall.

ROBERT O. BRADLEY, M.D.

Renal Tuberculosis in the Child (*La tubercolosi renale nel bambino*) GIORGIO MARO *Urologia*, 1948, 5, 6

Two thousand autopsies done on children at the Ospedale Maggiore at Milan Italy disclose that about 5.76 per cent died of millitary tuberculosis. About half of these exhibited renal tuberculosis in the first year of life. The lesions were unilateral in 7.5 per cent. Unilateral lesions were more frequent from the fifth to the twelfth year and were located usually in the medullary and papillary regions. Vesical lesions were observed in a third of these cases but always after the tenth year. There was only 1 case of concurrent involvement of the testicle, epididymis, and seminal vesicles, in a boy 13 years of age.

In addition to the autopsy material, there are reported 4 cases of surgical renal tuberculosis diag-

nosed clinically. This number when compared with the cases of congenital malformation and renal fistula, comprises 12.5 per cent of the whole and occupies third place. Surgical renal tuberculosis occurred more frequently in the female and predominantly in the left kidney. The lesion was always ulcerocavernous in character and in 1 case was associated with multiple renal calculi. In the latter case the tuberculous kidney was successfully removed however the patient died of anuria before the stage in the other kidney could be removed. In the case of another child the parents refused operation. In the remaining 3 cases the kidney was successfully removed with disappearance of all symptoms.

Search for the tubercle bacillus should be carried out in all children with frequency or urinary incontinence, those exhibiting a pyuria or hematuria, or in those with an intermittent or persistent pyelitis or cystitis, even when the colon bacillus or other common source of infection is established. A search should be made for the bacillus of Koch even in the presence of a roentgenologically diagnosed renal fistula. The search is particularly important in the presence of a ureterohydropyonephrosis on an apparent or sure congenital basis, since in the presence of tubercle bacilli the ureter must also be removed together with the kidney.

Once the tubercle bacillus is established in the urinary examination the establishment of the unilateral nature of the lesion should be accomplished by means of descending pyelography, chromocystoscopy and ureteral catheterization of the supposed healthy kidney. If Koch's bacillus is found in the urine from this supposedly healthy kidney the diseased kidney may perhaps be removed provided that its partner exhibit good function and absence of pain. Operation in these cases requires good surgical judgment nevertheless, the removal of an ulcerocavernous lesion in the diseased kidney relieves the organism of a source of tuberculous bacilli and of toxins and renders spontaneous cure of the other kidney more easy. If the lesion in this kidney also has reached the ulcerocavernous stage such a kidney appears to be incurable with present day methods.

Another argument for nephrectomy in these infants arises from the fact that the urine of these children is a potent source of infection to others, particularly other children and the family and the younger the child, the greater the danger.

Close co-operation between the pediatrician and the urologic surgeon is needed to get these children under the surgeon's care early and to overcome the reluctance of the parents to have anything done.

JOHN W. BRIDGMAN, M.D.

Anthrax of the Kidney. Eight New Personal Observations (*Anthrax del riñon. A propósito de 8 nuevas observaciones personales*) RICARDO EXCULI. *Rev. argent. med.* 1948, 17, 7

Observations of 12 patients with anthrax of the kidney are reported by the author. Four of them had been published previously.

Anthrax of the kidney is not such a rare condition as is generally assumed. As a rule, the condition has a tendency to spread toward the perirenal tissues and not toward the renal pelvis. In a relatively large percentage of cases a perirenal phlegmon results. Because of the fact that pyonephritis occurs only exceptionally in the course of anthrax, urinary findings are usually negative.

The past history may be suggestive of anthrax. The customary posterior location of the anthrax phlegmon produces a contracture of the perirenal ing muscles an intensive pain and immobilization and abnormal elevation of the involved side of the diaphragm. A pleural reaction may develop. In the shadow of the psoas muscle is conspicuous. There may be a lordosis of the spinal column and a shadow produced by the perirenal mass. An excretory urogram may render great aid in the diagnosis. However it should be remembered that the pyelographic image of anthrax of the kidney may be similar to that of a febrile cancer of the same organ. Ascending pyelography is of lesser value.

The proper treatment consists of an enucleation of the involved area. A cure can be obtained in this manner in early periods of evolution of the condition. The conservative surgical procedure should be supplemented by the administration of antibiotics especially penicillin. Nephrectomy should be reserved for far advanced cases in which nearly the entire organ is involved in the suppurative process.

JOSEPH K. NARAT M.D.

Injury of the Vena Cava During Nephrectomy (Herida de la vena cava durante la nefrectomía). A. POUVERT. *Arch. esp. urol.* 1948 5 66

Injury of the vena cava is one of the most serious accidents associated with renal surgery. Many outstanding surgeons have given especial consideration to this complication which demands immediate, quick action, clear judgment, and positive solution. The inundation of the entire abdominal cavity with blood is surprisingly rapid and can lead to considerable confusion with serious consequences before the source of the hemorrhage is identified.

Two cases are reported in which the vena cava was injured during the dissection of dense adhesions about the kidney and ureter. Digital tamponade quickly arrested the active bleeding and the injury to the vena cava was located after suction removal of the blood. Two forceps forming a "V" blocked off the injury and in one instance a free ligature sufficiently closed the defect, whereas in the other case continuous suture with a needle was required. On repair of the vein nephrectomy was completed.

STEPHEN A. ZIEGLER M.D.

Surgical Intervention in Ureteral Calculi (La intervención quirúrgica en los cálculos del ureter). PEDRO CURTIS. *Arch. esp. urol.* 1948 5 1

The author reports the removal of ureteral calculi by the lumbar approach (23 cases) the lateral ilio-

pelvic approach (30 cases) and the middle hypogastric approach for low pelvic ureteral stone (14 cases) and by simultaneous removal of the kidney because of complicating kidney stones and kidney destruction (15 cases).

The ureteral stones varied from 0.5 to 3 cm. in diameter whereas in 1 instance a stone in the pelvic ureter measured 3 by 5 centimeters. Simple roentgenographs were sufficient in most instances to identify and locate the stones. In other cases cystoscopy and ureteral catheterization were necessary. The operations as a rule were simple except when considerable periureteritis existed, when the stone was in the lower kidney pole, or when the patient was unusually obese.

There was 1 immediate postoperative death attributed to intestinal paralysis. 1 death occurred 2 years after operation and a third, 5 months from the date of surgery. The latter 2 deaths however followed bilateral renal lithiasis.

STEPHEN A. ZIEGLER M.D.

Transplantation of the Ureters into the Rectosigmoid and Cystectomy. CHARLES C. HIGGINS. *Surg. Clin. N. America* 1948, 28 1209.

With the use of modern techniques and follow up methods it has been shown that the ureters and kidneys following ureteral transplantation into the rectosigmoid remain in a normal or fairly normal condition over a period of years. The author lists the following indications for this procedure:

Exstrophy of the Bladder. The procedure of choice for exstrophy is transplantation of the ureters followed by cystectomy. The operation should be performed during the first year for the following reasons: (1) infants tolerate surgical procedures well (2) the operative mortality and morbidity are low (3) as years elapse recurring attacks of pyelonephritis result in irreparable kidney damage (4) it is probable that the organisms in the bowel of the infant are less virulent than in older children (5) early operation permits normal development from the physical and psychological standpoint (6) as the child grows older ureteral obstruction develops at the ureterocystic junction and results in dilatation of the ureters making the operation technically difficult and at times impossible.

Carcinoma of the Bladder. Cystectomy and transplantation of the ureters into the bowel are indicated in the following instances: (1) when extensive single or multiple infiltrating tumors are present (2) when the carcinoma at the base of the bladder encroaches upon the ureteral orifices or when the vesical sphincter and urethra are so involved that local treatment would destroy the ureteral orifices or cause incontinence, (3) when multiple recurring tumors develop so rapidly that they cannot be controlled by fulguration or irradiation (4) in the presence of early Grade 3 or Grade 4 neoplasms of the bladder. Neoplasms in this group may be treated by segmental resection which is preferable if the position of the tumor in the bladder favors the operation.

noted in the walls of the blood vessels that give rise to aneurysms elsewhere in the body among which arteriosclerosis and syphilis play a dominant role.

Most authors state that this lesion is asymptomatic. However a review of the symptoms recorded in published cases reveals that pain is more or less constant. In the author's 5 cases pain was a dominant factor. He believes that when a patient suffers from intractable pain in the kidney area, one should not hesitate to carry out operation for the purpose of performing renal sympathectomy and at the same time the renal artery and its branches should be explored for the presence of aneurysm.

The broken wreathlike shadow which is denser at its periphery is considered diagnostic. Brady and Hanten believe that when there is a defect in the calcified annular ring due to the connection between the aneurysm and the artery the differential diagnosis between aneurysm of the renal artery and other calcifications in and about the kidney can be positively made. Furthermore, laminograms taken in conjunction with an excretory urogram will reveal the shadow to be delineated in the same plane as the kidney. STEPHEN A. ZIEGLER, M.D.

Transplantation of the Ureters into the Rectosigmoid and Cystectomy. CHARLES C. HIGGINS. *Surg. Clin. N. America*, 1948, 28: 1209.

With the use of modern techniques and follow up methods it has been shown that the ureters and kidneys following ureteral transplantation into the rectosigmoid remain in a normal or fairly normal condition over a period of years. The author lists the following indications for this procedure:

Exstrophy of the Bladder. The procedure of choice for exstrophy is transplantation of the ureters followed by cystectomy. The operation should be performed during the first year for the following reasons: (1) infants tolerate surgical procedures well; (2) the operative mortality and morbidity are low; (3) as years elapse recurring attacks of pyelonephritis result in irreparable kidney damage; (4) it is probable that the organisms in the bowel of the infant are less virulent than in older children; (5) early operation permits normal development from the physical and psychological standpoint; (6) as the child grows older ureteral obstruction develops at the ureterocystic junction and results in dilatation of the ureters, making the operation technically difficult and at times impossible.

Carcinoma of the Bladder. Cystectomy and transplantation of the ureters into the bowel are indicated in the following instances: (1) when extensive single or multiple infiltrating tumors are present; (2) when the carcinoma at the base of the bladder encroaches upon the ureteral orifices or when the vesical sphincter and urethra are so involved that local treatment would destroy the ureteral orifices or cause incontinence; (3) when multiple recurring tumors develop so rapidly that they cannot be controlled by fulguration or irradiation; (4) in the presence of early Grade 3 or Grade 4 neoplasms of the bladder. Neoplasms in this group may be treated by segmental resection which is preferable if the position of the tumor in the bladder favors the operation.

Epispadias When the defect is so extensive that plastic operations fail and incontinence persists, transplantation of the ureters into the bowel may be desirable.

Tuberculous cystitis The presence of intolerable bladder symptoms after nephrectomy in unilateral renal tuberculosis may be an indication for a ureteral transplant if the ureter on the normal side shows dilatation with a coexisting early hydronephrosis.

Interstitial cystitis If conservative treatment is of no avail transplantation of the ureters into the rectosigmoid may be justified.

Incontinence following transurethral resection If the incontinence is permanent the patient should not be forced to wear a receptacle inasmuch as relief can be afforded by transplantation of the ureters into the bowel.

Vesicovaginal fistula In patients in whom the defect is so extensive that it involves the bladder sphincter and urethra, and incontinence remains even after closure transplantation of the ureters may result in complete relief.

In infants the operation for transplantation of the ureters and cystectomy is performed in two stages. The right ureter is first implanted into the bowel 10 days later the left ureter is transplanted into the rectosigmoid and the ectopic bladder is removed.

In adults, the general condition of the patient, the presence or absence of renal infection, and the caliber of the ureters influence the decision as to whether both ureters should be transplanted simultaneously or whether unilateral transplantation is preferable. Generally the author prefers to transplant the right ureter in one stage and then 7 to 10 days later he transplants the left ureter and performs the cystectomy.

The technique of the operation is described in detail, and the exact preoperative and postoperative care and orders are outlined, as the author states that no stage of the operation is more important than the initial preparation of the patient. The author concludes that adequate preoperative preparation, postoperative care, and the refinements in surgical technique have reduced the mortality from this procedure to a point where there should be no hesitancy in recommending the operation in selected cases.

The patients are comfortable, have complete control of the urine, and may lead a normal life.

Dilatation of the ureters, hydronephrosis, and renal sepsis may be avoided by careful attention to the technical details of the operation.

Radical operation is recommended for those cases of carcinoma of the bladder in which conservative treatment carries a high morbidity and little prospect of cure.

ROBERT O. BRADLEY, M.D.

Surgery of Upper Urinary Tract. WILLIAM J. BAKER
J. Urol. Balt. 94:3, 60: 97

Modern urology emphasizes the reasonable salvage of the urinary tract whenever it is possible. Conservative renal surgery is illustrated in the plastic operations on the renal pelvis and its junction with

the ureter to correct hydronephrosis. An attempt to provide adequate renal drainage is always justified, if the age of the patient and the condition of the renal parenchyma fulfill their part of the equation. It is very difficult, however, to predict how much repair of renal tissue will take place or how much function will return after the relief of obstruction has been accomplished. The end results of bilateral pyeloplasty are at times quite gratifying. The author's second case demonstrated that bilateral plastic operations on the ureteropelvic junctions in a 53 year old woman preserved renal tissue and would no doubt prolong her life for many years.

The mediocre results of conservatism in the management of hydronephrosis associated with aberrant renal vessels was discussed by the author. This was especially noted in those instances in which the vessels were cut and no corrective procedure was done at the ureteropelvic junction. A pyeloplasty as well as the severance of obstructing vessels and bands at the ureteropelvic junction is necessary for the best postoperative results.

Conservative management of unilateral ureterohydronephrosis requires consideration of the degree of destruction of the renal tissue, the duration of the obstruction, the cause of the obstruction, the age of the patient, and the existing blood pressure. Experimental work has shown that an obstruction in the ureter that has existed over 90 days produces irreversible renal damage, and a proper renal counterbalance cannot be expected after the obstruction has been relieved. One of the author's cases illustrated that a pyeloplasty of a long-standing unilateral advanced hydronephrosis associated with hypertension, even in a 36 year old woman, was contraindicated. In this case, a nephrectomy proved to be a conservative procedure. Ormand directed attention to the many nephrectomies following unsuccessful plastic operations for hydronephrosis, while Moore and Walters stated that unsatisfactory results can be expected in 30 per cent of plastic operations on the kidney pelvis.

Better results are to be expected if ureteral splicing and nephrostomy drainage can be prolonged from 3 to 6 weeks. Many patients obtain symptomatic relief after a plastic operation at the ureteropelvic junction without much change in the anatomical contour of the pelvis. The symptomatic relief may come from the nephroureterolysis while the same procedure disturbs the nerve supply enough to prevent return of normal or near normal anatomic form.

A stone-bearing calyx or a hydrocalyx is the principal indication for partial renal resection or calyctomy. Many authors have reported series of patients who have had successful partial resection of the kidney heminephrectomy for disease of one calyx or of the pelvis of a double kidney. Heminephrectomy is usually easy when there is a double kidney because the blood supply lends itself to removal of the half of the kidney bearing the disease. The upper half of a double kidney is usually the smaller part of the renal mass and the site of the disease.

Conservatism should play a part in the management of many large bilateral renal calculi. The symptoms condition of the kidneys and the age of the patient should help to decide whether these calculi should be surgically removed.

One of the greatest problems in conservative renal surgery concerns the procedure to be followed when the kidney and ureter have been obstructed with moderate sized or large calculi longer than 3 months. The removal of a long standing calculus obstruction at the ureteropelvic junction or the juxtavesical portion of the ureter will many times be followed by little or no return of anatomical form, and a symptom-producing dilated infected ureter and kidney remain. Strictures form very rapidly in these ureteral regions in spite of postoperative dilatations. Nephroureterectomy is frequently necessary in many instances in order to obtain a symptom free patient.

The author presented the case of a patient in whom a ureteral stone had been removed through a ureterotomy. Complete obliteration of the left ureter was observed 2 years after operation. A silent autonephrectomy had developed that was apparently caused by the reaction of the calculus in the lower ureter.

Congenital strictures may present a surgical problem. In a case of stricture of the upper third of the ureter along with hydronephrosis, a left ureteroplasty and nephrostomy with catheter drainage of 6 weeks duration justified this type of conservative surgery.

Conservative management is often indicated in the treatment of traumatic kidneys. Exploratory operations have been advocated if hematuria is present longer than 24 hours. The clinical picture usually suggests the necessity for operation upon the injured kidney.

Baker used conservative treatment on 2 patients with unilateral pyogenic kidneys. In a boy 11 years of age, he was able to enucleate the pyogenic area from the renal parenchyma. In the second case, a patient 45 years of age recovered his health following the removal of a walnut-sized renal carbuncle.

A complete nephroureterectomy is the procedure used for pedunculated renal tumors. In one of the author's cases however he was able to remove a pedunculated papilloma 6 inches in length with the electric cutting needle. The patient's recovery was uneventful. This is not the method of choice however in the treatment of all tumors of the ureter.

In summary the author stated that one should sincerely try to conserve renal tissue, but one cannot always prophesy the degree of success of his efforts. Failures and unfavorable results following surgery may be due to poor understanding of the neuromuscular physiology of the kidney and ureter. Improper estimation of final renal counterbalance may also account for many of the poor results of conservative renal surgery that have to be followed by a subsequent nephrectomy. The added experience of the surgeon and the use of the antibiotics should render conservative renal operations more successful.

BLADDER, URETHRA, AND PENIS

Deformities of the Male Urethra. SIR ARCHIBALD McINDOE. *Brit J Plast Surg.*, 1948, 1: 29.

The author discusses deformities of the male urethra from the viewpoint of a plastic surgeon. The general principles he stresses are:

1 Anatomical (a) It must be of adequate caliber (b) it must not contract to produce a stricture (c) it must be sufficiently long and elastic (d) the lining must not be hair bearing and (e) there should be a good cosmetic result.

2 Physiological Throughout the planning of repair the sexual function should be also taken into consideration.

3 Surgical It is necessary to direct the urinary stream and usually external urethrostomy is advisable. Hematoma and infection should be guarded against by the use of accurate hemostasis fine instruments and atraumatic sutures.

The author then discusses in detail the use of the above principles in the repair of 55 urethras comprising this report. The patients had penile injury (6) penile amputation (3) congenital short urethra (2) epispadias (6) and hypospadias (35).

JOHN A. LOFF, M.D.

The Value of Immediate Urethrography and Immediate Reconstruction of the Urethra Over a Support in Traumatic Ruptures of the Membranaceous and Perineal Urethra (Valeur de l'urographie immédiate et de la réfection immédiate de l'urètre sur tuteur au cours des ruptures traumatiques de l'urètre membraneux et périaérial). L. SABARDI. *J. chir.*, Par. 1948, 64: 420.

Only urethrography is able to furnish information concerning the exact location of a rupture of the urethra and the presence of periurethral injuries, but in the presence of a trauma of the urethra, urethrography has been dogmatically contraindicated because of the danger of embolism or spread of the infection by the contrast medium.

The author employed urethrography in 70 patients with recent ruptures of the membranaceous or prostatic portion of the urethra without untoward effects. He employed a 40 per cent solution of lipiodol 1 part, and 10 per cent oil, 2 parts as the contrast medium. The mixture is not only sterile but bactericidal.

Fractures of the pelvis without a lesion of the urethra may provoke a retention of the urine. Negative findings of urethrography in such instances contraindicate surgical intervention. From the medicolegal point of view visualization of a lesion of the urethra on the x ray film is of great value. More over clinical examination alone is not enough to detect penurethral lesions or to indicate their intensity. Demonstration of participation of the middle aponeurosis in certain perineal ruptures by urethrography is extremely valuable. In undergoing preliminary cystostomy the author derives great benefit from ascending and retrograde urethrography. No

infection, embolism or the slightest elevation of temperature has been observed by the author after the employment of this procedure.

The time allowed to lapse between the preliminary cystostomy and urethral repair depends on the site of the injury.

For the repair of a perineobulbar rupture a vertical scrotoperineal incision is made. The hematoma resulting from the tear of the superficial perineal aponeurosis is removed. The bulbocavernosus muscles are always found sectioned in a transverse direction. A longitudinal incision is made through these muscles and the corpora spongiosa. All devitalized tissues must be removed. The urethra is reconstructed over a rubber tube one end of which is pulled out through the cystostomy with a retrograde catheter. In some instances it may be easier to bring out through the perineal wound, by means of a curved clamp a catheter introduced through the cystostomy. The other end of the tube is brought out through the meatus.

For the repair of a rupture of the membranaceous portion of the urethra, a scrotosanal vertical incision is made and the retromembranoprosthetic space is exposed. The pelvic hematoma is removed and the prostatic space is exposed. The torn urethra is trimmed and a longitudinal incision is made through the bulbar urethra to provide a better exposure. No debris should be left as it is apt to produce stenosis. The urethra is reconstructed over a rubber tube. The anobulbar raphe is also reconstructed by uniting the bulb with the anterior wall of the anorectum. After the repair of the membranaceous portion, the bulbar urethra is reconstructed with catgut over a rubber tube. No drainage is employed. The author uses a soft rubber tube 30 cm. long with a gauge of from 18 to 20, according to the patient's age.

The author advocates repair of the urethra at the earliest date after the injury preceded by urethrogram. If the facilities for the repair are not immediately available, vesical puncture or preferably cystostomy should be done.

After the operation the urethral portion of the rubber tube is pulled out, washed with ether oil, and pulled back. No antiseptic solutions are employed for irrigation of the tubing or for injections between the tube and the urethra. The tube is left in place from 3 to 4 weeks, or more to prevent scar formation. Penicillin is employed routinely. After 3 or 4 weeks the tube is removed at the same time as the vesical drain and is replaced by a Nelaton catheter. Every second day a diathermy treatment is given to soften the scar. As a rule from 10 to 15 treatments are given. Disruption of the urethra is of no clinical importance because it is followed by complete restitution.

JOSEPH K. NABA, M.D.

Transurethral Resection in Childhood. JOHN L. ENRIGHT and HARVEY F. HELLMAN. *J. Urol.*, Balt., 64:5, 60:463

Urinary stasis, the cause of which is below the level of the ureteropelvic junction, continues to be one of

the most difficult problems in pediatric urology. All too often the etiology and pathogenesis of the condition is obscure so that the therapeutic problem is poorly defined. Even when the causative factor is clear-cut, therapy may be most difficult to carry out.

The treatment of a few well defined and rather rare obstructive conditions which occur at the ureterovesical junction such as ureterocele and congenital stenosis, is not considered, but the authors discuss the therapeutic efforts to correct urinary stasis (below the level of the ureteropelvic junction) which are directed toward infravesical conditions (affecting the vesical neck, prostate, and urethra).

The authors have selected all patients at the Mayo Clinic less than 20 years of age on whom a transurethral operation has been done for abnormal conditions at the vesical neck or in the prostatic urethra from October 1, 1941 through December 31, 1945. They did not include 5 patients in this age group who underwent resection because of a neurogenic bladder caused by transverse myelitis of traumatic, inflammatory or neoplastic origin. The study concerns 49 patients, of whom 34 were male and 15 female. By means of re-examination of the patients and follow up letters recent data concerning the condition of 49 of the 49 were obtained. For the remaining 9 patients the record of the patients at the time of dismissal were used in evaluating the results of the operations.

Urinary stasis in infants and children in which the causative lesion is below the level of the ureteropelvic junction may often be relieved by transurethral resection of the vesical neck.

Young people who require transurethral resection may be divided into two groups: (1) those who have vesical dysfunction which results from myelodysplasia and spina bifida, and (2) those who have congenital obstruction of the vesical neck.

There are two problems to consider in the group of patients with myelodysplasia and spina bifida: (1) relief of obstruction of the vesical neck and elimination of residual urine (which is essentially the same problem as in cases in which cord bladder results from acquired lesions of the spinal cord) and (2) correction of an incompetent external urethral sphincter. Because of the inability to combat the latter problem, normal vesical function can be re-established in only about 1 of 3 patients of this group.

The patients with congenital obstruction of the vesical neck respond to treatment with transurethral resection in a much more satisfactory manner. In more than 2 of 3 patients normal vesical function can be restored. The ultimate course of these patients depends on the amount of renal damage present. Early diagnosis is therefore important. In the authors' patients, no congenital urethral valves were encountered. The type of obstruction encountered consisted of lobar hypertrophies, bars, contractures of the vesical neck hyperplasia of the "internal sphincter" and redundant tissue at the vesical neck and normal-appearing vesical necks.

GENITAL ORGANS

Is the Roentgenological Appearance of the Spine and the Skeleton Always Diagnostic of Osseous Metastases from Cancer of the Prostate, and from Other Cancers? (L'aspect radiologique du rachis, et du squelette, permet-il de conclure toujours à l'existence de métastases osseuses dans le cancer de la prostate, et dans les autres cancers?) M. GEORGE KUNES. *Mém Acad chir. Par.*, 1948 74 237

Fey presented to the Radiological Society on April 30, 1947 the case of a patient who had "ivorization" of the body of the second lumbar vertebra. The type of lesion in the bone permitted him to make a diagnosis of vertebral metastasis from a previously undiagnosed cancer of the prostate. A roentgenogram taken 4 months later under the effect of diethylstilbestrol showed the body of the second lumbar vertebra to be clear with a return of its osseous structure.

M. Louis Michon reported the case of a man 65 years of age who had been treated by diethylstilbestrol and castration. Radium was applied from September 22 to 26, 1941. This treatment was followed by intense lumbosacral pain that was not relieved by diethylstilbestrol therapy. On August 10, 1945 a bilateral castration was done with total relief of pain within several hours following the operation.

The author described a patient who had been treated with diethylstilbestrol and glonoxins of Rubens-Duval. The patient's urine was clear and he had two or three nocturnal micturitions. Episodes of lumbar pain occurred from time to time. The author described in detail the roentgen findings during this period from August 13, 1945 when the first examination was made until the last roentgenograms were taken on December 27, 1947. The first pictures showed "ivorization" of the entire lumbar column: the vertebra L-1 to L-5 inclusive having a cloudy pagetoid appearance, along with the osseous pelvis and the superior extremities of both femurs. The second roentgen examination November 10, 1947 showed a similar pagetoid appearance. There was no deformation of the bodies of the vertebrae or the vertebral discs. The third examination made April 19, 1947 showed about the same condition. The author thought there was an osteoporosis of the lumbar column, the pelvis, and the femurs associated with a cellular diathesis of cottonlike appearance. The fourth and last examination made on December 27, 1947 showed the pagetoid appearance not only in the lumbar column but in the entire vertebral column: the entire pelvis, the femurs, the left tibia and the clavicles with profound modification in the structure of these bones. This modification was particularly marked in the pelvis and the spine. The lesions probably involved the entire skeleton, but without deformation, however of the vertebral bodies or the vertebral discs.

From a roentgenological point of view here was a case in which a diagnosis of cancer of the prostate with neoplastic metastases to the entire lumbar column, the osseous pelvis, and the superior extrem-

ity of both femurs, was made in December, 1947. The roentgenological interpretation of the film was given as a more or less pagetoid appearance of the bones with osteoporosis associated with a cellular diathesis. These pictures do not exclude the possibility of osseous metastases absolutely in fact they suggest at least the possibility of these metastases. While vertebral, pelvic, and generalized metastases are frequently found in cancer of the prostate it is the roentgen interpretation of these bone lesions that suggests metastases from silent or semisilent cancer of the prostate.

The author divided the localization of osseous metastases of cancer of the prostate in the spine, and especially in the lumbosacral spine, into three forms:

1. The osteoporotic and osteoclastic form shown by involvement of one or several vertebral bodies. The spreading involvement is shown by progressive bone destruction by the metastases. The intervertebral disc is not involved, however.

2. The osteoplastic form is more frequently encountered than the osteoporotic and osteoclastic. This form consists of a double process: one of osseous condensation and the other of proliferation of new bone. This results in osseous deformation, rarefaction and osseous destruction with decalcification. The two processes are manifested by clouding and marbling, suggestive again of the appearance of the bone in Paget's disease.

3. The third form is that of condensation. It is characterized by calcification of the vertebral body with metallike appearance or ivoryization of the vertebrae. The observer is surprised by the absolute opacity of the body of the vertebrae, there being no trace of the usual osseous structure.

There is no typical roentgenological or graphic appearance of the vertebrae that can be considered to be characteristic of cancer of the vertebrae, and especially that due to cancer of the prostate. Kunes draws attention to the fact that the same osteoporotic and osteoclastic lesions may be due to Kummel, Verneuil, decalcifications following fractures, trauma to the spine, spondylolithesis, epiphyseitis and certain forms of Pott's disease along with various generalized osseous infections.

In the condensation form the dark or black vertebra, or ivorylike vertebra shows progressive evolution of defense and hyperosteo-genesis reacting from diverse causes. Vertebral ivoryization is found in other osteopathies as well.

In short, one is able to encounter diseases of the hemopoietic system or reticuloendothelial system: myeloid leucemia, Sternberg-Hodgkin's disease, and other diseases of the same origin that present roentgen findings more or less frequently found in the diffuse type of Paget's disease. Of the three forms of roentgenological spinal metastases the intermediate or transitional forms are hard to classify.

The author stated that from his study he concludes that there was no characteristic picture of spinal metastases, for many diseases give the same roentgenological picture. This makes the differential

... of metastases very difficult and

... believes that the roentgenological findings are sometimes been interpreted as being characteristic of the absence of metastases when they are bone changes secondary to disturbances of osseous metabolism and especially to modifications in the phosphatase rate in old men who most often are affected with cancer of the prostate.

The elevation of the phosphatase is also observed in Paget's disease, Recklinghausen's disease, and in osseous rickets; therefore it is an error to use the term "metastases" with regard to bone changes in the presence of a prostatic neoplasm as they are simple changes due to modification of the phosphatase rate.

Kuess demanded that all of his colleagues make biopsies at autopsy and anatomical pathological examination of the vertebrae which they have recognized roentgenologically as being the site of cancerous metastases.

In the ensuing discussion Wolfrohm stated that he agreed with the author that without biopsies, one is not able to make a definite diagnosis of metastases from cancer of the prostate. He further observed that some testicles have been removed with only temporary relief of pain. One is not able, he stated, to establish a relationship between osseous alteration and the production of acid phosphatase in cancer of the prostate. The phosphatase is not able to construct or destroy bone, for this role is delegated to other hormones.

In Paget's disease presenting osseous tumors, non-prostatic in origin, the acid phosphatase is not increased but the alkaline phosphatase is. The amount of phosphatase reveals a paradox. The phosphatase is normal in patients with gross metastases from cancer of the prostate, yet the prostate may be filled with acid phosphatase. Wolfrohm suggested that it would be advisable to follow the clinical course of the patient by repeated acid and alkaline phosphatase determinations of the blood; however, this would be difficult because of the burden placed upon hospital personnel and the expense to the patient of tests that would only assist in diagnosis and not in therapy. He regretted that it was not always possible to obtain biopsies from the suspected zone.

confirmed the existence of osseous lesions a great number were found in the skin and liver and all were discovered to be from the cancer of the breast.

In concluding the discussion, the author confirmed the suggestion of Wolfrohm that biopsies and autopsies be obtained that would permit recognition or deny the metastatic character of the osseous alteration shown by roentgenography. He suggested that roentgenograms be taken of the vertebral column after autopsy, or a biopsy made if possible, and anatomic and pathologic examination of the lesions be made. Then a comparison of the known metastases with the evidence obtained by roentgenography in doubtful cases should be made in order to have more information about the roentgenological appearance in the living patient. It is easy, the author stated, to demand biopsies and autopsies, but in practice it is quite difficult to make these examinations. The prognosis depends upon the therapeutic decision above all, and this in turn very often depends upon the roentgenologic interpretation of the metastatic or other bone lesions.

The author cited a case of Cosaresco of Bucharest. This case was that of a woman having osseous lesions that could either be due to hyperparathyroidism or be metastases from epithelioma of the breast. The roentgen findings were considered to be the same in both diseases, and it was not possible to decide the diagnosis roentgenologically. The author removed the enlargement of the thyroid gland on the right side and thus removed the cause of the hyperparathyroidism. He noted postoperative improvement in the condition of the bone, and deduced from this finding that the patient had a hyperparathyroidism rather than metastases from cancer of the breast. This patient illustrated the author's view that roentgen examination alone is not sufficient to decide the proper diagnosis, the prognosis, and the best therapeutic approach.

CONRAD A. KOEHLER, M.D.

Cryptorchidism. LLOYD G. LEWIS. *J. Urol. Balt.*, 24:5, 60-64-5.

vided no anatomical or pathological condition prevents transit through the inguinal canal.

Anterior pituitarylike hormones will advance puberty in boys nearing that phase of their normal development. The use of gonadotropic hormones will hasten descent of the testis only in those patients whose testes would normally descend at puberty.

The use of hormones at or shortly before puberty may prevent unnecessary surgery.

If the testis does not descend after the use of 50,000 rat units of anterior pituitarylike substance in a dosage of 500 rat units twice or three times a week, surgery is indicated without delay.

The Torek operation or the traction suture method of orchiopexy apparently gives the best anatomical results.

Spermatogenesis following orchiopexy depends upon preservation of the internal spermatic vessels.

Division of the sheath of the internal spermatic vessels and straightening of their course under vision to allow placement of the testis in the scrotum deserves our serious consideration.

JOHN A. LOEF, M.D.

Malignant Tumors of the Testes (Tumores malignos del testículo) ALBERTO RAHAUSEN *Bol. Soc. cir. Chile*, 1947, 25, 203.

Of 73 malignant tumors of the testes observed by the author 74 per cent were seminomas.

The author has observed that seminomas are radiosensitive and that treatment can be given in such a manner that it does not harm the organism. It is essential to irradiate the regions in which glandular metastases are most frequently encountered.

In 45.2 per cent of the author's material the tumor was found in the third decade of life, in 30 per cent it was noticed in the second decade and in 19.1 per cent in the fourth decade. The oldest patient was 57 years and the youngest 2 years and 8 months of age. In 54.8 per cent of the patients the tumor was located in the right, and in 45.2 per cent in the left testicle.

In 2 of 6 patients with undescended testicles the tumor was discovered in the testis which was in its normal position. In 1 instance the tumor affected the ectopic organ. In 2 patients the tumor was located in organs which had been brought into the scrotum a few years previously by means of an operation. Finally, in 1 case the tumor developed in a testis which slipped into the abdomen after a herniorrhaphy. In only 6.8 per cent of the entire material was a seminoma located in an ectopic organ. In 35 per cent of the cases a trauma was recorded in the past history but the author does not attribute great importance to this factor because in many instances only a minor injury preceded the development of the tumor and the interval between the trauma and the discovery of the tumor was rather long.

The period of evolution of a seminoma is relatively short. Increase in size of the affected organ is usually the first sign. The pain has no characteristic fea-

tures. At the time of examination no metastases were detectable in 30 per cent of the cases.

The most frequent sites of metastases are the ilioinguinal and preaortic regions of the abdomen also the mediastinum and the left supraclavicular region.

The author prefers an aspiration biopsy to obtaining a specimen by means of an incision.

As to the diagnostic value of the Aschheim-Zondek reaction a positive finding is suggestive of a malignant tumor if a positive reaction is obtained after extirpation of the tumor the existence of a metastasis should be suspected. On the other hand a negative reaction does not exclude the existence of a seminoma.

After the establishment of the diagnosis of a seminoma, from 1,000 to 1,500 roentgen units should be applied to the involved organ. After this preliminary irradiation the organ should be removed and the common sites of glandular metastases should be subjected to x-ray therapy.

Of 60 patients treated by the author in this manner 26.6 per cent were cured.

JOSEPH K. NARAT, M.D.

MISCELLANEOUS

Genitourinary Injuries. JOHN B. WEAR. *J. Urol. Balt.* 1948, 60, 280.

A discussion of trauma to the genitourinary tract cannot follow a fixed pattern of general statements because the cause and extent of the injury must always be considered. It is difficult for the surgeon to determine the extent of the injury. In civil life the extent of the injury is usually determined by how people in that community work and play. In military life the same types of injuries may occur but, in addition, penetrating wounds from missiles of all sorts as well as an extreme degree of tissue loss may involve more than one organ.

The kidney is not often injured in either civil or military life. Because of its location it is well protected from all types of injury and the same position makes it possible for the kidney to recover without surgery in most cases. The mere fact that blood appears in the urine and a mass develops in the side does not call for immediate operation. Grave injury may occur without hematoma and without a lumbar mass but pain is usually a predominant symptom in these cases. In establishing the extent of the renal injury the retrograde pyelogram, the exploratory operation or clinical judgment based upon observation with the intravenous urogram may or may not give information that is desired for the proper management of the case.

Case 1 was chosen by the author to suggest that even though the patient had an apparently mild injury without loss of normal contour of the kidney examination demonstrated that 5 months later the function of the injured kidney had been so reduced that only a faint trace of diodrast was seen in the 20 minute film.

In Case 5 the patient had a severe injury to the kidney but recovered from the trauma without surgery.

Case 3 was that of an 18 year old sailor who fell while jumping over a fence. He was kept under observation because of hematuria and a large tender mass developed in the abdomen. The urine was free from blood in 5 days, but he developed a secondary hemorrhage on the twelfth day which necessitated an exploratory operation. This case demonstrated the value of bed rest in conservative treatment. Secondary hemorrhage always suggests the possibility of renal injury and when it does occur it is usually serious and demands immediate surgical treatment.

An 18 year old boy fell and struck the right side of the abdomen on a post. Subsequent examination revealed a large hydronephrosis containing 450 c.c. of urine. At the time of injury the hydronephrotic sac had ruptured. Recovery was uneventful following nephrectomy.

In the last case a 12 year old boy suffered an injury in which the ureter had been torn from the pelvis. On operation, it was found that the kidney was surrounded by dense adhesions. Hydronephrotic kidneys are prone to injury and early operation is usually indicated.

The author presented 5 cases of bladder and urethral injuries. The treatment in this type of case is usually clearly indicated. The results depend upon the extent of the injury, the first treatment given and the time required for definitive treatment. The drainage and diversion of the urinary stream is of primary consideration. When associated organs are injured their repair takes precedence over the urinary tract injury after diversion of the urinary stream has been established.

In Case 6 a marine was injured by a machine gun bullet entering his right thigh. The bullet had traversed the prostate near the bladder neck. The treatment in this case consisted of retrograde dilatation of the urethra through the previously established cystostomy. The balloon of the catheter was held in place against the internal vesical orifice by light traction. The patient was able to void normally 3 weeks later when the catheter was removed.

Case 7 was that of a naval officer who had suffered a 1/2 inch laceration of the bladder wall. The treatment in this case was a suprapubic cystostomy followed by a subsequent urethral dilatation.

Case 8 was that of a sailor who had suffered multiple pelvic fractures. A suprapubic cystostomy revealed a laceration of the right side of the bladder. The treatment consisted of evacuation of a considerable quantity of blood and urine and maintaining the catheter drainage.

Case 9 was that of a man who was hospitalized several months following a rifle shot that entered the abdomen over the bladder with its point of exit through the right buttock. Urine drained from this tract. The first operative procedures were laparotomy, indwelling catheter and right nephrectomy. The bullet had severed the right ureter as it left the bladder. A suprapubic cystostomy revealed that the right bladder wall was adherent to the pelvic bone. This area of the bladder was resected. The bladder was closed and the adherent tissue was then removed with a periosteal elevator.

The final case was that of a marine who had been shot in the perineum by a rifle bullet. Colostomy and suprapubic cystostomy were done in the forward area. Four months later the urethra was exposed and found to be completely severed just in front of the urogenital diaphragm. The scar tissue was cut away and the ends anastomosed over a urethral catheter. Recovery was uneventful. Two weeks later the colostomy was closed, and one week after that the suprapubic tube was removed. He was unable to void, but he was instructed to have periodic urethral dilatations. This case illustrated the management of a combined injury to the bladder and bowel.

The author summarizes the paper as follows: (1) even moderate renal trauma may cause loss of function, and repeated intravenous urograms several months after the injury are desirable. (2) after severe injury of the kidney it will frequently recover without surgery and without evidence of permanent damage, but secondary hemorrhage from too early ambulation requires immediate surgery. (3) lack of blood in the urine does not necessarily mean that the kidney is intact, and evidence of pelvic injury demands early surgery. (4) late surgery in kidney wounds usually results in nephrectomy. (5) in bladder wounds, immediate drainage is imperative. (6) when associated structures are injured, their care has precedence after bladder drainage. (7) late urethral repair means morbidity and difficult surgery.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES JOINTS, MUSCLES TENDONS ETC.

Meniscus Malformations as the Cause of Snapping of the Knee Joint (Meniscusmalbildungen als eine Ursache des Kniegelenkschnellens) ALFRED SOX KLINIKUM Helvet. chir. Acta, 1948, 15 218

Meniscus malformations occur in two forms as a disc which represents an ontogenetically and phylogenetically older stage and as a ganglion which is a cystically degenerated meniscus. Such menisci cannot fulfill their normal function as mobile cartilaginous sockets, but cause the phenomenon of knee joint snapping during flexion and extension of the joint. The author reports the case of 11 persons who were operated upon between the ages of 15 and 38 years.

The malformations were found only in the lateral meniscus even in 3 patients in whom both knees were involved. Although the defects were already present at birth they did not cause disturbances during childhood except in cases in which the size or form of the meniscus greatly altered its relations with the condyle. This was the finding in a child of 18 months. Usually the disturbances appeared in youth or at the latest about the time of the end of growth in cases of disc meniscus and at a later age in cases of ganglion meniscus the cysts of which developed gradually under the stimulation of mechanical damage. Subjective symptoms predominated over motility disturbances in cases of ganglion, while disc meniscus caused a painless impediment to movement. The first disturbances were often reported in connection with an injury although trauma has no etiologic significance in the disorder, it can influence the appearance of symptoms and it may play a part in the origin of the cysts.

The lining of the cysts consists of modified connective tissue cells which present a morphologic resemblance to those of the synovial accessory organs older cysts with a thin internal wall and fibrous thickened capsule show a similarity in structure with the joint capsule.

In the first 4 patients the extirpated menisci presented the form of a tough, thick plate which in 1 patient, was practically square and had a diameter of 4 to 5 cm. The plates were 8 mm. thick and were flat except for some knobby swellings on their borders. These menisci were incapable of playing their role of a mechanical sliding bed and produced a characteristic snapping of the knee joint during flexion when the angle of 160 degrees was being passed there was first an arrest then a sudden acceleration of the movement while the leg rotated outward or inward and then rotated back and completed the movement without further disturbance. During extension the same phenomenon occurred but was stronger. Simultaneously a popping noise was

heard and a swelling was observed at the lateral articular space. The jerking could be avoided when traction was exercised on the leg during flexion and extension.

Among the 7 patients with meniscus ganglion, there was only 1 in whom knee joint snapping could be demonstrated regularly and 1 in whom it occurred occasionally.

Treatment consists of extirpation of the lateral meniscus. In cases of cystic degeneration which often gives the impression of the presence of a single cyst and offers the temptation of puncture the ganglion is usually polycystic and puncture would fail because it could not reach all the cavities.

RICHARD KEMZL, M D

SURGERY OF THE BONES, JOINTS MUSCLES TENDONS, ETC.

Tendon Plastic for the Surgical Treatment of Dislocation of the Head of the Radius (Proposta di plastica tendinea per la cura cruenta delle lussazioni della testa del radio) VINCENZO LAUDICELLA Ann. Ital. chir., 1948 25 157

The author proposes a new type of surgical treatment for a dislocated head of the radius in which the tendon of the brachialis anticus is used to make a new annular ligament around the head of the radius once the dislocation is reduced.

A curved incision is used starting on the lateral aspect of the elbow about 4 or 5 cm. above the lateral condyle of the humerus and descending to about 3 or 4 cm. below the head of the radius. The incision is then curved upward and medially to the base of the olecranon. The skin and subcutaneous tissues are then reflected upward and the antibrachial fascia is exposed.

The head of the radius is exposed between the brachioradialis and the brachialis anticus. The insertion of the biceps tendon is retracted medially and the brachialis anticus is isolated. The radial half of the tendon is slit longitudinally leaving it attached to its insertion. It is then drawn around the neck of the radius under the muscles and is attached subperiosteally to the ulna on the posterior aspect.

Postoperative immobilization is attained by the use of a cast. This is removed after 2 weeks.

CARLO SCOTTONI M D

Results of Open Reduction of True Congenital Luxation of the Hip. JACQUES LEXOUY J. Bone Surg., 1948, 30-A 875

In dislocation there is interposition of the soft tissues between the head of the femur and acetabulum. On the other hand in subluxation interposition of soft tissues never exists. In true luxation established by arthrography, interposition of the soft tissues makes reduction impossible without open operation.

In Case 2 the patient had a severe injury to the kidney but recovered from the trauma without surgery.

Case 3 was that of an 18 year old sailor who fell while jumping over a fence. He was kept under observation because of hematuria, and a large tender mass developed in the abdomen. The urine was free from blood in 5 days, but he developed a secondary hemorrhage on the twelfth day which necessitated an exploratory operation. This case demonstrated the value of bed rest in conservative treatment. Secondary hemorrhage always suggests the possibility of renal injury and when it does occur it is usually serious and demands immediate surgical treatment.

An 18 year old boy fell and struck the right side of the abdomen on a post. Subsequent examination revealed a large hydronephrosis containing 450 c.c. of urine. At the time of injury the hydronephrotic sac had ruptured. Recovery was uneventful following nephrectomy.

In the last case a 7 year old boy suffered an injury in which the ureter had been torn from the pelvis. On operation it was found that the kidney was surrounded by dense adhesions. Hydronephrotic kidneys are prone to injury and early operation is usually indicated.

The author presented 5 cases of bladder and urethral injuries. The treatment in this type of case is usually clearly indicated. The results depend upon the extent of the injury, the first treatment given and the time required for definitive treatment. The drainage and diversion of the urinary stream is of primary consideration. When associated organs are injured their repair takes precedence over the urinary tract injury after diversion of the urinary stream has been established.

In Case 6 a marine was injured by a machine gun bullet entering his right thigh. The bullet had traversed the prostate near the bladder neck. The treatment in this case consisted of retrograde dilatation of the urethra through the previously established cystotomy. The balloon of the catheter was held in place against the internal vesical orifice by light traction. The patient was able to void normally 3 weeks later when the catheter was removed.

Case 7 was that of a naval officer who had suffered a 2 inch laceration of the bladder wall. The treatment in this case was suprapubic cystotomy followed by a subsequent urethral dilatation.

Case 8 was that of a sailor who had suffered multiple pelvic fractures. A suprapubic cystotomy revealed a laceration of the right side of the bladder. The treatment consisted of evacuation of a considerable quantity of blood and urine and maintaining the catheter drainage.

Case 9 was that of a man who was hospitalized several months following a rifle shot that entered the abdomen over the bladder with its point of exit through the right buttock. Urine drained from this tract. The first operative procedures were laparotomy, indwelling catheter and right nephrectomy. The bullet had severed the right ureter as it left the bladder. A suprapubic cystotomy revealed that the right bladder wall was adherent to the pelvic bone. This area of the bladder was resected. The bladder was closed and the adherent tissue was then removed with a periosteal elevator.

The final case was that of a marine who had been shot in the perineum by a rifle bullet. Colostomy and suprapubic cystotomy were done in the forward area. Four months later the urethra was exposed and found to be completely severed just in front of the urogenital diaphragm. The scar tissue was cut away and the ends anastomosed over a urethral catheter. Recovery was uneventful. Two weeks later the colostomy was closed and one week after that the suprapubic tube was removed. He was unable to void but he was instructed to have periodic urethral dilations. This case illustrated the management of a combined injury to the bladder and bowel.

The author summarizes the paper as follows: (1) even moderate renal trauma may cause loss of function, and repeated intravenous programs several months after the injury are desirable; (2) after severe injury of the kidney it will frequently recover without surgery and without evidence of permanent damage, but secondary hemorrhage from too early ambulation requires immediate surgery; (3) lack of blood in the urine does not necessarily mean that the kidney is intact, and evidence of pelvic injury demands early surgery; (4) late surgery in kidney wounds usually results in nephrectomy; (5) in bladder wounds, immediate drainage is imperative; (6) when associated structures are injured, their care has precedence after bladder drainage; (7) late urethral repair means morbidity and difficult surgery.

CORRAD A. KUTNER, M.D.

results of intra articular and juxta articular arthrodesis with bone grafting may be made. From the obtained bony union and 30 per cent, fibrous union. In the earlier series of 53 cases of intra articular arthrodesis with bone grafting about 85 per cent of the patients had bony union and 5 per cent fibrous union. The patients with fibrous ankylosis tend to do well on the whole but their hips are subject to strain, bony union would be more gratifying. It should be noted that the age grouping of the two series was fairly comparable.

The mortality rate is far from discrediting to the earlier operations. Only 1 patient of the 53 died. The average period in bed was 11.4 weeks but the author believes this can be cut to 10 weeks without adverse effects.

Bony ankylosis did not occur any earlier in the nailed group than in the earlier group. Simple trans-articular nailing without resection of sclerotic bone required a longer period for bony union than either the combined nailing or the intra articular arthrodesis with bone grafting.

While the nailing procedure was undertaken to reduce bed rest and was followed, in about 3 weeks by the simple transarticular nailing the advantage was not too great when the number of fibrous unions and fractured nails are considered. The procedure is a relatively simple one and it should find application among the elderly in whom minimal surgical trauma is indicated.

KENATH H. SPORSEL, M.D.

Treatment of Discrepancies in the Length of the Lower Extremities during Growth (Le traitement des inégalités de longueur des membres inférieurs pendant la croissance) PIERRE BERTRAND and ALBERT TRILLAT *Rev orthop*, Par 1948 34: 264.

Differences in leg length may be due to congenital factors (atrophy with or without skeletal anomalies) dyschondroplasia, exostotic disease, hypertrophy of vascular anomalies, hemarthroses of hemophilic origin (dislocation of the hip), infections (tuberculosis, osteomyelitis, suppurating arthritis), poliomyelitis tumors (fibrocystic osteitis Recklinghausen's neurofibromatosis chondroma giant cell tumor) and traumatism.

Two methods may be used to measure the discrepancies the clinical and the roentgenologic, which supplement one another. Evaluation of the prospective growth is of first importance for prognosis and treatment. Of the various methods proposed for this purpose the method of Green and Anderson for poliomyelitis has established averages of sufficient precision.

Before shortening is corrected it is necessary to eliminate the deformities and deviations which create apparent shortenings for instance adduction of the thigh and flexion of the knee or hip. The usefulness of some degree of shortening in certain disorders should not be overlooked.

The inequality in length may become fixed at a certain level after a period of increase or it may de-

crease or increase with growth. Therefore, the evolution of the condition should be observed by taking successive measurements to guide its treatment. Various methods to stimulate growth have been tried. They include direct action on the circulation by venous stasis and venous ligation physical therapeutic agents (diathermy or short waves) action on the lumbar sympathetic by infiltrations or resection, and direct action on the bone by the incorporation of foreign bodies. Ferguson's procedure and detachment of the periosteum. The methods used to inhibit growth include roentgen therapy epiphysiotomy resection of the conjugation cartilage the procedure of Haas and vascular operations.

In the present status of the technique of lengthening osteotomies these operations must be regarded as offering many risks and should be used only in naturally short patients having a short extremity with bones of sufficient diameter without previous or actual infection and after growth has stopped. In general shortening operations are functionally less serious and result less frequently in failure. In most cases the healthy extremity is shortened.

The indications for the various methods vary principally with the age of the children. Up to the age of 8 years the stimulating methods alone should be used vigorously and with perseverance, and even in mild cases since a shortening of 2 cm which is insignificant in an older child may indicate a serious involvement of the growth potential in a young child. When possible diathermy is preferred, second choice going to intra articular injections of blood. In severe cases i.e. those in which the difference in length increases regularly recourse may be made to surgical measures preferably detachment of the periosteum lumbar sympathectomy and venous ligations. These methods are probably those of the future they allow stabilization of shortening at its onset and are without danger. At the age of 8 years the question arises of slowing down the growth on the healthy side by epiphysiotomy as roentgen therapy does not fulfill the requirements. At the end of the growth period i.e., practically after the age of 13 or 14 years the equalization methods may be considered when the shortness becomes burdensome (5 cm or more). Lengthening being a serious operation which presents frequent complications should be reserved for special cases while shortening being safer should be recommended in most cases.

RICHARD KEMMEL, M.D.

Penicillin Therapy In Open and Closed Suppurative Arthritis of the Knee Joint (Penicillinoterapija na otvoreni i zatvoreni gnojni artriti na kolennata stava) GEORGI KRASTINOV *Chir orthop Sofia* 1948 No 8: 39.

Fifteen cases of traumatic suppurative arthritis of the knee have been observed at the university clinic of Plovdiv, Bulgaria, during the period from 1940 to 1948. Ten of these were open wounds received mostly from knife or hatchet cuts connected with woodworking; 4 were closed infections and 1 case

and operation is restricted to cutting away the soft parts which block the acetabulum.

The total number of operations performed was 318, made up of 119 primary open reductions, 96 open reductions with shortening of the femur and 103 secondary open reductions for luxation after closed treatment. There were 5 deaths. Among the patients under 2 years of age whose hips were operated upon, the ligamentum teres was present in 23 and absent in 12. Among the 23 cases in which the ligamentum was present epiphysitis developed in 11 (47.8%). Among the 12 cases without the ligamentum, epiphysitis developed in only 2 (16.7%). The results are better when the child is under 3 years of age. The period between second and third birthdays of the patient was selected as the most favorable one for open reduction. After open reduction with shortening of the femur a fair reduction was obtained in 77 per cent of the patients. Ankylosis a high degree of coxa vara, and necrosis of the head were the poor results. Operation for bilateral dislocation is advantageous only in children under 6 years of age and in older patients open reduction is good only for unilateral luxation. The results after open reduction followed by relaxation and secondary subluxation are not so satisfactory as after primary open reduction but they are good enough to justify an operation.

RICHARD J. BENNETT JR., M.D.

On Complications Following Nailing Arthrodesis of the Hip Joint. A. KALLER *Acta orthop scand* 94:8, 7-93.

This analysis is confined to hip arthrodesis for arthritis deformans. At first intra-articular and juxta articular arthrodeses were performed, but more recently various nailing arthrodeses have been practiced. It was hoped that absolute fixation would both relieve the uncomfortable postoperative symptoms and encourage earlier and firmer bony consolidation.

TABLE I.—RESULTS WITH RESPECT TO ANKYLOSIS IN 94 NAILING ARTHRODESSES PERFORMED

Operative method	Number of Operations	Results			
		Bony Ankylosis	Fibrous Ankylosis	No Ankylosis	Deaths
Transarticular nailing arthrodesis	46	14	20		
Intra-articular arthrodesis + transarticular nail (long)	3	16	3	2	
Intra-articular arthrodesis + transarticular nail (short)	7	9	4		3
Osteotomy + intra-articular transarticular nail	8	7			
	94	46	27	5	5
		48.9%	29.8%	100%	5.3%

In the nailed group 90 patients had 95 operations, each of 5 patients had a second operation. At first simple transarticular nailing arthrodesis was used, but frequently there was a gradual slipping of the nail. Then indented or fenestrated nails from 14 to 17 cm. long were used. These nails did not slip, but fracture of the nails occurred. Simple transarticular nailing arthrodesis has been largely discarded for nailing combined with intra-articular arthrodesis. In poor risk operative patients, a satisfactory procedure for the correction of deformity and arthrodesis is subtrochanteric osteotomy combined with intramedullary transarticular nailing.

The following complications have occurred: death from pulmonary embolism, fat embolism, or coronary failure in 5 cases; thromboembolism in 9 cases with 2 resulting in death; infection in 1 case resulting in only fibrous ankylosis; peroneal paralysis, 1 case; bilateral which cleared, and 1 case with residual paralysis of the anterior tibial muscle; slipping of the nail in several early cases; fracture of the long nail in at least 8 of 18 cases in which transarticular nailing only was performed; fracture of the femur in 9 cases, 3 being incident to the operative procedure, 1 being the result of trauma, and 3 diagnosed as insufficiency fractures.

Fracture of the nail was a disturbing factor and occurred in 9 of 27 or 33.3 per cent, of the patients subjected to simple transarticular nailing, and in 3 of 13 or 23.1 per cent, subjected to transarticular nailing combined with intra-articular arthrodesis. This probably occurred because of the shorter postoperative rest in bed. Thus it might be avoided by longer periods of bed rest, but then the operation would fall in one of its main purposes. Actually some patients were later kept in bed about 3 months. This gives no advantage over intra-articular and juxta-articular arthrodesis with bone grafting.

In referring to Tables I and 2 a comparison of the results of the nailing type of arthrodesis with the

TABLE II.—RESULTS WITH RESPECT TO ANKYLOSIS IN 53 PATIENTS SUBJECTED TO PARTIAL AND TOTAL INTRA-ARTICULAR ARTHRODESSES COMBINED WITH JUXTA-ARTICULAR BONE GRAFTING

† Died of bronchopneumonia. 24 months after operation.

Two-Stage Reduction of the Posterior Marginal Fragment in Dupuytren's Fracture (*Réduction en deux temps du fragment marginal postérieur dans la fracture de Dupuytren*) CH. A. PRAUET *Hérel. chir. act.*, 1948 15 235.

When Dupuytren's fracture is complicated by the presence of a large tibial, marginal posterior fragment which is displaced upward, and continuous extension obtained by means of a Kirschner pin passed through the calcaneus is used, the fragment does not always move down far enough to reassume its normal place and the functional result is often unsatisfactory. The fractured surface of the fragment and the corresponding surface of the tibia are rough and present bony prominences which prevent the fragment from sliding down. In addition the fragment is kept firmly in contact with the tibia by the traction applied to the muscles and tendons of the flexors of the foot and toes during the continuous extension, and the reflex tonus of these muscles is stimulated by the pain hematoma, and displacement of the fragment over which they slide without friction under normal conditions. Thus, manual or continuous extension keeps the two rough surfaces one against the other and prevents reduction. Another unfavorable factor may intervene after the foot is put back in place: traction is generally exerted parallel to the axis of the leg and the weight acts through the calcaneus and the posterior wall of the capsule of the tibiotarsal joint on the inferoposterior edge of the fragment which then tips backward and catches its inferoanterior edge against the fractured surface of the tibia.

To eliminate these obstacles to reduction in Dupuytren's fracture it is necessary to use the following method:

1 The foot must be temporarily kept in its position of subluxation backward and its lateroexternal displacement alone corrected.

2 From the onset, the traction must be exerted in an oblique descending direction which sometimes aggravates slightly the backward subluxation of the foot. Under these conditions a traction of from 5 to 7 kgm. opens the interfragmental space and pulls the inferoanterior edge of the fragment away from the tibia and dislodges it. This leaves the fragment in contact with the tibia through its proximal end only and allows it to descend.

3 As soon as the fragment is in its place and with continuance of the traction the subluxation of the foot is reduced manually under a short intravenous anesthesia. To maintain reduction a strong padded plaster splint is applied to the anterior surface of the leg and foot and bandaged to the supporting apparatus. Until complete consolidation of the fracture extension is exerted in a rather pronounced oblique ascending direction.

4 When the fracture is consolidated a walking plaster cast enclosing the leg from the knee down and the foot at a right angle and in supination allows the patient to get up and move about.

RICHARD KEMEL, M.D.

Treatment of Simultaneous Fractures of the Two Bones of the Forearm in Adults (*Le traitement des fractures simultanées des deux os de l'avant bras chez l'adulte*) R. SOZUK. *Rev. orthop.* Par 1948, 34 301.

Fresh fractures of the bones of the forearm, located in the region of the interosseous membrane and presenting displacement are relatively not frequent in the adult, but their treatment is difficult. In their orthopedic treatment under local or brachial plexus anesthesia, with the patient in dorsal decubitus the elbow flexed at a right angle, and the hand in functional position traction is made separately on the thumb and the fingers through finger cots of braided fiber, and the progress of the reduction is observed by fluoroscopy. Overriding angulation rotation and lateral displacement must be corrected. It is preferable not to pad the plaster cast, which consists of a dorsal splint fixed by a gauze bandage and then by plaster bandages over it. This apparatus must extend from the metacarpal heads to the upper third of the arm with the elbow flexed at an angle of 90 degrees. Immobilization is maintained until clinical and roentgenologic consolidation is obtained; this takes from 8 to 12 weeks and sometimes more. Secondary displacements may occur if the apparatus is supported by a sling. The method offers no danger is applicable to all cases, shortens hospitalization and provides successful results with rapid consolidation, minimal callus and easy functional recovery. Unfortunately it presents also some cases of failure: secondary displacements can be corrected if discovered in time and premature removal of the cast can be avoided but reduction remains the great obstacle no matter how experienced the surgeon may be. Reduction is successful only if the axial angulation is less than 5 degrees in any direction and if coaptation of the fragments amounts to 80 per cent.

Surgical reduction followed by the correct application of a plaster cast suffices to permit healing of many of these fractures but the advocates of this method admit that reduction is not always maintained and that, if the reduction seems unstable during the manipulation it is better to complete it with a prosthesis. Economical osteosyntheses (screws, plates, clips, sutures) have caused numerous disappointments. External fixation is still advocated by some for open fractures but has not been used in recent traumatism. Large half-exteriorized screws cause osteitis. Bone grafts still serve for pseudarthroses but their complicated technique has eliminated them in cases of fresh fractures. This leaves synthesis by plates, the coaptator of Denis, and medullary pinning or nailing.

During past years the plate method has been discredited. The coaptator of Denis consists of a thick hard stainless steel plate, having three holes on the side of its reinforced extremity. It has a groove, at the distal end of which there is a pressure screw. The screws used to fix the appliance to the bone are capable of resisting a tearing-out force from 4 to 5

Fig. 1. (Van Nee) Technique of partial turn-up-plasty

was a tuberculous arthritis with secondary suppurative infection. At first, general measures were instituted without immobilization with indifferent results then immobilization was started with the parenteral administration of the sulfonamides, still with unsatisfactory results finally penicillin therapy was instituted with immobilization in a plaster of paris splint or cast. The period of hospitalization then dropped from several weeks to a few days, and when treatment could be adequate, the functional results (both immediate and after follow-up periods of from 2 to 6 months) were invariably good.

The penicillin was always injected intra-articularly in dosages of 5,000 I U an equivalent quantity of joint fluid usually being withdrawn in closed cases. In 7 open case adhesive was used to seal the articular cavity so that the penicillin solution could be retained. As a rule, from 3 to 5 injections at 3 or 4 day intervals were sufficient to bring down any temperature present, to return the blood picture and sedimentation rate to normal and to produce a sterile joint fluid. Lately the joint has usually been sutured with or without trimming of the wound edges. This changed the open infection into a closed one and in nonsuppurative cases shielded the joint against secondary infection.

In 1 case the penicillin brought the temperature down initially but later the patient did not respond very well as there were subfebrile rises in temperature and puncture of the posterior recess of the articular cavity revealed turbid fluid. This recess was then injected separately with complete success. This result causes the author to discuss the anatomical work of Voyno-Yasenetski, who showed that the articular cavity of the knee is divided into anterior and posterior recesses which are connected by narrow communicating passages, and that the posterior recess is also partially divided into two cavities by a sagittal septum consisting of the posterior cruciate ligament with its synovial fringe and Robert's ligament. In infectious conditions these partial septa may become total. JAMES W. BRIDGMAN, M.D.

Fig. 2. Technique of total turn-up-plasty

Transplantation of the Tibia and Fibula to Replace the Femur following Resection "Turn Up-Plasty" of the Leg. C. P. VAN NEE. *J. Bone Surg.* 1945, 30-A: 854.

Transplantation of the tibia and fibula to replace the femur is indicated in partial or total resection of the femur in cases of tumors, osteomyelitis, or severe trauma. Under tourniquet an incision is made along the entire lateral aspect of the extremity. A partial or total resection of the femur is done. The tibia and fibula are turned up and inserted into the thigh bone in such a manner that the malleolus fits into the acetabulum. In partial resection of the femur, the cut section of the tibia fits the amputation stump of the femur. A small bone graft is inserted to hasten bony union.

The author reports the case of a 21 year old man in whom the femur was excised because of Ewing's tumor. A total "turn-up-plasty" was performed. His second case was that of a 33 year old woman in whom a partial excision of the femur had to be done because of a malignant giant-cell tumor. A partial "turn-up-plasty" was done.

Both patients were satisfactorily fitted with a prosthesis. The operation was successful from the cosmetic point of view. GEORGE L. REES, M.D.

FRACTURES AND DISLOCATIONS

The Treatment of Supracondylar Fractures of the Humerus by Kirschner Wire Transfixion. ALVIN L. SWINSON. *J. Bone Surg.* 1945, 30-A: 903.

After supracondylar fracture of the humerus, the fragments of bone are fixed by means of transfixing wires. This method of blind planing was used in 11 cases in which there was external swelling about the elbow. The wires held the fragments until union occurred except in 1 case. The wires were removed under local anesthesia.

This procedure is recommended when immobilization in acute flexion following closed reduction is not justified. RICHARD J. BROWNETT, JR., M.D.

Nine patients showed arthritic changes clinically and roentgenologically. One case of each of the following occurred: calcification in the joint capsule, persistent displacement of the acetabular fragment with no disability, avascular necrosis of the femoral head, failure of the reduction of the dislocation and open reduction and mold arthroplasty.

A later follow up was made in 15 of the 43 patients of 7 patients previously classified as normal 5 remained so, and 2 complained of slight aching and stiffness. Five arthritic hips remained unchanged. One patient with calcification of the capsule reported some aching. The patient with avascular necrosis remained unchanged and was awaiting arthrodesis. The patient with the mold arthroplasty had satisfactory function with about one half of the normal range of movement.

Cases of dislocation of the hip joint with fracture of the acetabular floor were classified in two groups 3 were of the central type of dislocation and 4 were posterior dislocations involving the floor of the acetabulum. In the central type the hip joint function was lost. The patients had arthritis, and/or fibrous or bony ankylosis. Two posterior dislocations were reduced by traction but eventually traumatic arthritis set in. This group of patients was subject to uniformly poor results relative to hip joint function. Two had sciatic paralysis with incomplete recovery.

In the treatment of dislocation of the hip joint with fracture of the head of the femur three factors had a bearing on the prognosis: (1) the degree of damage to the femoral head, (2) the ease with which displacement could be reduced and (3) the accuracy of replacement of the femoral fragment.

Only one of these patients could be considered normal after 16 months. This patient had a fracture with a fragment about one sixth of the femoral head that was in good position following reduction of the hip dislocation. Three fractures in the group of 5 could be reduced by manipulation. One patient with a small femoral head fragment obtained good hip function but had sciatic paralysis which did not leave completely and marred the result. One patient has traumatic arthritis and 2 others were subjected to arthrodesis.

In the whole series 3 patients had dislocations which remained unreduced. Experience showed that late operative reduction and reconstruction or arthrodesis were very difficult. The author cites 1 patient in his previous experience who had a simple dislocation and had excellent function for about 5 years and then developed aseptic necrosis of the femoral head. He wishes to point out that this is not an end result study. He expects that some of the apparently normal hips will develop necrosis of the femoral head and traumatic arthritis or both. Further he states that if the reported results of sciatic paralysis as a complication of acetabular rim fracture can be considered typical, exploration of the sciatic nerve should be performed at the earliest time possible after reduction of the dislocation.

KENNETH H. SPENCE, M.D.

Fractures of the Neck of the Femur

VAN GORDEL, *J Am Med Ass*, 1948 137 1181

The femoral neck fractures present certain inevitable problems. They occur in old persons at a site in the hip where the bone is narrowest and periosteal callus never forms and where the blood supply is poor. It is also a site of great mechanical strain.

Modern concepts of treatment, in particular the Smith Petersen nail, revolutionized the prognosis both for life and the solid limb of these patients but there is still need to survey the progress and problems of treatment in the light of accumulated experience.

Because of the comfort afforded the patient and the minimum risk involved, nailing may be done in all patients with fracture of the femoral neck, provided only they are not acutely or hopelessly ill. Most surgeons agree that the optimum time is within the first week of injury.

All types of anesthesia are advocated but most surgeons use either spinal or some form of general anesthesia for patients under 60 years of age and for others local, supplemented by gas-oxygen or ether at the time of reduction and nail insertion.

The success or failure of treatment depends upon securing an accurate reduction. Roentgenograms taken in both anteroposterior and lateral planes after 24 hours of moderate traction correct the external rotation and afford an appreciation of the distinctive features of each fracture so that the most effective means of reduction may be employed. At reduction an effort should be made to secure a position of valgus which converts the shearing force at the fracture site to a pressure force conducive to reunion. Careful study of clear roentgenograms, taken in both planes is necessary to be assured of accurate reduction.

Once reduction is secured the leg can be held satisfactorily by an assistant who maintains the proper degree of internal rotation and abduction and keeps the knee flexed at a right angle to help lock the fragments in place by keeping the extensor muscles tight. Special tables and traction set ups are not necessary.

Vertical subcapital fractures are the most difficult to manage, for even when reduced the weight bearing line falls across the fracture so as to shear it apart rather than impact it. Often it is necessary to supplement the nail fixation with a bone-graft peg parallel to the nail. When accurate reduction cannot be obtained, either open reduction or an osteotomy must be undertaken.

Under ordinary circumstances the fracture is least disturbed by so-called blind nailing which is generally used. The specific technique may be highly individualized and gadgetized, but the author prefers and describes the procedure as carried out at the Massachusetts General Hospital, Boston.

Aftercare varies tremendously in different clinics but most surgeons keep their patients in bed with or without support for from 3 to 6 weeks then

times greater than that of the usual screws they are very tightly seated in the respective holes and remain rigid like the teeth of a comb. No plaster cast is used, but the forearm is protected by a reinforced celluloid cuff which is laced in place when the patient goes out or wants to sleep. Consolidation was obtained in 34 cases in which the appliance was used, but synostosis occurred in 4 because of technical errors.

The theoretical objections against medullary pinning such as danger of embolism, massive infection of the bone marrow moving of the pin, have been refuted by the facts. The method is simpler than the other osteosyntheses, surgical trauma is minimal and reduction is necessarily good. Insertion of the pin is easy in the ulna but somewhat more difficult in the radius. Retention of the fragments is solid and allows early resumption of movements. Results are encouraging.

As to the question whether open reduction should be used systematically or efforts be made to perfect the subcutaneous method. Sourc thinks that, perfect reduction being essential, surgical exposure of the fragments is indicated. Medullary pinning or nailing is gaining in favor. However, this does not mean that the orthopedic method should be abandoned since there will always be some cases in which osteosynthesis is unnecessary or contraindicated.

RICHARD KEMEL, M.D.

Traumatic Dislocation of the Hip Joint. J. R. ARMSTRONG. *J Bone Surg* 94B, 30-B 430

This report deals with the types of traumatic dislocations of the hip joint and the early results in 101 cases in the Royal Air Force hospitals. The incidence of dislocation of the hip was 1 in 350 admissions.

Before the era of motor vehicles, the classical cause of dislocation was wide and forcible abduction of the lower limbs, the limb acting as a long lever to force the femoral head through the inferior aspect of the joint capsule. Anterior posterior or inferior dislocation occurred according to the amount of internal or external rotation of the extremity at the time of injury. In this series, only 8 dislocations were of this type, and 93 were due to considerable violence of high velocity acting in the line of the shaft of the femur.

The exact nature of the dislocation depends upon the position of the limb when the force is applied. If the hip joint is flexed and adducted, the head of the femur is driven out of the back of the joint where the capsule is weak and the acetabulum relatively shallow. With less flexion and less adduction the head is driven against the strong posterosuperior buttress of the acetabulum which is fractured. If the hip is extended and abducted a central fracture-dislocation is produced.

Dislocations of the hip joint can be classified into four main types: simple dislocations, dislocations with fracture of the acetabular rim, dislocations with fracture of the acetabular floor, and dislocations with fracture of the femoral head.

In simple dislocations the management was relatively easy. The treatment soon became uniform in the various centers: namely, reduction by manipulation under general anesthesia, immediate immobilization in a hip spica for 8 weeks, mobilization in nonweight bearing exercise for about 4 weeks, and finally treatment at a rehabilitation center for 1 month or 6 weeks with gradual return to full activity.

Patients were classified as normal if there was no muscle wasting, no limitation of movement, no roentgenographic evidence of abnormality and no real discomfort after engaging in full activity. Of 46 dislocations 35 (76 per cent) were associated with no symptoms or disability remaining after a period of treatment ranging from 4 to 7 months. Calcification in the joint capsule with no disability occurred in 3 patients. Arthritic changes in the joint were present in 6 patients. These had slight wasting of the thigh muscles, mild limitation of joint motion, and some discomfort or aching pain which was made worse by exercise. Avascular necrosis of the femoral head occurred once. Myositis ossificans resulted in 1 case in which the patient was treated by massage and early passive and active exercises immediately after reduction. This was continued for 10 weeks.

Late follow up was obtained in 19 of these 46 patients. Fourteen had been considered normal at the conclusion of the early treatment. From 1 to 4 years after the injury only 3 reported that their hips were still quite normal, 6 complained of trivial aching and pain, 3 had vague symptoms only after exertion.

Forty three patients suffered posterior dislocations with fractures of the acetabular rim. Both reduction of the dislocation and accurate replacement of the bony fragment had to be accomplished. Frequently the fragment will be reduced well with reposition of the hip. In this case treatment was similar to that of simple dislocation. If satisfactory reduction of the acetabular fragment was not obtained in this way the limb was immobilized in traction. In most instances the fragment fell back accurately into place within a few days. Traction was maintained about 6 weeks and then immobilization maintained by plaster spica.

In 1 case with associated sciatic paralysis, the fragment could not be reduced conservatively and open operation with screw fixation was performed. At operation the sciatic nerve was found to be impaled over the fragment. Complete nerve recovery occurred in 6 months. This was the only complete recovery among 3 cases of complete sciatic paralysis and 5 cases of external popliteal nerve paralysis. Two other patients were explored several months later but nerve function did not improve. In these 2 cases, the nerve was likewise sharply indented by a bony fragment of the acetabulum.

Results in dislocation with fracture of the acetabular rim were not as good as in simple dislocations. Twenty-seven of the 43 patients (63 per cent) were considered normal after completion of the early treatment. Two patients died shortly after injury.

Nine patients showed arthritic changes clinically and roentgenologically. One case of each of the following occurred: calcification in the joint capsule, persistent displacement of the acetabular fragment with no disability, avascular necrosis of the femoral head, failure of the reduction of the dislocation and open reduction and mold arthroplasty.

A later follow up was made in 15 of the 43 patients. Of 7 patients previously classified as normal 5 remained so, and 2 complained of slight aching and stiffness. Five arthritic hips remained unchanged. One patient with calcification of the capsule reported some aching. The patient with avascular necrosis remained unchanged and was awaiting arthrodesis. The patient with the mold arthroplasty had satisfactory function with about one-half of the normal range of movement.

Cases of dislocation of the hip joint with fracture of the acetabular floor were classified in two groups: 3 were of the central type of dislocation and 4 were posterior dislocations involving the floor of the acetabulum. In the central type the hip joint function was lost. The patients had arthritis, and/or fibrous or bony ankylosis. Two posterior dislocations were reduced by traction but eventually traumatic arthritis set in. This group of patients was subject to uniformly poor results relative to hip joint function. Two had sciatic paralysis with incomplete recovery.

In the treatment of dislocation of the hip joint with fracture of the head of the femur three factors had a bearing on the prognosis: (1) the degree of damage to the femoral head, (2) the ease with which displacement could be reduced, and (3) the accuracy of replacement of the femoral fragment.

Only one of these patients could be considered normal after 16 months. This patient had a fracture with a fragment about one-sixth of the femoral head that was in good position following reduction of the hip dislocation. Three fractures in the group of 5 could be reduced by manipulation. One patient with a small femoral head fragment obtained good hip function but had sciatic paralysis which did not leave completely and marred the result. One patient has traumatic arthritis and 2 others were subjected to arthrodesis.

In the whole series, 2 patients had dislocations which remained unreduced. Experience showed that late operative reduction and reconstruction or arthrodesis were very difficult. The author cites 1 patient in his previous experience who had a simple dislocation and had excellent function for about 5 years and then developed aseptic necrosis of the femoral head. He wishes to point out that this is not an end result study. He expects that some of the apparently normal hips will develop necrosis of the femoral head and traumatic arthritis, or both.

Further he states that if the reported results of sciatic paralysis as a complication of acetabular rim fracture can be considered typical, exploration of the sciatic nerve should be performed at the earliest time possible after reduction of the dislocation.

KEMATH H. SPOKES, M.D.

Fractures of the Neck of the Femur. GEORGE W. VAN GONDER. *J. Am. Med. Ass.* 1948 137 1181.

The femoral neck fractures present certain inevitable problems. They occur in old persons at a site in the hip where the bone is narrowest and periosteal callus never forms and where the blood supply is poor. It is also a site of great mechanical strain.

Modern concepts of treatment, in particular the Smith-Petersen nail, revolutionized the prognosis both for life and the solid limb of these patients but there is still need to survey the progress and problems of treatment in the light of accumulated experience.

Because of the comfort afforded the patient and the minimum risk involved, nailing may be done in all patients with fracture of the femoral neck, provided only they are not acutely or hopelessly ill. Most surgeons agree that the optimum time is within the first week of injury.

All types of anesthesia are advocated but most surgeons use either spinal or some form of general anesthesia for patients under 60 years of age and for others local supplemented by gas-oxygen or ether at the time of reduction and nail insertion.

The success or failure of treatment depends upon securing an accurate reduction. Roentgenogram taken in both anteroposterior and lateral planes after 24 hours of moderate traction, correct the external rotation afford an appreciation of the distinctive features of each fracture so that the most effective means of reduction may be employed. At reduction an effort should be made to secure a position of valgus which converts the shearing force at the fracture site to a pressure force conducive to reunion. Careful study of clear roentgenograms again taken in both planes, is necessary to be sure of accurate reduction.

Once reduction is secured, the leg can be held satisfactorily by an assistant who maintains the proper degree of internal rotation and abduction and keeps the knee flexed at a right angle to help lock the fragments in place by keeping the external muscles tight. Special tables and traction set-ups are not necessary.

Vertical subcapital fractures are the most difficult to manage for even when reduced, the weight-bearing line falls across the fracture so as to shear it apart rather than impact it. Obviously it is necessary to supplement the nail fixation with a bone-graft perpendicular to the nail. When accurate reduction cannot be obtained, either open reduction or an osteotomy must be undertaken.

Under ordinary circumstances the fracture is least disturbed by so-called "nailing" which is generally used. The specific technique may be highly individualized and the author prefers and describes "nailing" as tried out at the Massachusetts General Hospital.

Aftercare varies tremendously—different doctors but most surgeons keep the patients in bed, with or without support for 6 to 8 weeks.

permit crutch-walking without weight-bearing. Early weight bearing may be dangerous and only when there is roentgen evidence of solid union may it be safely permitted.

The prognosis in fractures of the femoral neck depends largely upon the site and obliquity of the fracture line. Excellence of nursing care is the other major factor in survival of this elderly type of patient.

FRANCIS E. BRENNER, M.D.

ORTHOPEDICS IN GENERAL

Criteria for Spine Fusion Following the Removal of a Protruded Nucleus Pulposus. GUY A. CALDWELL and WILLIAM B. SHEPPARD. *J Bone Surg* 94B, 30-A: 97.

In follow-up studies for from 3 to 7 years it was found that excellent results were obtained in about as many cases treated by laminectomy as in those treated by the combined operation. Hypertrophic changes were found in nearly two-thirds of all the patients operated on, with or without narrowing of the intervertebral space.

Recurrences were observed in 8 per cent of all patients treated and had no relation to the history, physical findings, anomalies or postoperative observations.

The author suggests that spinal fusion be limited to a selected group of cases of protrusion of the intervertebral nucleus pulposus.

GEORGE I. REIN, M.D.

Clinical Study of Muscular Torticollis (Die Klinik des muskulären Schiefbalzes). C. J. GAUDE. *Geburtsh. & Frauenh.* 947: 7, 121.

On the basis of 40 years of study of the clinical aspects of muscular torticollis the author is inclined to reject the theory of a traumatic or traumatic inflammatory origin of this condition. He is more inclined to favor the theory of intrauterine pressure as a causative factor, thus admitting the possibility of indirect heredity in the nature of a familial predisposition to breech presentation.

Roentgenograms taken during pregnancy (lateral flexion of the head with elevation of the posterior shoulder) as well as postnatal demonstration of

threatening caput obstipum (atrophy of the sternocleidomastoid muscle) of beginning caput obstipum (induration of this muscle) and of fully developed caput obstipum (shortening of the muscle with inclination of the head) serve to complete the clinical picture of congenital torticollis.

With the diagnosis of threatening caput obstipum possible at birth, the immediate institution of orthopedic measures may spare many patients later surgical intervention. A valuable prophylactic measure would be the early conversion of a breech presentation during pregnancy, which would likewise serve to reduce infant mortality considerably and would be justifiable for this reason alone.

EARTH SCHWARTZ MOORE.

The Response of the Quadriceps Femoris to Progressive-Resistance Exercises in Poliomyelitic Patients. THOMAS L. DELORME, ROBERT S. SCHWAB, and ARTHUR L. WATKINS. *J Bone Surg* 94B, 30-A: 834.

This study is based on 27 quadriceps femoris muscles. Spring scales and ergograms, work capacity, limb volume, electrical activity, and the ability to perform ordinary activities with less effort and fatigue were used to evaluate the progress of the treatment.

It was found that the remaining innervated muscles following acute anterior poliomyelitis increased in strength and work capacity in much the same manner as normal muscles.

GEORGE I. REIN, M.D.

Policlization of the Index Finger. JAMES B. COTTEBERT. *Bril J Plast. Surg* 94B, 56.

A case of successful substitution of the index finger for an amputated thumb is presented in this article. Only a short first metacarpal stump remained following a gunshot wound of the hand. Operation was carried out in stages, great care being taken to preserve the nerve and blood supply of the new digit. In five stages, a useful new thumb with an excellent cosmetic result was obtained. The principles of policlization of the index finger and the details of each stage are presented.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Discussion on Primary Treatment of Varicose Veins.
A. DICKSON WRIGHT, J. B. KIMMONT, A. M. BORD
PETER MARTIN and Others. *Proc. R. Soc. M. Lond.*
1948 41 631

DICKSON WRIGHT A radical attack now in use by this author for the primary treatment of varicose veins is to ligate as many veins as necessary while the patient is under a general anesthetic. One hundred cubic centimeters of 30 per cent saline solution is used to inject every varix thoroughly and obtain obliteration of the whole network of varices and the deep communicating veins at once. Bandaging the leg with elastoplast reduces the bulk of the clot. Any vein escaping this onslaught is injected at postoperative visits.

The contraindications to treatment are old age, obesity and diabetes. If arterial disease is present, great caution is indicated.

The complications of treatment are important. If a thrombophilia is stirred up anticoagulants must be used.

Allergic response to the solution is treated with adrenalin, ephedrine and benedrine.

The complications of varicose veins, thrombosis, eczema, and pruritus are all cured by obliteration of the varicose vein, except in patients with incompetent deep veins or old femoral thrombosis. These are treated with various types of compressive bandages, bed rest or both.

KIMMONT reports a study of 100 venograms made at operation and on outpatients. Histological studies were also carried out on portions of veins removed at operation from some 20 patients who had had previous vein injections.

1 Retrograde injection at operation. A series of venograms made by injecting from 1.5 to 8 c.c. of a radiopaque solution suggests that this method is inefficient because (a) much of the dye goes straight into the deep veins (b) spasm of the great saphenous vein occurs because of the irritation of the catheter so that little injected fluid stays in the vein (c) little fluid goes below the knee as it tends to pass into the communicating veins or even normal veins. With larger quantities of fluid than 8 c.c. the excess goes straight into the deep veins.

2 Fluoroscopic screening. Dye injected into normal superficial leg veins never passes distally even if there is a tourniquet above the site of the injection. Dye injected into varicose veins with the patient standing sinks rapidly toward the ankle. Dye injected into a varicose vein with the patient lying remains at the site of the injection until the patient moves the limb.

3 Serial venograms of direct injections into leg varicosities show that from 1 to 1.5 c.c. is the optimum amount for a single injection. Larger amounts

tend to spill over into the deep veins. Entry to the deep veins is particularly likely to occur as would be expected in tributaries of the small saphenous vein at the back of the calf.

Serial pictures also revealed that fluid passing into the deep veins remains there longer than one would expect it is not instantly swept away but may often be seen still lying in some concentration a minute or more after injection. It remains for a longer time still in the communicating veins and can often be seen lingering around the valves. As valves are delicate structures this observation is to be considered a significant one.

Histological studies. Small portions of veins were excised from patients who had injections a few days beforehand. Often inadequate clinical takes revealed edema of the walls and clotting. These changes were most marked at the region of the valves, which often were adherent when no clinical take had been obtained.

CONCLUSIONS AS TO TREATMENT

1 For serious cases with incompetent great saphenous valves a high saphenofemoral ligature, probably combined with ligature at the knee level or in the thigh if a communicating vein blow-out is indicated should be made. No retrograde injections are to be made. Local injection of the calf varicosities should be done if necessary at a later date.

2 For mild cases the affected vein should be in limb horizontal. Often inadequate clinical takes revealed edema of the walls and clotting. These changes were most marked at the region of the valves, which often were adherent when no clinical take had been obtained.

3 For mild cases the affected vein should be in limb horizontal. Not more than 1.5 c.c. should be given in each injection. The leg is to be kept still for 5 minutes and then moved vigorously to sweep the fluid away.

BOYD A follow up study of 60 patients treated at St. Bartholomew's Hospital over an 8 year period revealed a steady increase in the recurrence rate year by year. The reason for these unsatisfactory results lies in the etiology of varicose veins. Varicose veins are primarily due to a congenital weakness of the valves. The condition is progressive. No angle operation is likely to cure them.

Pain in varicose veins is caused by varices in the muscular communicating veins of the calf complete dilatation of the internal saphenous vein involvement of the cutaneous nerves in periphlebitis or deep phlebitis of the calf.

Deep phlebitis is not a contraindication to ablation of the superficial varices it is in fact an indication for operative treatment.

Chronic swelling of the leg with no history of phlebitis may at times be due to varicosities of the deep veins.

Treatment. The sheet anchor of treatment is ligation. In addition to proximal ligation distal ligations at the sites of incompetent perforating veins should be undertaken.

It is important to look for an accessory saphenous vein, which at times perforates the fascia distally and joins the femoral vein below the fossa ovalis.

Despite older opinions, no harm can come from leaving a stump of the internal saphenous vein and one will not injure the femoral vein if he ligates at a safe distance.

A short segment of the internal saphenous vein including the perforating vein should be removed in the lower third of the thigh. The communicating vein often found behind the knee between the external and internal saphenous veins should be ligated if present.

Deep phlebitis occasionally follows retrograde injection of sclerosing solutions. A retrograde injection of pylectan into the distal end of the saphenous vein divided in the groin has been shown by roentgenograms to enter the femoral vein via the perforating veins in every case in which it was used.

If the retrograde injection is carried out at the knee level the radiopaque solution could only occasionally be seen in any quantity in the popliteal vein.

These tests show that retrograde injection at the groin is unsafe, and that injections of not more than from 3 to 5 c.c. at knee level are in most cases quite safe.

EDMUND R. DOMOCHOW, M.D.

The Symptoms and Treatment of Arterial Aneurysm of the Upper Extremities (*Das Aneurysma der Arterien der oberen Gliedmaßen, seine Erscheinungen und Behandlung*) KARL BASTENIER. *Chirurgia*, 1935, 9, 204.

The author presents a series of 27 cases of arterial aneurysm of the upper extremities. Because of favorable anatomic conditions, a good collateral circulation often develops, so that in a certain number of cases ligation is possible. Routine ligation is not to be recommended, however, since it may be followed by serious circulatory disturbances and necroses. If the collateral circulation cannot be rated as 100 per cent efficient before or during operation, an attempt must be made to restore the normal passages after removal of the aneurysm. The simple technique of lateral and circular suture can be used in only a few cases. If a large arterial defect remains following removal of the aneurysm, it must be repaired by plastic operation on the veins.

The majority of the sutured arteries appeared permeable in the arteriogram following operation but even with nonpermeable sutures and transplants, the clinical results were satisfactory since the sutures and transplants heal only gradually and only with a properly functioning collateral circulation. At any rate, the excellent clinical results obtained by sutures and transplants, in contradistinction to

ligation, indicate a satisfactory restoration of the normal blood route.

The marked involvement of the nerves in almost all arterial aneurysms of the upper extremities was a striking feature. The nerves were affected chiefly by pressure of the aneurysmal sac, which stressed the indication for the earliest possible operation. However, nerve injuries occur also in cases of pure fistula. The disturbances are particularly marked following the anastomosis of an arteriovenous fistula with a large aneurysmal sac, because in these cases not only pressure injuries but also poor circulation in the periphery plays a part. Removal of the aneurysm and restoration of the normal channel by early operation may prove a requisite for the return of nerve function. Prolonged delay in operating may lead to most severe atrophy and dystrophic disturbances with contracture of the muscles and ankylosis. The best prophylaxis of these serious complications lies in primary suture of the vessels. The diagnosis, nerve involvement, treatment and results of treatment in these 27 cases are tabulated. The cases include aneurysms of the axillary artery and of the brachial artery and its branches. The diagnostic value of arteriography is stressed. This procedure permits demonstration of the exact site of the aneurysm, the venous involvement and frequently also of the state of the collateral circulation. Ligation is justified when arteriography reveals a good collateral circulation when the distal portion of the main artery is obliterated and its function has been assumed by a larger branch, or when the main artery is so narrow that a good collateral circulation must be assumed.

Ligation of the afferent artery without radical operation on the aneurysm cannot be recommended, except in certain special cases of ligation of the hypogastric artery in aneurysms of the gluteal artery. An arteriovenous aneurysm can be cured only by complete separation of the artery and vein. Because of the poor results obtained by ligation of the main artery the author attempted restoration of the natural route in all cases with a good collateral circulation. Lateral suture, although yielding excellent results, is rarely feasible because the arterial defect is usually so large that a resection of the area is necessary. The arterial stumps have then to be united by direct suture. This yielded excellent results in 3 cases. In 10 cases the arterial defect was repaired by venous transplantation. In 6 of these cases the aneurysm was purely arterial with a very large sac. In some cases, in 2 cases there was an arteriovenous aneurysm and in 2 others a pure arteriovenous fistula. No significant circulatory disturbances ensued. In 21 of the 27 cases, the nerves were involved.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE

POSTOPERATIVE TREATMENT

Entity and Significance of Variations in Plasma Proteins in the Normal Postoperative Course (Entità e significato delle variazioni proteinemiche nel decorso postoperatorio normale). ANTONIO LARA LARA, ALDO VITI and FRANCO CRUPPINI. *Polichinico sez. chir.*, 1948, 55 : 75

The causes of hypoproteinemia may be summarized under three headings (1) chronic malnutrition (2) loss of protein from the body and (3) deficient protein formation. Studies of plasma proteins were undertaken in eight groups of surgical disorders to ascertain the presence or extent of these factors in the normal postoperative course. Treatment consisted essentially in the replacement, volume for volume, of fluid lost.

For the quantitative determination of plasma proteins a refractometric method was employed the results of which are likely to run from 7 per cent to 10 per cent higher than those obtained by the Micro-Kjeldahl method.

In 14 cases of thyroid surgery only minor and insignificant changes were observed in the total proteins. In those instances of simple goiter as in Basedow's disease the albumin-globulin ratio declined postoperatively but regained the preoperative level by the seventh day.

In 24 patients who underwent gastroduodenal surgery all showed normal preoperative protein values. The average postoperative values for total protein as well as for albumin-globulin were more markedly reduced than in the first group.

Five of a total of 11 gynecological cases showed inversion of the albumin globulin ratio.

The 10 patients who underwent appendectomy differed from preceding groups in that they showed less variability in postoperative protein values.

Four further groups, including patients with diseases of the biliary tract diseases of the lungs patients who had undergone minor surgical procedures and one patient who had undergone major surgery demonstrated total protein and albumin globulin curves at minor variance only from those of the other groups.

The authors conclude that the variations noted in the albumin-globulin ratio are of humoral origin and that surgical procedures with uneventful recoveries are not characterized by significant shifts in plasma protein concentration.

EDITH B. FARNSWORTH, M.D.

The Significance of Urine Chloride Determination in the Detection and Treatment of Dehydration with Salt Depletion. K. KELLER AND SYLVIE EVERETT LOUIS EVANS. *Ann Surg* 1948, 128 : 391

Primary water depletion is a form of dehydration due to the inadequate intake of fluids while primary

salt depletion is due to the abnormal loss of salt from the body also resulting in dehydration because of the fact that the kidneys will not retain water without salt.

In primary water depletion plasma chloride concentration remains normal the extracellular fluid becomes hypertonic, water passes across the cell membrane into the extracellular space, and there is a diminished output of water by the kidneys. As a result, intracellular dehydration becomes marked but no change may be detected in the plasma volume or in the electrolyte concentration.

In primary salt depletion hypotonicity of the extracellular fluid is averted by excretion of water without salt by the kidneys. The urine of patients with either water depletion or salt depletion shows more significant variations in volume and salt concentration than those found in the plasma. The severity of the depletion can be ascertained by changes in the chloride the carbon dioxide the specific gravity and the hematocrit of the blood.

Water and salt depletion and replacement were studied in 3 healthy volunteer students. From these experiments the authors concluded that salt and water balance was normally maintained when urinary excretion exceeded 1,500 ml and the salt excreted averaged 3 gm. per liter. Urine salt determination by the Fanning method served to indicate the type of intravenous therapy needed. Thus an excess of 3 gm. of salt per liter of urine justified an infusion of water whereas a concentration of salt less than 3 gm. per liter indicated the infusion of a saline-containing fluid. Measurement of the urine volume were indicative of the need of water replenishment. In patients with impaired kidney function the plasma chloride should be measured to determine the degree of salt depletion.

In every case the discussed laboratory guides should be accompanied by clinical examination for edema, skin turgor thirst respiration and mental status.

BENJAMIN G. P. SHAFIROFF, M.D.

Further Experiences with Peritoneal Irrigation for Acute Renal Failure. HOWARD A. FRANK, ARTHUR M. SELIGMAN and JACOB PINE. *Ann Surg* 1948 128 : 561

This report is based on a study of 18 cases of acute renal insufficiency treated by peritoneal irrigation. Since the earlier work on hemodialysis, improvements have been made in the apparatus and in the irrigating fluid. The amount of sodium chloride was reduced to prevent hyperchloremia calcium ions were doubled because of the hypocalcemia due to uremia, phosphates were omitted from the solution because of the hyperphosphatemia, and gelatin was added to obviate the absorption of water. Heparin and penicillin were no longer added to the irrigating solution. The sump drain is placed under the costal

margin and through a subcutaneous tunnel which is directed into the peritoneal cavity at the lower end of the abdomen. Three lines feed the mechanism one to the fluid carboy another to the suction line and a third to the air inlet. The drainage fluid is frequently examined for bacteria and lymphocytes. Irrigation is stopped after 72 hours to avoid peritonitis. Because of anorexia, vomiting and ileus, the gastrointestinal tract is intubated. Parenteral fluids are limited to about 1 liter daily in order to prevent overhydration. By means of peritoneal irrigation, from 25 to 50 gm. of urea can be extracted from the blood in 24 hours.

Peritonitis remains as the most serious complication of irrigation with the colon bacillus as the causative organism. Streptomycin was given only after the peritonitis was diagnosed but penicillin and sulfaalidine are used for prophylaxis.

In the present series 14 of the 18 patients died, 5 because of irreversible kidney lesions. Three patients died because of the peritonitis which developed as a result of irrigation. The etiology of the renal insufficiency in the 4 patients who recovered was sulfathiazole poisoning, shock incompatible blood, and eclampsia. Renal recovery consisted in the return of glomerular function followed by the slower return of tubular function. Urine volume excretion becomes markedly increased. Its specific gravity ranged from 1.003 to 1.010 the urine was usually alkaline and had a urea concentration not greater than twice the urea of plasma. The large loss of chlorides during the phase of diuresis may cause severe dehydration and is indicative of inadequate renal function. With improvement of tubular function the specific gravity of the urine rises acidity increases and acidosis and hyperphosphatemia subside. Complete recovery to normal kidney function is not attained. Peritoneal irrigation is not suitable for routine clinical use.

BENJAMIN G. P. SHATTROFF M.D.

The Treatment of Renal Insufficiency in the Surgical Patient. FREDERICK A. COLLIER, KENNETH N. CAMPBELL, and VIVIAN IOR. *A. n. Surg.* 943, 28, 379.

Acute renal insufficiency can be divided into four clinical phases the period of hypotension, the period of oliguria or anuria, the phase of diuresis and the final or recovery phase. The treatment in the first period consists of the use of blood transfusions, oxygen, and intravenous fluids. This is a preventive period. When the diagnosis of anuria is made, the blood type should be carefully checked and extrarenal causes for renal obstruction should be eliminated. During the second phase the total fluid intake should be restricted to the insensible loss due to perspiration and respiration. The amount of fluid intake should be limited to about 1 liter given either orally or intravenously. The nonprotein nitrogen and the carbon dioxide combining power of the blood are determined at frequent intervals. When the latter falls to 40 per cent or lower correction is made

by means of the oral administration of sodium bicarbonate or the intravenous administration of sodium lactate. Calcium gluconate is administered intravenously each day to prevent tetany. If tolerated, the patient is allowed food by mouth with limitation of salt to from 200 to 800 mgs. daily. If edema is present the salt and fluid intake is rigidly limited.

During the phase of recovery diuresis with the loss of abnormal amounts of water and salt may cause severe dehydration and hypopotassemia. Urine examinations should be made frequently for the estimation of potassium, sodium, and chloride. The large urine output is replaced by intravenous administration of equivalent amounts of Ringer's solution and oral administration of fluids, or both. After the return to a normal urine output, renal function tests are made to determine the degree of tubular recovery or regeneration.

As a result of this disease process nitrogenous excretion usually does not return to the normal level. Autopsy examination of 4 patients who died of acute renal insufficiency showed lower nephron nephrosis with various stages of regeneration of the tubular epithelium.

BENJAMIN G. P. SHATTROFF M.D.

Intraosseous Infusions in Infants. E. CLETON TAYLOR and D. H. KAUFMANN. *J. Mich. M. Soc.* 1913, 47: 602.

A report of 383 intraosseous infusions given to 125 infants is presented, and in only one case was the attempt unsuccessful. The only complications were a subcutaneous abscess in 1 case and a local osteomyelitis in 2 cases, which were controlled by chemotherapy. The infusions consisted of blood and/or electrolyte solutions. Most of the infusions were given into the tibia by positive pressure with a closed system. Twenty five infants expired but in none of the cases was death attributable to the intraosseous infusion. This method is quite useful when continuous infusion is indicated as in cases of diarrhea or major surgery. The authors feel that the risk of osteomyelitis has been overemphasized, and roentgenographic studies indicate no significant changes in the bone.

ROBERT MARY TERRY M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

The Treatment of Lymphedema. RAINFORD MOWLEM. *Brit. J. Med. Surg.* 943, 148.

Lymphedema may be caused by injury such as circumferential avulsion of the skin and subcutaneous tissue, or it may be observed as an idiopathic lesion in which the obstruction is in the proximal nodes. The author defines three phases of the clinical and pathological course of the condition and correlates the treatment according to the phase present.

Pha	tested by s	}	a most
depen	the limb.		

present, and the swelling subsides with elevation and rest. This condition may be held in abeyance by a pedicle flap of skin and full thickness subcutaneous tissue from an area of intact lymphatic drainage which bridges the obstruction.

Phase 2 is characterized by marked pitting edema and trophic changes in the skin. Spontaneous weeping from the skin may occur. Progressive fibrosis of the dilated lymphatics and surrounding tissue is manifest in the pathologic section. A pedicle bridging the obstruction may halt further progress but will not correct the damage already present.

Phase 3 shows irreversible changes in the skin and subcutaneous tissue, which have become sclerosed. There is no response to elevation and rest, and a pedicle flap will not alter the appearance of the limb. The author recommends excision of the and subcutaneous tissue down to the deep fascia, and replacement with skin grafts upon the intact deep fascia.

Eighteen patients have been treated by the methods described. The article contains several photographs of patients before and after treatment. A short review of other methods of treatment is included.

JOHN L. BILL, M.D.

The Intra Arterial Administration of Penicillin in the Treatment of Infections (Penicillina intrarterial no tratamento das infecções) DOWATO D. ANGELO. *Rev. brasil. cir.*, 1948, 17: 431

The technique used by D Angelo is that of sub-diastolic pressure adopted by Shaffer in 1947. The of an infected area at the site of injection. In this technique 1 gm. of papaverine hydrochloride is given subcutaneously 30 minutes before the injection of penicillin to help vasodilatation, and the extremity is washed with a tepid solution of potassium permanganate (1:9,000), which acts as a fungicide and deodorant (gangrene) and also as an adjuvant vasodilator because of its temperature. An arterial pressure cuff is applied directly above the lesion, and a 30 c.c. syringe with a short beveled needle is used. The site of injection is in the fold of the elbow for the upper extremity and in the inguocrural region for the lower extremity; the technique for infiltration of the lumbar sympathetic on the left side may be used for the descending aorta with compression of the two femoral arteries to restrict diffusion of the solution if the carotids are used they may or may not be compressed after the injection.

Under local asepsis the surgeon immobilizes the artery between the index and third finger of his left hand. Introduces the needle vertically into the vessel, and injects the penicillin solution at the rate of 1 c.c. per second. As soon as the injection starts the assistant inflates the cuff raising the mercury column to 80 mm. where he keeps it for 10 or 15 minutes. If for any reason it is necessary to repeat the puncture which is difficult because the artery is contracted it is best to wait a few minutes before another attempt is made. Injections may be made twice a day at the

same site and also on the following days without any inconvenience. The injection must be given after incision and drainage if these are called for since the pain caused by venous stasis is then less severe.

Empirically injections of 50,000 units of penicillin in 5 or 10 c.c. of isotonic serum were used in 15 cases of localized infection of the extremities with good results. In 1 case of osteomyelitis of the left frontal bone, penicillin was injected alternately in the two carotids without any disagreeable sensation for the patient. The first dose consisted of 250,000 units in 10 c.c. of physiologic serum the subsequent doses were of 100,000 units.

In the treatment of localized infection of the hand it was noted that the results were the same whether the penicillin was started immediately after incision and drainage, or 48 or 72 hours later the purulent secretion stopped completely in 24 hours and one additional injection was sufficient to obtain healing.

RICHARD KEMEL, M.D.

The Treatment of Malignant Lip Furuncles with Emetine. EDUARD MELCHIOR. *Surgery* 1948, 74: 724.

Emetine is usually considered strictly an anti amebic drug. However the good results obtained in the treatment of nonamebic liver abscesses with this drug led the author to extensive trial of emetine in other bacterial infections such as peritonitis, biliary infections, and septicemia with good results. He believes that the therapeutic capability of emetine demonstrated in these infections is an antitoxic effect rather than a bactericidal one.

Furuncles which are characterized by acute swelling and pain progressive purulent infiltration of the surrounding tissues formation of multiple millary abscesses in this spreading periphery and the development of signs of systemic involvement are referred to as "malignant furuncles" — more commonly called carbuncles. Emetine was used in a series of 8 malignant furuncles of the lip with significant clinical improvement in all cases. In the first 3 cases the furuncles were treated simultaneously with emetine and incision and these patients showed the most dramatic response to treatment as evidenced by their temperature curves. In Case 1 for example the temperature on admission was 39 degrees. In the temperature rose to 39.5 degrees, a level which persisted the following morning until emetine was started. Immediately there was a drop in temperature, a normal level being reached 3 days later.

Similar results were obtained with treatment by emetine alone. Three of these 5 patients had low or normal temperatures to start with but the immediate increase in well-being of the patient decreased in swelling and relief of pain were indices of the effectiveness of the treatment.

In Case 4 for example the patient suffered from pain, low grade fever and insomnia from a lip furuncle of 5 days duration. Emetine was started and that night the patient slept well for the first

margin and through a subcutaneous tunnel which is directed into the peritoneal cavity at the lower end of the abdomen. Three lines feed the mechanism, one to the fluid carboy, another to the suction line, and a third to the air inlet. The drainage fluid is frequently examined for bacteria and lymphocytes. Irrigation is stopped after 72 hours to avoid peritonitis. Because of anorexia, vomiting, and ileus, the gastrointestinal tract is intubated. Parenteral fluids are limited to about 1 liter daily in order to prevent overhydration. By means of peritoneal irrigation, from 15 to 50 gm. of urea can be extracted from the blood in 24 hours.

Peritonitis remains as the most serious complication of irrigation with the colon bacillus as the causative organism. Streptomycin was given only after the peritonitis was diagnosed but penicillin and sulfathiazole are used for prophylaxis.

In the present series 14 of the 18 patients died, 5 because of irreversible kidney lesions. Three patients died because of the peritonitis which developed as a result of irrigation. The etiology of the renal insufficiency in the 4 patients who recovered was sulfathiazole poisoning, shock, incompatible blood and eclampsia. Renal recovery consisted in the return of glomerular function followed by the slower return of tubular function. Urine volume excretion becomes markedly increased. Its specific gravity ranged from 1.003 to 1.01; the urine was usually alkaline and had a urea concentration not greater than twice the urea of plasma. The large loss of chlorides during the phase of diuresis may cause severe dehydration and is indicative of inadequate renal function. With improvement of tubular function the specific gravity of the urine rises, acidity increases, and acidosis and hyperphosphatemia subside. Complete recovery to normal kidney function is not attained. Peritoneal irrigation is not suitable for routine clinical use.

BENJAMIN G. P. SHAFROFF, M.D.

The Treatment of Renal Insufficiency in the Surgical Patient. F. EDENCK, A. COLLIER, KENNETH N. CAMPBELL, and VIVIAN TOR. *A. & S. Surg.* 1945, 8: 379.

Acute renal insufficiency can be divided into four clinical phases: the period of hypotension, the period of oliguria or anuria, the phase of diuresis, and the final or recovery phase. The treatment in the first period consists of the use of blood transfusions, oxygen, and intravenous fluids. This is a preventive period. When the diagnosis of anuria is made the blood type should be carefully checked and extra renal causes for renal obstruction should be eliminated. During the second phase the total fluid intake should be restricted to the insensible loss due to perspiration and respiration. The amount of fluid intake should be limited to about 1 liter given either orally or intravenously. The nonprotein nitrogen and the carbon dioxide combining power of the blood are determined at frequent intervals. When the latter falls to 40 per cent or lower, correction is made

by means of the oral administration of sodium bicarbonate or the intravenous administration of sodium lactate. Calcium gluconate is administered intravenously each day to prevent tetany. If tolerated the patient is allowed food by mouth with limitation of salt to from 200 to 800 mgm. daily. If edema is present the salt and fluid intake is rigidly limited.

During the phase of recovery diuresis with the loss of abnormal amounts of water and salt may cause severe dehydration and hypopotassemia. Urine examinations should be made frequently for the estimation of potassium, sodium, and chloride. The large urine output is replaced by intravenous administration of equivalent amounts of Ringer's solution and oral administration of fluids, or both. After the return to a normal urine output, renal function tests are made to determine the degree of tubular recovery or regeneration.

As a result of this disease process nitrogenous excretion usually does not return to the normal level. Autopsy examination of 4 patients who died of acute renal insufficiency showed lower nephron nephrosis with various stages of regeneration of the tubular epithelium.

BENJAMIN G. P. SHAFROFF, M.D.

Intravenous Infusions in Infants. E. CLYTON TITUS and D. H. KAUFER. *J. Michigan M. Soc.* 1945, 47: 1002.

A report of 383 intravenous infusions given to 125 infants is presented, and in only one case was the attempt unsuccessful. The only complications were a subcutaneous abscess in 1 case and a local osteomyelitis in 3 cases which were controlled by chemotherapy. The infusions consisted of blood and/or electrolyte solutions. Most of the infusions were given into the tibia by positive pressure with a closed system. Twenty-five infants expired but in none of the cases was death attributable to the intravenous infusion. This method is quite useful when continuous infusion is indicated, as in cases of diarrhea or major surgery. The authors feel that the risk of osteomyelitis has been overestimated and roentgenographic studies indicate no significant changes in the bone.

ROBERT MAYO TENERY, M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

The Treatment of Lymphedema. RADKINOS MOWLEM. *Brit. J. Plast. Surg.* 1945, 1: 43.

Lymphedema may be caused by injury such as circumferential avulsion of the skin and subcutaneous tissue, or it may be observed as an idiopathic lesion in which the obstruction is in the proximal nodes. The author defines three phases of the clinical and pathological course of the condition and correlates the treatment according to the phase present.

Phase 1 is manifested by swelling of the most dependent part of the limb. No pitting edema is

Respiratory obstruction was another contraindication and relative contraindications were anemia and disease of the lower bowel and of the liver and kidney.

One hour preoperatively atropine sulfate was administered by hypodermic injection. The dosage of pentothal employed was 0.2 c.c. of a 10 per cent solution per pound of body weight. The depth of basal anesthesia was assessed by gentle supraorbital pressure or pressure on the ear cartilage. Narcosis was never deep enough to prevent a response to this stimulus. Induction was carried out with whatever agent or technique the anesthetist deemed advisable: open drop ethyl ether, open drop divinyl ether followed by ethyl ether, nitrous oxide, ethyl ether and oxygen, nitrous oxide and oxygen or pentothal.

Operations performed included all surgical specialties other than thoracic surgery. Tonsillectomy was performed in 103 patients. In 238 of the 300 patients the basal state was classified as good with the patient asleep and there was no response to stimuli other than pain. 56 cases were classified as fair and 6 as failures. The optimum time for administering rectal pentothal was found to be 30 minutes before operating time. Rectal irritations and signs of toxicity or intolerance to the drug were absent. The postoperative course was uneventful. The children became conscious in from 30 minutes to 2 hours without delirium. The incidence of vomiting was 25.76 per cent as compared with 60 per cent in a group of 150 patients who received morphine and atropine as premedication and 38.53 per cent in 150 patients who received atropine only as premedication. It was found that less ether was required to maintain satisfactory levels of anesthesia when basal narcosis with pentothal was used.

MARY KARP, M.D.

The Use of Myanescin in Anesthesia (L'impiego della mianescina in anestesia) FRANCESCO BAUM *Poli clinica sez. prat.*, 1948, 55, 901

In the attempt to find a substitute for curare, Berger and Bradley of England studied the glycerites of ether and it was found that several of these substances provoked relaxation of the skeletal muscles in animals. Of these, myanescin (3-ortho-toloxyl 1,2 propanediol) proved particularly active therapeutically and was found to possess a wide margin of safety. The substance is stable, may be sterilized by heating and may be mixed with a solution of sodium chloride, glucose and with derivatives of barbituric acid. The author has used myanescin exclusively by the intravenous route, either associated with pentothal or with local anesthesia. It has also been employed together with pentothal in the induction of ether anesthesia, and has been given in association with pentothal anesthesia to relax the laryngeal spasm complicating the use of pentothal as an anesthetic agent. The recommendations of Mallison regarding the manner of employing this agent have been followed, however, the large doses (50 c.c.) as proposed by that author were not given.

There seems to be a synergistic relationship between pentothal and myanescin so that less pento-

thol may be used or the anesthetic period can be lengthened out considerably with the same amount of pentothal. With myanescin there is no such discomfort as accompanies the use of curare and none of the paralytic accidents. The only drawback in the use of the former has been a cerebral form of vomiting which lasted a couple of days following the operation. This vomiting has been particularly bothersome when the patient was operated upon while conscious (local anesthesia and myanescin).

Myanescin does not affect the indications for curare; the latter will still be used in operations on the chest in which an absolute arrest of the motions of breathing is desired, and myanescin will find its field of usefulness in abdominal surgery where its peculiar efficacy in relaxing the abdominal musculature is valuable.

JOHN W. BRENNAN, M.D.

The Action of Curare in Anesthesia (A ação do curare em anestesia) VIRGÍLIA DE ABREU *Gaz. Méd. Portuguesa*, 1948, 1, 399.

The author states that clinically 1 mgm. of Burroughs Wellcome's tubarine produces the same effect as 6.6 mgm. of Squibb's intocostin. Curare is a safe drug to use in combination with certain anesthetic agents and its association with cyclopropane is regarded as giving an ideal anesthesia. With ether the dose of curare must be reduced one third because ether itself has a curariform action. The advantages of curare in anesthesia are that it provides optimal muscular relaxation and thereby facilitates abdominal surgery; avoids laryngeal spasm; allows the giving of small amounts of anesthetic to maintain the anesthesia on a superficial plane and permits control of respiration in thoracic surgery. The patient wakes up a few minutes after the operation and vomiting with its pulmonary complications are thus avoided or reduced to a minimum.

In thoracic surgery Cecil Gray administers part of the curare before induction of anesthesia; this serves not only to verify the effect of the drug on the patient but also to facilitate endotracheal intubation since laryngeal spasm is eliminated. This technique gives excellent results with any type of endoscopy. Thus, when intending to use 15 mgm. of tubarine in adults, 5 mgm. are administered and 3 minutes are allowed for observation of the reaction of the subject. If it is normal the remaining 10 mgm. are injected and the barbiturate is then given. The pulse, heart, and respiration must be constantly watched. Oxygenation in bronchoscopy is easy since the oxygen can be connected with the instrument. Patients wake up at the end of 10 minutes. To shorten the action of curare, 5 mgm. of prostigmine with 0.5 mgm. of atropine are given intravenously.

In prolonged operations, as on the lungs, the best anesthesia consists of nitrous oxide, pentothal, and curare in sufficient dosage to cause apnea. The endotracheal tube and a closed circuit must be used to control respiration. No more than 1.5 gm. of pentothal and 30 mgm. of curare should be used, and 0.1 gm. of pentothal and from 2 to 4 mgm. of

time since the onset. Within 24 hours the pain was entirely gone, and the swelling subsided rapidly during the next few days. A few weeks later a small abscess developed in the cheek. The abscess was opened and in 3 days had completely healed.

One remarkable feature of the emetine therapy was the marked increase of comfort and well-being in at least 4 of the patients, even before objective clinical signs showed a response to treatment.

The dosage of emetine hydrochloride used was 0.03 to 0.05 gm. twice daily with a total of 0.4 to 1.0 gm. necessary to obtain full effect from the treatment. This treatment, with or without incision, resulted in cures in all 8 cases of malignant lip tumors reported, even when septicemia was present as indicated by positive blood cultures.

STANLEY W. TUTTLE, M.D.

Auromycin. LOUIS T. WRIGHT, MURRAY SANDERS, MYRA A. LOGAN, ALBERT PRIOT and LYNDON M. HILL. *J. Am. M. Ass.* 948, 38 408.

Realizing the need for specific therapy in lymphogranuloma venereum, the authors treated 25 patients with auromycin, a new antibiotic active against many rickettsiae and certain viruses, and not previously used in human beings. Cases were divided into 3 groups: (1) buboes, (2) proctitis and (3) benign rectal strictures.

All patients gave a detailed history and complete physical examinations and extensive laboratory studies were made. The drug was given intramuscularly in daily doses varying from 10 to 40 mgm.

Eight patients with buboes were treated and showed a decided reduction in the size of the nodes at the end of 4 days of treatment. In 3 cases, smears from aspiration of the bubo revealed inclusion and elementary bodies which had all disappeared within 1 week after treatment.

Three patients with proctitis were treated and all improved with cessation of rectal discharge, bleeding, and tenderness. After treatment, proctoscopic examination showed normal rectal mucosa.

Fourteen patients with benign rectal stricture were treated. All showed clinical improvement, with decrease in rectal bleeding, discharge, and pain, and an increase in stool diameter. However, no gross pathologic change in the fibrous rectal stricture was apparent.

Auromycin suspended in isotonic saline solution occasionally produced a mild easily rectified hypochromic anemia. No other toxic effects were noted. Since very small amounts of auromycin were used in treatment, the amount of circulating antibiotic in the blood was not accurately demonstrable by present methods of assay. S. LEON TETELMAN, M.D.

ANESTHESIA

Balanced Anesthetics for Thoracoplasty. CLARENCE L. HERBERT. *Anesthesiology* 948, 9, 537.

The requirements of anesthesia for thoracoplasty include a nontoxic agent giving adequate oxygen,

smooth rapid induction, regular and quiet respiration, a short recovery period, minimal postoperative complications, and nonexplosibility. A form of balanced anesthesia was utilized for the past 3 years at the United States Marine Hospital, Staten Island, New York for 75 patients receiving 147 posterolateral thoracoplasties. The technique is described in detail. Preliminary medication consisted of pentobarbital 0.1 gm. by mouth 1 hour before operation, morphine, 10 to 15 mgm., and scopolamine 0.43 mgm. subcutaneously about 30 minutes before regional block was begun. The technique of paravertebral spinal nerve block is essentially that described by Lundy with the patient placed face down on the operating table and the chest raised on a small pillow. From 8 to 10 cc. of 1 per cent metycaine solution is carefully injected into each of the paravertebral needles then intravenous pentothal sodium is infused, and a 50 per cent nitrous oxide oxygen analgesia is given and maintained throughout surgery.

Results of the study indicate that the balanced anesthesia described provides a safe and satisfactory method to meet the special requirements of patients undergoing thoracoplasty. This type of anesthesia is nonexplosive and is therefore suitable for use with an electrosurgical unit. Paravertebral nerve block is a safe procedure in the hands of those trained in regional anesthesia. The incidence of postanesthetic complications appears to be no greater with this type of anesthesia than with other agents and methods. MARY KARP, M.D.

Basal Anesthesia in Children, with the Use of Sodium Pentothal by Rectum. R. W. BURNAP, E. A. GARD and E. H. WATTS. *Anesthesiology* 1948, 9, 534.

For the past 3½ years, anesthesia produced in children with sodium pentothal has been used routinely in the University of Alberta Hospital, at Edmonton (Canada). This technique was used in 300 cases. Its advantages were the avoidance of psychic trauma, especially in cases in which multiple surgical procedures were required, the smooth and rapid gas ether inductions, the rare occurrence of laryngeal spasm, hypoxia, shock, emergence delirium and vomiting, and the absence of disturbance of respiratory rhythm. The main disadvantage was the time required for the anesthetist to go to the ward and give rectal intubation, for it was considered necessary that the patients be watched from the time of administration of the pentothal until they regained consciousness, which increased the nursing care.

Pentothal given by rectum was considered indicated for surgical procedures in children weighing under 75 pounds, and in those over this weight who were unsuitable for venipuncture. By supplementing the basal state with nitrous oxide and oxygen, sufficient analgesia was obtained to reduce simple fractures and to suture lacerations.

The technique was contraindicated in patients who did not have control of the rectal sphincters.

curare are given from time to time. Twenty milligrams of tubarine are enough to obtain paralysis of the diaphragm, the action lasting 40 minutes or more. Naturally reactions vary greatly from individual to individual, as they depend on the condition of the subject and on the length of the operation. There are even patients who respond with excellent muscular relaxation to 5 mgm. of curare.

Curare and cyclopropane have been used in numerous cases of cesarean section with satisfactory results since curare does not depress the child and allows a decrease in the amount of anesthetic used.

As the barbiturates are precipitated with curare, the two drugs should never be administered through the same needle unless some saline solution is passed through it.

The use of curare is contraindicated in myasthenia gravis.

RICHARD KEMEL, M.D.

Effect of Procaine on Liver Function. An Experimental and Clinical Study J. J. JACOBY, J. M. COOK, M. P. WOOLP, P. R. SALZMAN, and H. M. LIVINGSTONE. *Anesthesiology* 948, 9-18

Because of the increasing popularity of the intravenous administration of procaine and because the liver seems to be the principal site of detoxification of this drug, these experiments were planned to test the acute and subacute effects of massive doses of procaine on the liver. Rats and dogs were subjected to repeated large but sublethal doses of procaine hydrochloride. Histologic examination of the liver, spleen, heart and kidney of the rats, and liver function tests in all animals revealed no evidence of damage.

Liver function tests following the intravenous administration of procaine to human beings for the control of postoperative pain showed no evidence of liver damage. It appears that the administration of moderate doses of intravenous procaine ordinarily employed for the control of postoperative pain is not harmful so far as the effect upon the normal liver is concerned. A previously damaged liver, however, may respond in a different manner and investigations dealing with this problem are under way.

MARY FRANCES FOX, M.D.

SURGICAL INSTRUMENTS AND APPARATUS

Modern Architectural Conception of Operating Room Suites (Conception moderne des groupes opératoires) F. MASSOUMI. *Rev. chir. Par.* 948, 67-76.

The author begins his article by saying that the architecture of operating suites is being fully revised. The main revision which must be undertaken in all climates is the creation of an atmosphere approaching absolute asepsis. Surgery under the shield of antibiotics is a fortunate, but palliative, conquest. It is better to operate without organisms than with neutralized organisms. Unfortunately for the great majority of surgeons, sterilization of the air in the operating room is

still a problem of secondary importance. For the past 10 years the author has operated in a sterilized atmosphere and he states that major surgery performed in an aseptic operating room has become almost minor surgery as far as infection is concerned. To obtain such asepsis of the air everything must be considered: the disposition of the rooms, their shape, their size, their equipment, and the ventilating system.

The modern operating room must be of restricted dimensions. The ideal dimensions are approximately 6 by 4.5 meters and 2.50 meters high, giving a displacement of 60 cubic meters. Demirean has reduced the dimensions to 40 cubic meters. In order that students and visitors may observe a gallery is built above the operating room, with a transparent air tight partition.

The operating room must not open directly on the halls but must be separated from them by an adjoining room, which is used for anesthesia. Moreover the operating room must not serve as a hall to the sterilization room.

The shape of the operating room is not immaterial. While hard to ventilate the elliptical room is to be preferred to the rectangular or circular rooms. The floor of the room must be sloped for drainage and be of a tilelike material and the heat radiation must be outside the room (Fig. 1).

The lighting must be athermanous, and the author recommends that the lighting equipment include a rheostat.

The ventilation has been the subject of extensive studies. The contamination of operating room air comes from two sources: (1) the agitation of the air when the patient is wheeled into the room or when the operating team moves in, and (2) the emission of bacteria from the throat and nose of the occupants. The latter source is the most active and the most difficult to neutralize. The mask interferes with the propulsion of large particles into the operative field, but does not in any way interfere with their diffusion in the atmosphere. To obviate this, the author has devised a ventilating system designed to catch such bacteria at their source and direct them upwards or downwards through air shafts to the filters of the sterilizing machine. For this purpose, in the ceiling are built openings with valves to aspirate the contaminated air while at the periphery of the room are the openings for the entrance of sterilized and conditioned air. The efficiency of this new ventilation is undisputable. The author placed Petri dishes in several places in the operating room and found that the contamination of the air was reduced to 2 and 4 colonies.

The operating rooms should be grouped two by two and should be preceded by rooms for anesthesia.

The sterilizing room should be behind the operating rooms and should communicate with the latter through apertures opening only from the operating room side.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

The Roentgen Ray Examination of the Paranasal Sinuses with Particular Reference to the Frontal Sinuses. SÖDER WILHELM. *Brit. J. Radiol.* 1943, 16, 45

Because of the difficulty of clinical examination of the frontal sinuses, the author emphasizes the need for a roentgen technique which will overcome in turn some of the difficulties encountered in the interpretation of roentgenograms of these structures. He presents diagrams and roentgenographic reproductions to show the positions used in sinus radiography at the Caroline Hospital of Stockholm. Most of these are made with a horizontal beam and conform to popular techniques employed in this country but two unusual positions for the frontal sinuses are described in detail.

One of these is a modified submentovertical view which he calls the "overshot axial projection." It is made with a vertical beam, with the head so hyperextended that the region of the frontal bone just posterior to the hairline is in contact with the film-holder thus placing the radiographic baseline at an angle of 40 degrees to the film. This projects the anterior and posterior walls of the frontal sinuses through the maxilla posterior to the symphysis of the mandible. The view is stated as being particularly valuable in comparing the relative thicknesses of the walls of the sinuses on each side. One set of roentgenograms is reproduced, and indicates in the standard projections that one frontal sinus is either bented or its lumen is completely occluded. The overshoot axial view however clearly reveals the appearance to be due to a marked right-left variation in thickness of the walls of the sinuses.

The other unusual projection is essentially a lateral decubitus view with the head in the Caldwell position, the image being projected by a horizontal beam. Convincing illustrations are included, which show how this position, if done with both right and left sides down, will reveal the presence of fluid levels which would otherwise scarcely be suspected. The author describes and illustrates an ingenious little film marker which he states will unfailingly show which side is lowermost in this position. He explains that small amounts of fluid are best visualized in the lateral extent of the frontal sinus in this "decubitus" position whereas if the volume of fluid is large in proportion to the contained air the fluid is best seen collected against the medial septum of the sinuses. The latter view is used only to clarify doubts after routine examination. P. OL W. EYLER, M.D.

Pneumoencephalography in Carotid Arteriosclerosis. L. UEMAN. *Am. J. Roent.* 1943, 60: 393

Cerebellar atrophy is usually observed in males of middle age. The most common clinical findings are a

staggering gait with a broad base, and tremor of the head and extremities.

A pneumoencephalogram usually shows slight enlargement of the ventricles of the brain without displacement, the cortical subarachnoid pathways appear to be slightly enlarged, and the basal cisternae are enlarged. Characteristically there is marked enlargement of the cisterna cerebello-medullaris (cisterna magna) an excess collection of air under the tentorium and widening of the cerebellar sulci.

VAN W. RITTER, M.D.

Miliary Calcification of the Lungs: Ecologic Aspects. HOWARD P. DOWN. *Radiology* 1943, 5: 430

Early writers believed that miliary calcifications of the lungs represented a healed stage of miliary tuberculosis. The author reviews the literature which contributes to this belief. He also reviews the more recent literature indicating that in patients with tuberculin negative miliary calcification, frequently the cause of calcification is either histoplasmosis or coccidioidomycosis and both of these conditions tend to exist in endemic areas in the United States. More recently it has been found that *Aspergillus* and *Monilia* may cause pulmonary disease characterized by miliary bilaterally spread lesions.

The author presents the case of a family consisting of a mother and 4 children with chronic respiratory disease which was characterized by miliary lesions. Cultures from bronchoscopy secretions showed *Monilia* in 2 cases, and the others had *Aspergillus* by culture. These cases were followed for 10 years and roentgenograms were made at yearly intervals. All patients recovered completely with smooth, densely calcified miliary lesions of the lungs.

The author suggests that miliary tuberculosis of the lungs may have a similar end result in some instances. Two cases supporting this view are also presented. JAMES C. MACMILLAN, M.D.

Idiopathic Pulmonary Fibrosis: Roentgenologic Findings. LAURENCE L. ROSENBERG. *Radiology* 1943, 5: 459.

Idiopathic pulmonary fibrosis is found in the small group of cases in which no one factor can be found to cause the generalized fibrosis of clinical significance. This, then, excludes inflammatory processes such as tuberculosis, syphilis, and bronchiectasis, also radiation asthma, pneumoconiosis, and the rarer processes associated with Raynaud's disease, scleroderma, and periarteritis nodosa.

The author presents 16 photographs of roentgenograms of the chest, and on the basis of the fluoroscopy followed by a posteroanterior roentgenogram, with lateral and both obliques when indicated, gives a very definitive discussion of the roentgenological appearance of pulmonary fibrosis. The statement is made that idiopathic pulmonary fibrosis is, as a

rule, a diffuse process. In its early stages, it may not be distinguishable from numerous other processes. In its later stages, the most common roentgen appearance is that of a generalized process with more or less systematically arranged areas of fibrosis interspersed with areas of emphysema. Accurate diagnosis requires correlation of clinical pathologic, and roentgenologic findings.

JANE C. MACMILLAN M.D.

Acute Obstruction of the Small Intestine IRA H. LOCKWOOD, ARTHUR B. SMITH, and JOHN W. WALKER. *Radiology* 1948 51: 310.

The authors correlate the roentgenologic findings and the clinical picture in acute obstruction of the small intestine, and outline a course of successful management. They were induced to do this by the fact that an analysis of 100 consecutive cases revealed that death occurred in no less than 15 in instances, whereas with the exception of one patient all should have been saved.

The management is divided into 5 phases (1) speedy and accurate diagnosis (2) decompression (3) restoration of physiological equilibrium (4) surgery (5) postoperative management.

1. If intestinal colic (with borborygmi at the acme of pain) and vomiting are present, and when the abdomen is distended it is imperative that a plain film of the abdomen be obtained immediately. A roentgenogram can give not only the site and degree of the obstruction but often furnishes information regarding the type. In mechanical obstruction a loop (or loops) of gut is distended with gas, the degree of distention depending upon the site of the lesion and the duration and degree of obstruction. In ileus the gas lies in multiple pockets; it stops where it may. In the former the green light is given for immediate surgery; in the latter a decompression is recommended.

In conjunction with the mechanical obstruction, the authors stress certain roentgenologic signs which are pathognomonic of gangrene or embarrassment of blood supply of the bowel. One of these signs is the visualization of a smooth-walled tube distended with gas. The picture corresponds to a single loop of bowel distended with gas but which in view of loss of tone and edema has become completely void of its physiological pattern. Another sign has to do with the geometrical pattern of the gut. Single or multiple C-shaped loops of small bowel arising from a common source or pedicle always indicate a volvulus. This pattern is accompanied by a loss of the valvulae conniventes, the extent of which is proportionate to the degree of embarrassment of the blood supply.

The authors consider roentgenography of the abdomen as an absolute emergency day or night. When the examination reveals obstruction of the small bowel, the patient is operated upon immediately. This avoids the phase of distention.

2. When however distention has progressed to the stage at which surgery seems unwise decom-

pression is undertaken. The type of decompression is an age-old controversy. The authors themselves believe that only the Miller Abbott tube should be used and this only as an adjunct to eventual operation. The procedure was resorted to 39 times in the 100 cases of intestinal obstruction with a single failure.

The technique of passing the tube which must be handled by the department of radiology is described in considerable detail. A warning is sounded against overexposure to roentgen rays in inexperienced hands.

3. The restoration of the electrolyte balance of the patient is important. Not only the chloride levels, but also those of the nonprotein nitrogen and particularly in the aged, of the serum proteins must be known. The repeated use of whole blood and plasma preoperatively and postoperatively is necessary to re-establish the electrolyte and protein balance.

4. The technical aspects of the surgical intervention are beyond the scope of the present article. A statistical compilation of the cause of obstruction revealed that postoperative adhesions were to blame by far the most commonly. All patients who died with the exception of one had histories of over 72 hours duration. Gangrene of the bowel and resection contributed greatly to the seriousness of the case.

5. The postoperative management closely follows that used generally. The average hospital stay was 18.5 days, including the period of preoperative intubation.

The article is well illustrated with typical roentgenograms.

T. LUCUTIA, M.D.

On the Roentgen Aspect of Prostatic Cancer on Urethrocytography NILS P. G. EDLUND. *Acta radiol., Stockh.* 1948 29: 461.

The author reports the findings in urethrocytography in 68 proved cases of carcinoma of the prostate studied at the Caroline Hospital in Stockholm and compares them with the findings in a similar number of cases of benign prostatic hypertrophy, also histologically proved. The two groups of cases covered essentially the same age group—from the middle forties to the middle eighties, with the highest rate of disease in the seventh and eighth decades.

The roentgenograms were made during the injection of water soluble contrast material into the anesthetized urethra at a time when the bladder had begun to fill. Frontal and both right and left oblique views were obtained and in some cases micturition views were attempted.

Study of the films showed that elongation of the prostatic urethra combined with narrowing and irregular deformity of the lumen abrupt kinking of the luminal course displacement laterally or anteriorly of the entire prostatic urethra and irregular bulgings into the base of the bladder formed a rather characteristic picture in carcinoma of the prostate. The urethrocytogram may of course fail to show several or all of these signs in spite of good clinical evidence of carcinoma of the prostate. This

Fig. 1. (Edling) Prostatic cancer (hard prostate, osteoplastic metastases in spinal column and pelvis). Displacement of the entire prostatic urethra forward and to the right.

is true particularly of lesions located far posteriorly. Most of the 68 cases of carcinoma, however, showed some change in the urethrocytogram. For example, there was elongation of the prostatic urethra in 66 cases, narrowing of the lumen (mostly supracollicularly) in 43, deformation of the lumen in 63 cases, angulation in 45, displacement of the entire prostatic urethra in 30, and irregular bulging into the base of the bladder in 25.

Elongation of the prostatic urethra also occurred in the cases of benign hypertrophy but was less likely to involve its whole length, and was commonly associated with a ribbonlike compression of the lumen, and in some cases with smoothly curving impressions of the urethra and base of the bladder rather than with irregularly distorted urethral narrowing and kinking as seen in carcinoma. Anterior angulation of the urethra occurred in both conditions but was more pronounced in carcinoma. Lateral displacement of the whole prostatic urethra was seen in nearly half of the carcinoma cases (Fig. 1) but in none of the hypertrophic ones. Trabeculation of the bladder and diverticulum formation occurred with about equal frequency in both conditions, and occasionally prostatic calcification and cavity formation were found in both.

The author also found that some cases showed a combination of urethral changes suggestive of the presence of both carcinoma and hypertrophy. While this adds to the difficulty of roentgen differentiation, it is to be expected in some cases since it is not uncommon

for a carcinoma to arise in a hypertrophic prostate. It was noted that the urethrocytographic signs here considered suggestive of prostatic carcinoma could be well imitated by the local changes residual to an electroresection for benign hypertrophy and the author therefore stresses the importance of possessing a trustworthy clinical history before attempting to interpret the films.

Finally, mikturition films were obtained in 30 cases of prostatic carcinoma. Sixteen of these showed some decrease in dilatability of the prostatic urethra, but 4 of them showed good dilatability although the injection views gave distinct signs of malignancy. Hence it was concluded that mikturition dilatability does not have universal value as an early sign of prostatic cancer.

LILIAN DONALDSON M.D.

Irradiation of Pituitary Tumors. H. DARNET KERR. *Am. J. Roentg.* 1948, 60: 348.

The author discusses the diagnosis and irradiation of pituitary tumors. He reports his findings in a follow-up survey of 25 cases presented in 1941 and reviews an additional series of 30 cases.

Acidophilic tumors of the pituitary body are usually suspected because of a disturbance in hormonal growth activity. There is roentgenographic evidence of enlargement or erosion of the sella turcica in about 60 per cent of the cases. The signs and symptoms of chromophobic cell tumors are chiefly headache, visual disturbance, or hypopituitarism, due entirely to pressure on surrounding cells or structures. Usually the rare basophilic adenoma is small; it does not enlarge the sella turcica and causes the well known Cushing's basophilism. It must be differentiated from certain adrenal tumors that produce a similar clinical syndrome.

The author believes that all types of pituitary tumors—acidophilic, basophilic, and chromophobic—should receive primary irradiation. The exceptions are those cases in which it is suspected that the tumor is cystic in type, cases in which there are symptoms suggesting hemorrhage into the tumor or the presence of increased intracranial pressure. Patients who do not show adequate response in 3 months should be operated upon, and patients operated upon primarily should receive postoperative irradiation to cause regression of the remaining remnants of the tumor.

Treatment is given using factors of 200 kilovolts, 1.95 mm. of copper half value layer, 50 cm. distance, through four 5 cm. circular fields directed toward the sella turcica—2 temporal, 1 frontal, and 1 vertical. A small dose of 100 roentgens is given to one field on the first day and if no reaction ensues, two fields are given 100 roentgens each the second day and from then on 200 roentgens to each of two fields daily to a total of 2,000 roentgens per field (air dose). This delivers approximately 2,400 roentgens into the pituitary fossa in the average sized calvarium.

An over-all good and apparently permanent result in 70 per cent of this series of 55 cases indi-

cates that irradiation is a very satisfactory primary method of treatment. Chromophobic tumors responded as well as the acidophilic type. Although there was a suggestion of possible brain injury in one or two cases following intensive pituitary irradiation there was no proof that such occurred

Pathology of Pulmonary Fibrosis, Including Chronic Pulmonary Sarcoidosis. TRACY B. MALLORY
Radiology 1948 51: 468

The author states that in contrast to emphysema pulmonary fibrosis is an uncommon disease having been diagnosed at the Massachusetts General Hospital 59 times in 6 000 autopsies as multifocal or generalized involvement of dubious origin. In only 23 of these cases was the severity of the condition of clinical importance.

Widespread fibrosis of the lung interferes with normal pulmonary function by increasing the collagen elasticity of the lung and decreased efficiency of ventilation. With the loss of respiratory function of a large part of the alveolar tissue two conditions develop: (1) a disproportion between thoracic and pulmonary volumes leading to emphysema bronchiectasis or both; and (2) a decrease in the vascular bed resulting in pulmonary hypertension and cor pulmonale. Pulmonary fibrosis therefore may produce either the symptoms of pulmonary insufficiency or of right-sided heart failure. The reserve factor however is very great.

The most frequent of the pathogenetic types of the condition are (a) bronchial asthma, (b) x radiation of the chest lesions, and (c) sarcoidlike lesions. A detailed discussion is given of each of these types.

The author states that the incidence of organized pneumonia in patients with chronic bronchial asthma is too high to be a coincidence, and that radiation pneumonitis is complicated by scars of necrotizing pneumonia and healed neoplasia. A progressive form of granulomatous pneumonitis healing by fibrosis is described, and the author's evidence for fibrosing this a form of localized pulmonary sarcoidosis is presented. Ten photomicrographs are included.

JANE C. MACFILLAN M D

Treatment of Deep-Seated Malignant Tumors with Multiple Port Technique Simulating Rotation Therapy. IRA I. KARLSON and SIDNEY I. ETKIN
Radiology 1945 51: 183.

The authors recommend the use of 12 narrow rectangular portals placed 2 cm apart and girdling the entire chest for irradiation of advanced carcinoma of the esophagus and inoperable pulmonary neoplasm. By such multiple port technique they believe a homogeneous carcinocidal dose of 200 kv x-ray can be delivered to the tumor while sparing the skin and peripheral intrathoracic structures to a greater degree than with methods in which fewer portals for cross-firing are employed. The disadvantage of the method is that a large volume of

normal tissue must be irradiated hence, the tumor dose which can be administered is limited by the total energy absorption which the patient will tolerate.

The location and extent of the tumor is determined by teleroentgenography with the patient in postero-anterior and true lateral positions and then at directly over the center of the lesion. The twelve portals are then outlined on the skin around the chest. Each field must be wide enough for the beam passing through it to cover the whole breadth of the tumor and long enough to extend well beyond the periphery of the gross lesion in order to catch the creepers spreading up and down the wall of the esophagus. Fields 7 by 15 cm were found satisfactory for most esophageal and pulmonary hilar neoplasms. Within these narrow portals the beam must be angled with exactitude to allow cross-fire exactly on the tumor and for accuracy in angling the authors recommend use of the Demy protractor, which also allows easy determination of the tumor-skin distance for each portal. When the esophageal tumor is situated behind the clavicles, projection of the shoulders makes the lateral fields useless. In such cases 1 central portal and 2 to each side of it are placed front and back, giving 10 fields and then 4 portals 5 by 5 cm. in diameter are added at the root of the neck through which the beam is directed slightly downward.

It is assumed from what is known of tumors of histology similar to those of the esophagus that a tumor dose of 5 500 to 6 500 roentgens delivered within 4 to 5 weeks is the approximate sterilizing dose. The factors used in the cases here reported were 200 kv, 20 ma, 50 cm distance. Thorax film taken with high value layer 1.9 mm. of copper.

Supportive care of the patient is stressed particularly adequate nourishment. Intramuscular administration of 50 mgm. of pyrimidine 1 hour before and again 1 hour after treatment was found very useful in preventing radiation sickness. Weekly blood counts gave the first indication of falling tolerance to large volume irradiation but mild leucopenia developed in only 2 of the 8 cases presented and in spite of large daily doses all patients remained ambulatory during treatment.

The authors report their results with this method in 4 cases of advanced carcinoma of the upper or mid esophagus proved by pretreatment biopsy and in 4 cases of carcinoma of the lung found inoperable at previous thoracotomy. In each of the cases of esophageal carcinoma, the patient's dysphagia was improved within 2 weeks of initiation of treatment and had disappeared by the time treatment was completed. The roentgen appearance of the esophagus greatly improved for its wall became mobile again the rugal pattern linear and only slight narrowing remained to mark the site of lesion. However within 2 to 5 months after the beginning of treatment the first 3 patients developed dyspnea, chills, low grade fever and rales and showed film

Fig. 1. (Edling) Prostatic cancer (hard prostate, osteoplastic metastases in spinal column and pelvis). Displacement of the entire prostatic urethra forward and to the right.

is true particularly of lesions located far posteriorly. Most of the 68 cases of carcinoma, however, showed some change in the urethrocytogram. For example, there was elongation of the prostatic urethra in 66 cases, narrowing of the lumen (mostly supracollicularly) in 42, deformation of the lumen in 63 cases, angulation in 45, displacement of the entire prostatic urethra in 30, and irregular bulging into the base of the bladder in 25.

Elongation of the prostatic urethra also occurred in the cases of benign hypertrophy but was less likely to involve its whole length, and was commonly associated with a ribbonlike compression of the lumen, and in some cases with smoothly curving impressions of the urethra and base of the bladder rather than with irregularly distorted urethral narrowing and kinking as seen in carcinoma. Anterior angulation of the urethra occurred in both conditions but was more pronounced in carcinoma. Lateral displacement of the whole prostatic urethra was seen in nearly half of the carcinoma cases (Fig. 1) but in none of the hypertrophic ones. Trabeculation of the bladder and diverticulum formation occurred with about equal frequency in both conditions and occasionally prostatic calcification and cavity formation were found in both.

The author also found that some cases showed a combination of urethral changes suggestive of the presence of both carcinoma and hypertrophy. While this adds to the difficulty of roentgen differentiation, it is to be expected in some cases since it is not uncommon

for a carcinoma to arise in a hypertrophic prostate. It was noted that the urethrocytographic signs here considered suggestive of prostatic carcinoma could be well imitated by the local changes residual to an electroresection for benign hypertrophy and the author therefore stresses the importance of possessing a trustworthy clinical history before attempting to interpret the films.

Finally, micturition films were obtained in 20 cases of prostatic carcinoma. Sixteen of these showed some decrease in dilatibility of the prostatic urethra, but 4 of them showed good dilatibility although the injection views gave distinct signs of malignancy. Hence it was concluded that micturition dilatibility does not have universal value as an early sign of prostatic cancer.

LILIAN DONALDSON M.D.

Irradiation of Pituitary Tumors. H. DASENY KERR. *Am. J. Roentg.* 94B, 60: 348.

The author discusses the diagnosis and irradiation of pituitary tumors. He reports his findings in a follow-up survey of 25 cases presented in 1941 and reviews an additional series of 30 cases.

Acidophilic tumors of the pituitary body are usually suspected because of a disturbance in hormonal growth activity. There is roentgenographic evidence of enlargement or erosion of the sella turcica in about 60 per cent of the cases. The signs and symptoms of chromophobic cell tumors are chiefly headache, visual disturbance, or hypopituitarism, due entirely to pressure on surrounding cells or structures. Usually the rare basophilic adenoma is small; it does not enlarge the sella turcica and causes the well known Cushing's basophilism. It must be differentiated from certain adrenal tumors that produce a similar clinical syndrome.

The author believes that all types of pituitary tumors—acidophilic, basophilic, and chromophobic—should receive primary irradiation. The exceptions are those cases in which it is suspected that the tumor is cystic in type, cases in which there are symptoms suggesting hemorrhage into the tumor or the presence of increased intracranial pressure. Patients who do not show adequate response in 2 months should be operated upon, and patients operated upon primarily should receive postoperative irradiation to cause regression of the remaining remnants of the tumor.

Treatment is given using factors of 200 kRovolt, 1.95 mm. of copper half value layer, 90 cm. distance, through four 5 cm. circular fields directed toward the sella turcica—2 temporal, 1 frontal, and 1 vertical. A small dose of 100 roentgens is given to one field on the first day and if no reaction ensues, two fields are given 100 roentgens each the second day, and from then on 200 roentgens to each of two fields daily to a total of 2,000 roentgens per field (air dose). This delivers approximately 2,400 roentgens into the pituitary fossa in the average sized calvarium.

An over-all good and apparently permanent result in 70 per cent of this series of 55 cases indi-

cates that irradiation is a very satisfactory primary method of treatment. Chromophobic tumors responded as well as the acidophilic type. Although there was a suggestion of possible brain injury in one or two cases following intensive pituitary irradiation there was no proof that such occurred.

Pathology of Pulmonary Fibrosis, Including Chronic Pulmonary Sarcoidosis. TRACY B. MALLORY
Radiology 1948, 51, 468.

The author states that in contrast to emphysema, pulmonary fibrosis is an uncommon disease having been diagnosed at the Massachusetts General Hospital 59 times in 6 000 autopsies as multifocal or generalized involvement of dubious origin. In only 23 of these cases was the severity of the condition of clinical importance.

Widespread fibrosis of the lung interferes with normal pulmonary function by increasing the collagen which is associated sooner or later with diminished elasticity of the lung and decreased efficiency of ventilation. With the loss of respiratory function of a large part of the alveolar tissue two conditions develop: (1) a disproportion between thoracic and pulmonary volumes leading to emphysema, bronchiectasis or both; and (2) a decrease in the vascular bed resulting in pulmonary hypertension and cor pulmonale. Pulmonary fibrosis therefore may produce either the symptoms of pulmonary insufficiency or of right-sided heart failure. The reserve factor however is very great.

The most frequent of the pathogenetic types of the condition are (a) bronchial asthma, (b) x-radiation of the chest lesions and (c) sarcoidlike lesions. A detailed discussion is given of each of these types.

The author states that the incidence of organized pneumonia in patients with chronic bronchial asthma is too high to be a coincidence, and that radiation pneumonitis is complicated by scars of necrotizing pneumonitis and healed neoplasia. A progressive form of granulomatous pneumonitis healing by fibrosis is described and the author's evidence for considering this a form of localized pulmonary sarcoidosis is presented. Ten photomicrographs are included.

JANE C. MACMILLAN M.D.

Treatment of Deep-Seated Malignant Tumors with Multiple Port Technique Simulating Rotation Therapy. IRA I. KAPLAN and SIDNEY I. ETKIN.
Radiology 1948, 51, 185.

The authors recommend the use of 12 narrow rectangular portals placed 1 cm apart and girdling the entire chest, for irradiation of advanced carcinoma of the esophagus and inoperable pulmonary neoplasm. By such multiple port technique they believe a homogeneous carcinocidal dose of 200 kv. roentgen rays can be delivered to the tumor while sparing the skin and peripheral intrathoracic structures to a greater degree than with methods in which fewer portals for cross-firing are employed. The disadvantage of the method is that a large volume of

normal tissue must be irradiated; hence, the tumor dose which can be administered is limited by the total energy absorption which the patient will tolerate.

The location and extent of the tumor is determined by teleroentgenography with the patient in postero-anterior and true lateral positions and then at fluoroscopy indicators are fixed front and back directly over the center of the lesion. The twelve portals are then outlined on the skin around the chest. Each field must be wide enough for the beam passing through it to cover the whole breadth of the tumor and long enough to extend well beyond the periphery of the gross lesion in order to catch the creepers spreading up and down the wall of the esophagus. Fields 7 by 15 cm. were found satisfactory for most esophageal and pulmonary hilar neoplasms. Within these narrow portals the beam must be angled with exactitude to allow cross-fire exactly on the tumor and for accuracy in angling the authors recommend use of the Demy protractor, which also allows easy determination of the tumor skin distance for each portal. When the esophageal tumor is situated behind the clavicles, projection of the shoulders makes the lateral fields useless. In such cases, 1 central portal and 2 to each side of it are placed front and back giving 10 fields and then 4 portals 5 by 5 cm. in diameter are added at the root of the neck through which the beam is directed slightly downward.

It is assumed from what is known of tumors of histology similar to those of the esophagus that a tumor dose of 5 500 to 6 500 roentgens delivered within 4 to 5 weeks is the approximate sterilizing dose. The factors used in the cases here reported were 200 kv., 20 ma., 50 cm. distance Thoracul fil. tration with high value layer 1.0 mm. of copper.

Supportive care of the patient is stressed particularly adequate nourishment. Intramuscular administration of 50 mgm. of pyridoxine 1 hour before and again 1 hour after treatment, was found very useful in preventing radiation sickness. Weekly blood counts gave the first indication of falling tolerance to large volume irradiation but mild leucopenia developed in only 2 of the 8 cases presented and in spite of large daily doses all patients remained ambulatory during treatment.

The authors report their results with this method in 4 cases of advanced carcinoma of the upper or mid esophagus proved by pretreatment biopsy and in 4 cases of carcinoma of the lung found inoperable at previous thoracotomy. In each of the cases of esophageal carcinoma, the patient's dysphagia was improved within 2 weeks of initiation of treatment and had disappeared by the time treatment was completed. The roentgen appearance of the esophagus greatly improved for its wall became mobile again the rugal pattern linear and only slight narrowing remained to mark the site of lesion. However within 2 to 5 months after the beginning of treatment the first 3 patients developed dyspnea, chills, low grade fever and rales, and showed film

evidence of pulmonary infiltration spreading from the hila. Within a few more weeks they died, apparently of radiation pneumonitis. In the one case in which an autopsy was obtained the pathologist could find no evidence of residual esophageal neoplasm.

It was evident that some change in the method of administering the treatment must be made. These 5 patients had received tumor doses of 5,800, 6,170, and 8,147 roentgens, respectively, in 23 to 30 days, 2 adjacent portals having been treated daily in rotation around the chest, with each portal receiving 600 roentgens in air (750 r. with backscatter) per treatment. The daily tumor dose under this method was estimated at 350 roentgens. It was decided that the daily tumor dose could be reduced to 165 to 170 roentgens, each portal receiving only 300 to 360 roentgens in air, and that two opposite portals should be used daily instead of two adjacent ones in order to avoid creation of a hot-spot due to overlapping of beam pathways within peripheral tissue. These changes increased the total treatment time required to achieve the desired tumor dose from just over 3 weeks to about 5½ weeks.

The fourth patient with esophageal carcinoma was treated by this modified method. The depth dose achieved in 35 days was estimated at 6,300 roentgens. This patient made the same initial clinical and roentgen improvement in the esophagus as had the previous patients but so far he had not developed signs of pneumonitis. In the 4 months of observation he had gained 25 pounds in weight and had returned to work.

For the 4 cases of inoperable carcinoma of the lung presented, the girdle distribution of portals had to be modified to allow for the eccentric position of these tumors, 2 of which were in a main stem bronchus, the other in an upper lobe. One patient, a man only 48 years of age, received a tumor dose of 7,532 roentgens in 30 days at the rate of 600 roentgens in air per portal, but the other 3 patients were treated by the modified method recounted above to achieve tumor doses of approximately 6,500 roentgens in a little over 5 weeks. Their chest pain disappeared during treatment, slight weight gain ensued and in each instance the roentgen appearance of the chest became spectacularly improved with only mild pulmonary scarring and pleural thickening remaining visible. At the time of this report 8 months, 7 months, 4 months, and 3½ months, respectively after initiation of roentgen treatment these 4 patients were all working and maintaining their weight.

The authors present this multiple portal technique as one which offers hope of substantial palliation in advanced esophageal and inoperable pulmonary carcinoma provided care is taken to avoid severe radiation pneumonitis. They recognize that the elapsed time is as yet too short to allow evaluation of the possible duration of the palliation or to indicate whether any cure is possible.

LESLIE DONALDSON, M.D.

Observations upon the Lymphopenia of X-Ray Irradiation. C. H. G. PIRCE. *Brit. J. Radiol.*, 1948, 21: 48

The author's article is based on cases observed at the University of Bristol and the Bristol Royal Hospital in England. A mathematical correlation was demonstrated between radiation dosage and response of the total lymphocyte count in a group of 16 women receiving a standardized course of pelvic irradiation, in most of the cases for carcinoma of the ovary. All patients were in good general condition, and were free of any clinical evidence of lymph node or bone marrow involvement.

The irradiation factors used were 230 kilovolts, a filter of 1 mm. copper plus 1 mm. of aluminum, giving a high value layer of 1.6 mm. of copper administered through two anterior oblique and one posterior direct pelvic portals at a constant time of day daily for 5 successive days each week, and at a constant daily dose, to achieve a total tumor dose of between 2,800 and 3,500 roentgens for each patient. The pre-treatment level of the total lymphocyte count was first established, and then differential counts were made daily 5 hours after each treatment, using Leishman-stained films of single celled depth. A minimum of 400 cells arranged in battlement distribution along film edges were counted in each film.

From the daily lymphocyte total, mean totals for the 5 day periods were calculated and plotted against time in days, producing in each case a curve showing the greatest change in total lymphocyte count in the initial 24 days of treatment following which the rate of change diminished fairly rapidly to a minor order. For each patient, the curve so obtained was similar.

When curves were re-plotted upon logarithmic graph paper and an attempt was made to fit a straight line to the observed points on the graph, it was found that there was a general tendency for the earlier two or three points to be above the line which best fitted the rest of the values, so that the mathematical expression correlating the total lymphocyte count with the integral dose appeared to be a composite one having the general form $C = A \cdot 10^{-\frac{1}{2}D} + B \cdot 10^{-\frac{1}{2}D}$ where C = per cent survival of total lymphocytes for values of D , A = a proportion of the total lymphocyte count which appeared to diminish less rapidly than the component $10^{-\frac{1}{2}D}$, B = $100 - A$, and $\frac{1}{2}D$ = indices representing the rate of diminution of the two components A and B , D = integral dose in megagram-r.

The values for all of these functions were calculated for each of the 16 cases. It appeared that the value of component B in the integral dose curves was mainly responsible for the major change in total lymphocyte count that takes place during the early days of a course of treatment. The author suggests that this component may represent the result of the direct action of the radiation, and that the further but smaller drop in lymphocyte count represented by component A may be due to an indirect action of radiation. After several weeks a stage is reached at which further irradiation, at the level of dosage used

in these cases, causes only a very small change in lymphocyte count.

Clinical assessment of tolerance (good, fair or poor) to x irradiation revealed no correlation between age, initial or final lymphocyte count, the rate of change of total lymphocyte count, the total dose of radiation, or the rate of dosage. The author therefore concludes that the total lymphocyte count from a quantitative point of view is not a good index of tolerance to radiation, although its characteristic pattern of change under standardized conditions of fers an approximate index of the degree of radiation dosage.

MISCELLANEOUS

Radioactive Iodine: Its Use as a Tool in Studying Thyroid Physiology RULOV W. RAWSON and BENGT N SKANKE. *Radiology* 1948, 51 525

Three types of radioactive iodine have been used in the study of thyroid function: I^{131} with a half life of 25 minutes, I^{132} with a half life of 12 hours and the more practicable I^{131} with a half life of 8 days.

The earliest studies in 1938 by Hertz and others showed that hyperplastic thyroids concentrated a greater percentage of radioactive iodine than the normal controls.

Anatomical changes in the thyroid have also been studied. The first changes observed in an animal receiving thyroid stimulating hormone were hypertrophy of the thyroid cell and a loss of thyroid iodine.

Oral radioactive iodine is rapidly absorbed by the gastrointestinal tract and is demonstrable in the thyroid within 20 minutes. Most of the material (80%) is excreted during the first 5 days in urine. Hypothyroid patients collect very little iodine. Myxedematous patients excrete from 85 to 90 per cent of the iodine in the first 24 hours. The excretion rate is slower than in normals.

Benign tumors collect iodine whereas malignant thyroids do not collect radioactive iodine. In those cases of thyroid cancer in which the primary tumor was removed surgically or was destroyed by radioactive iodine the sites of distant metastases were shown to have a definite affinity for iodine.

The studies carried out by these authors indicate a definite need for determining the minimum tracer dose so that there may be no interference with normal thyroid function. MAURICE D. SACHS, M D

Treatment of Hyperthyroidism with Radioactive Iodine (I^{131} 12 Hour Half Life, and I^{131} 8 Day Half Life) EARLE M. CHAPMAN, BENGT N. SKANKE, and ROSELEY D. EVANS. *Radiology* 1948, 51 558

The authors treated 65 hyperthyroid patients between 1943 and 1947 with radioactive iodine having a half life of 12 hours isotope I^{132} . Between August, 1946 and the present time another 65 were treated with 8-day isotope I^{131} . Radioactive iodine I^{131} with a half life of 12 hours has been used effectively alone in a single retained dose averaging 20 millicuries per estimated gram of thyroid 90 per cent of whose

radiation dose is delivered in the first 36 hours. Myxedema has been produced. The histologic changes seen in the thyroids 1 and 2 years after treatment show fibrosis and regenerative hyperplasia according to the unanimous judgment of 5 pathologists. Relapse or recurrence of hyperthyroidism has not been observed. Toxic effects of this short lived form of radioactivity have been nausea, slight fever and swelling and tenderness of the thyroid for a few days. Effective doses in the second and fifth months of pregnancy have not caused cretinism. Radioactive iodine I^{131} with a half life of 8 days is an effective single therapeutic agent. In 41 of the patients who responded the average retained dose was 0.142 millicuries (142 microcuries) per estimated gram of the thyroid tissue 97 per cent of this dose of radiation is delivered in 30 days. In most cases the administered effective dose was from 8 to 14 millicuries by mouth. Myxedema has been produced in only 4 cases. The only histologic study as yet available is from a gland removed at autopsy only 19 days after treatment. The gland shows edema and separation of the cells from the basement membrane but no fibrosis. Toxic effects of treatment with the 8-day isotope may be related to an exacerbation of the thyrotoxicosis that sometimes occurs in the first 1 or 2 weeks following treatment during which time the release of stored thyroid hormone may be reflected in the rising blood protein bound iodine.

FRANK L. HUSSEY M D

Radioactive Iodine Studies of Functional Thyroid Carcinoma VIRGINIA KINKELAND FRANTZ, EDITHE H. QUIMBY and TITUS C. EVANS. *Radiology* 1948 51 532

In 1940 Hamilton Foley reported the results of his studies on the deposition of radioactive iodine in human thyroid tissue. The article was accompanied by radioautographs of two thyroid carcinomas which failed to take up radioactive iodine. Foley concluded therefore, that it was inadvisable to treat such lesions with radioactive elements. However since there are different types of thyroid cancer it is still possible to consider the treatment of these lesions.

A 20 year study (1924-1944) of 4 707 thyroids revealed 151 cases of cancer. Three fourths of 130 primary cancers of the thyroid studied up to June 1 1947 were slow growing lesions with late metastasis. In this group the papillary and adenomatous or follicular, types of lesion were equally divided. Papillary lesions are multiple with local invasion and they metastasize to the lymph nodes and lungs, but not to the bone. The adenomatous or follicular type of tumor appears to be benign histologically, usually occurs singly is encapsulated with spread to the bone (not to the lymph nodes) and to the lungs only late in the disease.

All patients with thyroid enlargement in whom malignancy is suspected receive a presurgical tracer dose of radioactive iodine, thyroid uptake and urine output are measured. At the time of surgery the gross specimen is examined *in situ* by the surgeon

and pathologist. The type of surgical procedure is then determined. Portions of the tissue are measured directly with the geiger counter and radioautographs are taken if necessary.

Up to May, 1943 a total of 68 potential carcinomas of the thyroid had been studied with tracer doses of I^{131} . Of these, 32 were benign (26 nodular goiters, 4 inflammatory and 2 adenomas). Of the thyroid cancers, the undifferentiated grades II and III showed no uptake of radiiodine. Of 8 malignant adenomas, 7 showed uptake in bone metastasis. Fifteen tracer studies for metastasis were made. Studies were made also at the time of operation to determine the efficacy of total thyroidectomy.

The present work is a preliminary study accompanied by excellent radioautographs showing the uptake of radiiodine in tissue. With regard to future plans, the authors state that in the cases of malignant adenomas with bone metastasis and multiple tumors in the lateral neck, with or without involvement of the gland treatment will consist of thyroidectomy, followed by from 50 to 100 mc. of radiiodine for bone metastasis if necessary. Patients with multiple lesions in the neck will receive a smaller prophylactic dose of radiiodine postoperatively. In most instances operative treatment is preferable to radiiodine for total removal of the thyroid. Radiiodine therapy is believed to be too time-consuming.

MAURICE D. SARGENT, M.D.

Factors Involved in the Experimental Therapy of Metastatic Thyroid Cancer with I^{131} L. D. MARSHALL, J. B. THOMPSON, R. F. HILL, and F. W. FOOTE. *Radiology* 94:3, 533.

The treatment of metastatic cancer of the thyroid by radioactive iodine presents features of interest and importance. Efforts to localize radioelements in neoplastic cells have been made but thus far a concentration of practical value has not been obtained. The experience gained in the last decade in the treatment of hyperthyroidism with I^{131} or I^{129} cannot be utilized fully in the treatment of cancer of the thyroid. In the case of hyperthyroidism, remission of symptoms is sought by partial inactivation of the thyroid gland, whereas in the case of cancer radical devitalization of extensive tumor masses is attempted under conditions of differential uptake which, as a rule, are not as favorable.

In the course of the past year, 18 patients have been investigated to determine their suitability for treatment with I^{131} . In all of them metastases were present. The authors present one case in which satisfactory initial retention of I^{131} in the tumor warranted immediate experimental therapy with massive doses. The patient had a primary tumor excised in 1941. A month later multiple bone metastases appeared. In 1944, it was found that the lesions concentrated I^{131} . Due to a lack of availability of isotopes in large quantities, the treatment was not begun until 1946. Two days after a small tracer dose, 60 millicuries of radiiodine I^{131} were given orally and 7 days later a larger dose of 121 millicuries was

given orally. Definite improvement followed. Soon afterward however an acute thyrotoxicosis developed. The hypothesis was advanced that under the influence of intracellular radiation the thyroid follicle cells of the tumor had broken down thereby releasing large amounts of thyroglobulin in the organism. A blood specimen taken at this time verified this hypothesis. The report of 36 micrograms of protein bound iodine per 100 c.c. of plasma confirmed the suggested mechanism. The thyrotoxic symptoms cleared and the patient developed a carcinoma of the larynx which was treated by roentgen rays. Thyrotoxic symptoms reappeared on resuming isotope therapy. Propylthiouracil was administered for 76 days in an attempt to empty the tumors of their stored thyroglobulin. A dose of 121 millicuries of radioactive iodine was given at this time with no reaction of any kind. The patient has shown much improvement having gained 55 pounds of weight, and he is able to drive his own car.

Preliminary results warrant further clinical trial of this type of therapy. FRANK L. HURST, M.D.

Cancer of the Cervix Uteri. JOHN F. HINCK, *Am. J. Roentg.*, 94:3, 606-663.

This report consists of an analysis of 296 consecutive cases of cancer of the cervix uteri referred for treatment during the period from 1935 to 1944. A combination of roentgen and radium therapy with occasional supplementary intravaginal cone therapy was used and the method is described. The radiation treatment is carried to the maximum tolerance level, and the total treatment is given in from 6 to 8 weeks. Unnecessary treatment to surrounding normal parts should be avoided. When indicated, supportive therapy is used to improve or maintain the general health of the patient and to reduce the frequency of radiation sickness.

The Schmitz classification is used in the staging of the disease and lesions classified as stage 1 and stage 2 are considered operable.

The results are based on an analysis of 203 determinate cases. This includes all previously untreated lesions in patients who received treatment in this clinic, except 8 cases in patients dying of unrelated intercurrent disease and 1 case which was lost to follow-up when the patient was free of disease for more than 3 years. These 9 cases are classified as indeterminate along with cases which recurred after treatment elsewhere. Cases in patients referred but not treated, and cases seen only in consultation.

The relation of survival to stage of the disease, age and race of patients, and duration of symptoms is tabulated. A relatively high incidence of associated syphilis is reported but this did not appear to influence the prognosis nor the response to treatment. The various complications following radiation therapy are recorded and discussed. A 3 year survival of 57 per cent of all cases and of 75 per cent of operable cases, and a 5 year survival of 51 per cent of all cases and of 71 per cent of operable cases are reported.

JOHN H. FARRER, M.D.

Effects of Radiation on Hemopoiesis. JOHN S. LAW
KENNEDY ANDREW H. DOWDY AND WILLIAM N. VAL-
ENTINE. *Radiology* 1948 51 400.

The authors present the observations of the various members of the Manhattan Project relative to the effects of radiation on the hemopoietic tissues. In considering the effects of radiation of hemopoiesis the following facts should be recognized. The cells in the blood are relatively resistant to radiation. The peripheral blood picture produced by radiation is affected markedly at any one period following irradiation by the length of life of the different morphological elements in the peripheral blood. The effect of radiation on the peripheral blood picture is influenced by radiosensitivity of the various parent cells. The ability of the tissues to regenerate is of great importance.

The most worthwhile observations of the effects of roentgen radiation applied to the body as a whole have been made on animals. In one study a large series of rats was used. These were divided into groups receiving different amounts (25 to 1500 roentgens) of irradiation in single doses, and the findings in the animals were followed closely for 25 days. In another large series of rats 550 roentgens were given to the whole body and blood studies were made at frequent intervals up to 41 days. Little change was noted in the red blood cells receiving 200 roentgens or less. Questionable changes occurred in the group receiving 300 to 500 roentgens during the first 168 hours. There was however appreciable reduction in both erythrocyte and hemoglobin levels between 168 and 448 hours. In animals receiving 600 to 800 roentgens significant drops in both erythrocytes and hemoglobin were present at 168 hours also. In the series given 550 roentgens to the whole body a precipitous drop in red blood cells and hemoglobin levels occurred. Reticulocytes were not reduced when less than 100 roentgens were used. Marked reductions, however, occurred with dosages of 200 to 500 roentgens, beginning at 72 hours and persisting for 120 hours in the animals receiving 200 roentgens and for 180 hours in those receiving 500 roentgens. Regeneration of reticulocytes became apparent at 168 to 180 hours in the groups receiving 600 to 800 roentgens. No significant changes in platelets were noted in those receiving less than 200 roentgens. Platelet reduction occurred in the rats receiving 300 to 500 roentgens after 120 to 168 hours. In rats receiving 500 to 800 roentgens platelet reduction occurred by the fifth day. From 70 to

90 per cent of the leucocytes in the normal rat are lymphocytes. No unquestionable changes occurred in the neutrophils until dosages greater than 100 roentgens were used. A dosage of 25 roentgens was found to cause a drop in the lymphocyte level in 24 hours. It was found that the lymphocytes exposed to 550 roentgens were reduced as early as at 15 minutes after irradiation. With a single dose of 550 roentgens the effects of radiation injury in the lymph nodes were present at one hour after irradiation. At 6 hours after irradiation cytolytic of the cells in the lymph follicles had reached its maximum and the cellular debris was rapidly being removed by macrophages. Twenty four hours after irradiation regeneration and repair of the lymph nodes were actively progressing and by the twentieth post irradiation day regeneration was complete. It should be noted that the findings in the lymph nodes did not show good correlation with the peripheral blood picture since the total number of the lymphocytes in the peripheral blood at the end of 25 days was still appreciably below normal. The changes in the spleen after irradiation followed closely those observed in the lymph nodes except that the whole process was somewhat more prolonged.

Regeneration was first observed between the thirtieth and the thirty fifth hours after irradiation and was not complete until 40 days after exposure. Cellular destruction in the bone marrow reached its maximum between 2½ and 3 hours after irradiation. Most of the accumulated cellular debris was removed by the thirtieth postexposure hour. By the eighth day hypoplasia was very severe, but at no time was complete aplasia observed. Active regeneration began approximately 12 days after irradiation and was completed on the fortieth day. The greatest reduction in the megakaryocytes occurred between the fourth and twelfth days after which regeneration began.

Experimental studies on animals exposed repeatedly to small doses of roentgen and gamma radiation are more difficult to summarize. In every species studied a daily exposure of 10 roentgens per day resulted in detectable change in some of the hemopoietic elements within a year's time. Observations as to local area irradiation point to the fact that hemopoietic tissue not in the area exposed is not affected. The purpose of all of the studies which have been reviewed is to get a better idea of the effect of radiation on man.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Precocious Puberty (Pubertas precox). J. M. CARA
WELL, A. SECARELLI and L. E. TERRADES *Acta
endocr. Cym.* 94B, 17

Precocious puberty has many symptoms all of them referring to an exaggerated, earlier than normal sexual development. Along with this are the secondary changes which usually follow such as quality of voice and distribution of hair. The etiopathogenesis permits classification into (1) constitutional, (2) endocrine and (3) cerebral groups. The last includes those cases which are of a meningo-encephalitic, hydrocephalic, or of intracranial tumor origin. The constitutional type is the most frequent of the three examples which are reported.

The first was a case of hypothalamohypophysis anomaly which demonstrated the characteristic findings of sexual alterations hypogonadism hyperostosis of the frontal bones, angiomatous nevi and obesity. These changes were placed on familiar and hereditary bases. The second case revealed obesity alterations of the sella turcica, and ovarian hypofunction and the third showed the usual morphologic changes and the presence of active gonadotropic and estrogenic substances but there was no progesterone obtainable. Cyclic menses with ovulation resulted. The fourth case of supranasal hyperfunction associated with neoplasm of the left gland is described as an example of the endocrine type, which also included pineal body supranasal, and other gonadic dysfunctions. Extremely high elimination of 17-ketosteroids characterized this last case.

STEPHEN A. ZIDMAN, M.D.

Hypervitaminosis A. Report of 2 Cases in Infants.
PHILIP E. ROTHEMAN and E. ELIZABETH LEON
Radiology 94B, 5 358

The current popularity of vitamin preparations requires the physician to be alert for signs of overdosage. Two cases of hypervitaminosis A in infants over one year of age are presented by these authors. In each child the daily intake of vitamin A was estimated to be in excess of 100,000 international units.

The salient clinical features include a history of excessive intake of vitamin A preparations, anorexia with failure to gain weight irritability bone sensitivity sparse hair, cracking of the lips, hepatomegaly and generalized pruritus. Roentgenographic examination shows evidence of periosteal proliferation, most common in the ulna. Increased vitamin A and carotene levels in the blood are further diagnostic aids. In one child a yellowish tinge to the skin was present.

The treatment consists of discontinuing vitamin A preparations and the reduction of foods containing a high content of vitamin A. Both patients responded

clinically to this treatment in 10 to 24 days, although the blood levels of carotene and vitamin A did not fall to normal for several months.

A similarity exists between bone changes in infantile cortical hyperostoses and hypervitaminosis A. The former differs clinically in the absence of a history of excessive intake of vitamin A, the presence of fever a subacute course with recurrences, and onset usually before the age of one year. The periosteal reaction in infantile cortical hyperostoses involves principally the mandible and frequently a lamellated appearance is seen in the film indicative of the recurrent course of the disease.

According to the authors, the huge capacity of the liver to store vitamin A rarely necessitates the administration of vitamin A in excess of 5,000 international units. A bibliography of experimental and clinical studies on vitamin A is presented.

JOHN L. BRILL, M.D.

Clinical and Experimental Study of Thyroid Inhibitory Substances. Comparative Experimental Study of 31 in Derivatives of Thiourea (Ricerche cliniche e sperimentali sulle sostanze tireostatiche. Studio sperimentale comparativo sui principali derivati tioureici). LUCIO PARONI and MAURIZIO DE GUR
Arch. Ital. Biol. 1948, 70: 199.

In addition to thiourea, the following substances have been investigated in regard to their inhibitory effect on hyperthyroidism derivatives of the aliphatic series such as diethylthiourea and thioisamine, derivatives of the aromatic series, such as phenylthiourea derivatives of the heterocyclic series, such as thioracil, methyluracil, aminothiazole, thiobarbituric acid, aminothiodiazole and aminoethylthiodiazole.

The authors studied the effect of thioracil methylthioracil, and aminothiazole on the histologic structure of the thyroid gland, hypophysis, thymus, and other organs and the peripheral and medullary blood, and made histochemical determinations of glycogen in the liver and of calcium, sugar, nitrogen, cholesterol, fibrinogen and prothrombin in the blood.

The experiments were performed on albino mice guinea pigs and dogs. The goitrogenic effect was estimated by calculating the ratio of the thyroid gland removed at the autopsy to the body weight of the animal.

Two classes of phenomena produced by thyroid-inhibitory substances may be distinguished initial changes (the intensity being in proportion to the dose of the drug) which are the result of the toxic-necrotic effect of the substance administered, and later changes which are, to a certain degree, independent from the entire dose and due to the specific inhibitory effect of the substance on the thyroid gland.

During the first 2 to 5 days after the beginning of the experiment the following changes take place in the thyroid gland: hyperemia of the glandular tissue, nuclear pyknosis, desquamation of the follicular epithelium and the appearance of hemorrhagic and necrotic-degenerative foci. Later on a liquefaction and absorption of the colloid substance and hypertrophy and hyperplasia of cellular structures of the follicular epithelium take place.

The greatest sensitivity to the substances studied was found in mice then in guinea pigs and dogs. The smaller the regressive changes the greater the intensity and rapidity of the appearance of hypertrophy and hyperplasia. The regressive lesions were more pronounced after administration of aminothiazole than after thiouracil or methylthiouracil.

The goitrogenic effect of methylthiouracil was stronger than that of thiouracil while aminothiazole had the weakest effect.

Thyroidinhibitory substances produce a deficiency of thyroxin with a resulting compensatory increase of the secretion of thyrotropic hormone by the anterior lobe of the pituitary gland. This hormone stimulates the thyroid gland in an abnormal manner so that vacuolization and absorption of the colloid substance, and hypertrophy and hyperplasia of the follicular epithelium take place.

The authors were not able to detect any histologic modifications in the hypophysis. The following changes were noticed in the blood: diminution of hemoglobin and in the number of red and white blood corpuscles, neutropenia, and relative lymphocytosis. The examination of the bone marrow did not show any changes. The sugar and nitrogen contents of the blood fell. This was probably due to a diminished metabolic activity. The amount of cholesterol in the blood increased in the course of the experiments.

JOSEPH K. NARAT, M.D.

The Relationship Between Heparin Dosage and Clotting Time. L. B. JACQUES and ANN G. RICK. *Blood* 1948 3 1197

The authors have studied the effect of heparin dosage on the clotting time in the dog both in vitro and in vivo. It was found that the clotting time reached a maximum in 5 to 15 minutes after the intravenous injection of moderate doses of heparin and that this maximum clotting time was greater than that occurring when the same amount of heparin was added to the blood in vitro, because of the increased anticoagulant effect of heparin which is incubated with blood. Clotting times returned to normal after short intervals and were constant with given dosages.

The clotting time response to certain concentrations of heparin added to the blood in vitro was considered a measure of the sensitivity of the clotting system to heparin. The clotting time response to a fixed dose of heparin injected intravenously was considered a measure of the body's ability to remove heparin from the circulation when interpreted in the light of the in vitro response.

This test was then used on animals subjected to anesthesia with pentobarbital, ether or urethane the injection of India ink (reticuloendothelial blockade) removal of both kidneys and removal of the gastrointestinal tract. The results indicated that neither the reticuloendothelial system the kidneys nor the gastrointestinal tract were involved in the disappearance of heparin from the circulation since none of these procedures had any effect on the duration of heparin action in the body.

When the sensitivity of the blood to the anticoagulant action of heparin was tested pentobarbital and nephrectomy had no effect, ether caused an increase in sensitivity and urethane India ink and evisceration caused a decrease. Coagulability of the blood was decreased by pentobarbital, increased by India ink and evisceration, and little affected by urethane, ether or nephrectomy.

Circulating Anticoagulant as a Cause of Hemorrhagic Diathesis in Man. C. LOCKARD CONLEY, HOWARD K. RATHBUN, WILLIAM I. MORRIS, II, and JAMES E. ROBINSON, JR. *Bull. Johns Hopkins Hosp.*, 1948 83 188.

The hemorrhagic syndromes are generally explained on the basis of a deficiency of one of the plasma components necessary for coagulation. While this may be true in a majority of cases, the authors present evidence to show that abnormal bleeding may be due to the spontaneous occurrence of an anticoagulant in the blood.

Three cases of abnormal bleeding are presented, with clotting times of 68 minutes, 60 minutes, and 5 hours. The last is a hemophilic, but neither of the other cases showed any laboratory findings to explain the increased clotting times. All three cases were found to have circulating anticoagulant by the following procedure. Fresh, whole blood from each case was centrifuged and the supernatant plasma was found to be free of platelets and remained clot free indefinitely. When small amounts of this plasma were added to portions of normal blood, the coagulation time of the latter was prolonged, indicating the presence of some anticoagulant in the plasma specimens. Similarly prepared plasma from normal persons or from unaffected hemophiliacs had no effect on the clotting time of normal blood.

Studies were made to determine the nature of these anticoagulants. Toluidine blue and protamine, which counteract the effect of heparin in normal blood, had no effect on the clotting times of these patients so it seems that the unknown clotting inhibitors are not related to heparin. Assays revealed normal values for proteolytic enzyme and proteolytic enzyme inhibitor in all 3 patients. The anticoagulant was apparently unaffected by heat at 65 degrees centigrade for 5 minutes.

Plasma mixtures containing measured amounts of thrombin and the plasma under study were prepared and subsequent thrombin times showed no variation from controls. This suggests that the anticoagulant

Hypervitaminosis A. Report of 2 Cases in Infants. PHILLIP E. ROTHEMAN and F. ELIZA STEER LEON. *Radiology* 1948, 5: 358

The current popularity of vitamin preparations requires the physician to be alert for signs of overdose. Two cases of hypervitaminosis A in infants over one year of age are presented by these authors. In each child the daily intake of vitamin A was estimated to be in excess of 100,000 international units.

The salient clinical features include a history of excessive intake of vitamin A preparations, anorexia with failure to gain weight, irritability, bone sensitivity, sparse hair, cracking of the lips, hepatomegaly and generalized pruritus. Roentgenographic examination shows evidence of periosteal proliferation, most common in the ulna. Increased vitamin A and carotene levels in the blood are further diagnostic aids. In one child a yellowish tinge to the skin was present.

The treatment consists of discontinuing vitamin A preparations and the reduction of foods containing a high content of vitamin A. Both patients responded

clinically to this treatment in 10 to 24 days the blood levels of carotene and vitamin fell to normal for several months.

A similarity exists between bone changes of cortical hyperostoses and hypervitaminosis A. The former differs clinically in the absence of excessive intake of vitamin A, the fever, a subacute course with recurrence usually before the age of one year. The action in infantile cortical hyperostosis principally the mandible and frequently appearance is seen in the film, indicative of a recurrent course of the disease.

According to the authors, the huge capacity of the liver to store vitamin A rarely necessitates administration of vitamin A in excess of 1000 units. A bibliography of experimental studies on vitamin A is presented.

JOHN L.

Clinical and Experimental Study of Thyroid Substances. Comparative Study of Main Derivatives of Thyronine. A. SPERL and H. L. SPERL. *Arch. internat. pharmacodyn.* 1948, 70: 1

In addition to thiouracil the following have been investigated in regard to effect on hyperthyroidism: derivatives of the thiouracil series, such as diethylthioamide, derivatives of the aromatic phenylthiourea derivatives of the thiouracil series, such as thiouracil, methylthiouracil, thiobarbituric acid, aminothiodiethylthiodiazole.

The authors studied the effect of thiouracil, and aminothiodiethylthiodiazole on the structure of the thyroid gland, and on other organs and the peripheral blood and made histochemical glycogen in the liver and of calcium cholesterol fibrinogen and peripheral blood.

The experiments were performed on guinea pigs, and dogs. The effect was estimated by calculating the gland removed at the autopsy of the animal.

Two classes of phenomena inhibitory substances may be changes (the intensity being dose of the drug) which have a toxic-necrotic effect of the thyroid gland and later changes which are dependent from the entire endocrine inhibitory effect of the thyroid gland.

does not act by an antithrombotic mechanism. Similar mixtures with controlled prothrombin content showed similar results except that one patient (not the hemophilic) who had had a slightly prolonged prothrombin time clinically showed a persistence of this finding. Thus, the prolonged prothrombin time of this individual was apparently due to the unknown anticonagulant in his blood.

With the addition of adequate thromboplastin the plasma specimens clotted immediately and while lesser concentrations of thromboplastin had varied effects, it seems that the anticonagulant may act by preventing the formation of thromboplastin in some way.

Several cases of atypical hemorrhagic syndromes are reviewed from the literature and it is suggested that many of these may have been caused by circulating anticoagulants such as are reported here. Anticoagulant assays of all blood exhibiting prolonged clotting times will likely reveal many more such cases. No therapy is known for this condition.

STANLEY W. TURELL, M.D.

Iachial Decubitus Ulcer. EUGENE BOSS and A. ESTES
COMA R. Surgery 94:3, 4 650

This article summarizes the authors' experience with 47 iachial decubitus ulcers in 41 patients on a paraplegic service. These ulcers were not dependent upon the nutrition of the patients nor did they appear to be related to the level of the spinal cord lesion. The sore-free interval varied greatly from 3 months to 13 years, after which the local trauma of weight bearing pressure broke the urine-moist skin. Atrophy of the gluteal muscles and absence of adequate soft tissue between skin and iachial tuberosity were believed to be contributing factors.

Systemic preoperative preparation consisted of the correction of hypoproteinemia and avitaminosis, liberal transfusions of whole blood and the administration of both penicillin and sulfonamides. Local treatment of the wound consisted of simple débridement.

Operative treatment of the simple ulcer with bursa formation was confined to excision, with suturing of a protective layer of gluteus maximus muscle over the tuberosity and closure of the skin margins. For the more frequently encountered deep ulcer which had involved the bone, removal of the ulcer and bone en bloc was performed. Two methods of closure were then employed. In one (the "primary method") redundant gluteal musculature was pulled over the bone defect by means of stainless steel wire sutures. In the "secondary method," a medially pedicled flap of gluteal muscle was brought down over the bony prominence. In both procedures steel wire was used to close the skin, and the wounds were drained. Fluff gauze pressure dressings were applied and partial immobilization was achieved by the use of an Ace bandage spica.

With this type of treatment cures were effected in 85 per cent of the cases. One operation was sufficient in 66 per cent of the patients. In another 19

per cent, success was achieved after more than one intervention. Comparison of the rates of recurrence and of numbers of cases requiring more than one operation makes the "secondary method" seem slightly more desirable. Of the 7 failures (15 per cent of the series) the first one may be attributed to faulty interpretation of roentgenograms wherein the bone changes were unrecognized and hence untreated. A second failure resulted from a series of unfortunate postoperative incidents. A third patient, whose repair failed to hold, had a periproctitis and sat up for unduly long periods during the healing of the wound. Two other patients also sat for unduly long periods, driving their cars. A sixth patient developed a postoperative hematoma in spite of the use of drains in the wound. The seventh patient left the hospital on an emergency leave before the scar had become stable.

The authors advocate early use of braces and thorough instruction of the patients as prophylaxis against the development of ulcers.

BENJAMIN F. LOUGHEUR, M.D.

Skin Lesions Due to Pitch and Tar. PHILIP ROSE.
Brit. M. J. 91:8, 350.

The widespread use of tar and pitch for various industrial purposes has led to an appreciable incidence of skin lesions among workers who repeatedly handle these materials. Tar is produced by the distillation of coal, and pitch is the residue left after the distillation of tar. Both materials contain hydrocarbon compounds of varying complexity, one of which, benzo(a)pyrene, is carcinogenic. In addition heavier oils, tar and pitch have the following common characteristics: they are all skin irritants; they are solvents of lipid and cholesterol; and they are astringent and keratoplastic.

In his own experience, the author has been unable to differentiate between the effects of the two materials, but he has noted the following types of reaction: tar burn; tar erythema; allergic excretory dermatitis; folliculitis; acne; and comedones; pitch and tar melanosis; shagreen skin; neoplastic changes; and epitheliomas. Tar erythema follows the action of bright sunlight on skin rendered sensitive by some as yet unknown ingredient in pitch and tar. The ultraviolet of sunlight appears also related to the development of epithelioma, accelerating the action of the carcinogen in tar and pitch by some mysterious mechanism. For skin malignancy has occurred much more rapidly in country workers than in city workers whose environment differs appreciably only in that they are exposed to much less sunshine. The earliest macroscopic change resulting from tar and pitch exposure is seen in the cornified layer of the skin, where keratoses occur. Somewhat later the papillomas—simple wart, typical pitch wart, and soft papillomas—appear on the face, neck, scrotum, forearms, and backs of the hands.

By way of prophylaxis against these skin changes, and especially against the development of malignant changes which may occur years after the exposure

has ceased certain suggestions are made. Workmen's clothing should be relatively impermeable secured at ankles, wrist, and neck and it should be changed frequently. Protective gauntlets and goggles should be worn. Barrier creams should be applied to all susceptible parts of the body before each working shift, and a thorough bath should be taken after each shift. Frequent inspection of the skin of exposed employees is essential to prophylaxis as well as to treatment of established lesions.

This article contains 6 good color plates depicting typical skin lesions, statistical tables on the situation and latent periods of the various lesions, and a formula for starch kaolin paste used to prevent tarry erythema.

BENJAMIN F. LOUNSBURY, M.D.

Acanthosis Nigricans and Plastic Surgery (*Acanthosis nigricans et chirurgie plastique*) GEORGES CLOUTIER and PAUL POULIER *Univ. med. Canada*, 1948 77 931

Plastic surgery as an adjunct in the management of far advanced acanthosis nigricans is discussed by these authors. The case of a 22 year old female with chronic dermatitis of 6 years' duration is presented. On physical examination and subsequent biopsy the skin lesions were typical of acanthosis nigricans involving chiefly the cervical, axillary, mammary and inguinal regions and manifesting itself by exaggeration of the normal folds of the skin, numerous papillary excrescences and hyperpigmentation. The involved skin of both axillary regions was removed and replaced by skin grafts from both thighs in three operative procedures. A good cosmetic and functional result was obtained.

History revealed carcinoma in a immediate relatives. Laboratory studies disclosed an elevated basal metabolic rate on 2 occasions. The remaining portions of the history, physical and laboratory examination were not contributory.

Acanthosis nigricans is a disease of the skin characterized by an exaggeration of the normal skin folds with papillary growths and hyperpigmentation. Its frequent occurrence in cases of intra-abdominal carcinoma has been noted. Although its etiology and pathogenesis are for the most part unknown, endocrine factors are believed important, as was shown by the elevated basal metabolism in this patient. The author distinguishes two types: the juvenile (benign) and the adult (those cases usually associated with intra-abdominal adenocarcinoma).

C. FREDERICK KITTEL, M.D.

Pigment Nephropathy in Battle Casualties. HOWARD E. SWEENEY and JAMES W. CULBERTSON *Arch. Surg.*, 1948 56 651

Deaths among soldiers of the Fifth Army who were wounded in battle during the period from January 1, 1944 to May 31, 1945 included 99 in whom pigment nephropathy was a direct or indirect cause, and another 57 in whom this syndrome was suspected of contributing to a fatal outcome. Of the 1,411 deaths on which reports were available, 68 were be-

lieved to be caused directly by pigment nephropathy whereas in another 31 it was at least a contributing cause. Autopsy was performed in 90 of these 99 cases.

Although the authors describe pigment nephropathy or lower nephron nephrosis in connection with battle casualties, they point out that it may occur in a variety of traumatic situations. In wounded soldiers the condition consists of progressive oliguria and anuria developing in patients who have undergone extensive surgery after resuscitation from shock and who appear to be recovering. Those patients most severely affected died from 4 to 8 days after being wounded. The renal damage appears to stem from ischemia of the kidney and concomitant excretion of pigment, either hemoglobin (from transfused blood intravascular hemolysis or other sources) or myoglobin (from extensive crushing of muscle). The ischemia is vasoconstrictive in nature, but it has not been determined whether the vasoconstriction results from the action of a toxin liberated from injured tissues or is a reflex phenomenon.

Analysis of the 99 deaths shows that in most instances the primary wounds were relatively severe. There were many associated wounds of varying severity. All but 3 of the patients had been in shock of some degree. Four of the 5 had sustained a transfusion reaction, crush injury or poisoning by sulfadiazine whereas the record of the fifth was so inadequate as to permit of no valid conclusions. The data on recorded blood pressures and amounts of plasma and blood administered serve as rough measures of the degree and duration of the shock. As a further indication of the severity of the wounds, it is noted that in the 56 cases for which the operating time was stated, only 1 case required an operating time of less than an hour, whereas 17 cases required 5 hours or more.

The authors discuss the work of investigators who have studied the syndrome in experimental animals, and the observations of clinicians. They conclude that treatment should be prophylactic. Shock should be combated and blood volume restored to normal as soon as possible. They feel that oxygen therapy should be employed more often to combat the anoxia which must result from vasoconstriction in the renal circulation. Since dehydration has been established as an etiologic factor, they advocate adequate hydration of the patient as soon as possible. When used, sulfadiazine must be carefully administered and the patient closely observed. Where the potentialities exist for nephropathy, such drugs should be discontinued.

BENJAMIN F. LOUNSBURY, M.D.

Necrotic Lesions of the Leg in Arteriosclerosis. EDWARD A. EDWARDS. *N. England J. M.*, 1948 339 571

Six cases of arteriosclerotic necrosis of the skin and subcutaneous tissue of the lower extremities are presented. This condition carries the same import as necrosis of the toes or feet. It may arise spontaneous-

The therapeutic response observed, as well as the striking similarity between the calculated dose and the actual dose needed to produce therapeutic effects lends support to the validity of the original thesis upon which these studies were undertaken.

It is also significant that the observations reported here give insight into the mechanism of adaptation by malignant cells. Although the phenomenon of adaptation still constitutes a major limitation in this and other chemotherapeutic modalities, it appears that it does not involve the creation of enzymatic mechanisms *de novo* but rather the utilization of previously existent secondary pathways.

There were no deleterious effects observed particularly as regards the retina and intestinal mucosa. These tissues have been reported as having metabolic activity similar to neoplastic tissue particularly with regard to a high glycolytic activity.

DAVID H. LYNN, M.D.

Review of the Problem of Air Contamination in Operating Rooms and of the Diverse Procedures of Air Sterilization (Revue sur le problème de la contamination de l'air des locaux opératoires et sur les divers procédés de stérilisation de l'air) FRANK DIASCONTI and MARC FLEURY. *Rev. chir. Par.* 1948, 67: 140.

Dust particles containing bacilli may travel in the air either in dry form or as minute droplets of about 0.1 micron in diameter. A number of physical factors contribute to purify the air from bacterial contamination and have been used in attempts to sterilize the air. Rise of the temperature causes evaporation and lowering of the temperature causes condensation and precipitation of these droplets. A cold object brought into a warmer room causes condensation of droplets on its surface. Therefore it is dangerous to bring a tray with sterile instruments into an unsterilized warm operating room. If the temperature of the tray is lower than that of the room, droplets containing bacteria will precipitate on its surface.

Other physical factors that have been used for purifying purposes are lowering of the air pressure, high humidity leading to precipitation, ultraviolet rays, radioactivity, electric ionization, and filtration of the air through different absorbing materials.

Also a great number of chemical substances have been used for air sterilization, especially oxidizing agents (ozone, formalin, glycol, propylene, and others). However, they are inconvenient because of their odor and irritation of the respiratory passages or they are too expensive or not effective or both.

The authors criticize the different methods in use at the present time. They have devised a method which they claim to be effective, rapid, and economical before an operation: the air of the operating room is saturated with water vapor until a dense mist forms. The very small droplets of this mist fix immediately the small dust particles containing bacteria. This mist is then condensed on the surfaces of a large condenser which is cooled by water.

WERNER M. SOLMITS, M.D.

Biologic Studies of Surgical Shock. Paroxysmal Arterial Hypertension Following Any Tissue Trauma Is Due to Adrenalin Secretion by the Suprarenal Gland (Étude biologique du choc chirurgical. L'hypertension artérielle paroxysmique secondaire à tout traumatisme tissulaire est due à une décharge adrénalinique des surrénales) J. DRIESSEN. *Rev. chir. Par.* 1948, 67: 139.

In an earlier publication the author showed that the drop of the blood pressure in surgical shock is always preceded by a very short period of marked hypertension. By systematic continuous registration of the pressure inside of the carotid artery it could be demonstrated that this hypertensive period consists of a sequence of momentary very transitory shocks which are of too brief duration to be observed with the usual sphygmomanometer.

In the present article the author reports a series of experiments on the curarized dog to prove that the hypertension preceding the hypotension of shock is due to the secretion of adrenalin which is caused by traumatism of the tissue.

The hypertension lasts only a few seconds, the blood pressure rising about 25 to 30 seconds above the normal level. It can be repeated any number of times by a new trauma in the same animal (cutting of the skin, manipulation of the intestine, or severing of a portion of muscle). Parallel to the hypertension there occurs hyperglycemia, a further proof of the adrogenic nature of the hypertension. By the intravenous injection of adrenalin the same characteristic curve of the elevated blood pressure and hyperglycemia can be brought about.

Furthermore the volume of the spleen was measured in a plethysmograph and it was shown that the volume decreased considerably with each trauma exerted on the curarized animal.

When the lumbodrenal vein was ligated proximally and distally to the gland, subsequent traumatism failed to produce hypertension and hyperglycemia. When the splanchnic nerves were paralyzed by cocaine infiltration, subsequent trauma produced only a very slight elevation of the blood pressure.

EXPERIMENTAL SURGERY

Attempts at the Production of Experimental Neoplasms by the Injection of Thorotrast (Versuche peritoneale Untersuchungen zur Frage der Geschwulstentstehung durch intravenöse Thorotrastinjektionen) LUDWIG RULAND. *Chirurg.* 1947, 17-18: 540.

The author states that several writers have remarked that a tumor forming process may require a latent period of from 10 to 25 years in the human before the neoplasm comes into being. In certain animals latent periods have been accurately worked out for carcinogenic agents. Thus the author decided to observe a series of animals beyond the maximum of the latent period to observe the carcinogenic properties of a 25 per cent colloidal suspension of thorium dioxide.

ly or may follow local trauma or infection. Because of the advanced age of the patients and the marked arteriosclerosis the tissues limit infection poorly and septicemia is common. It is frequently accompanied by thrombosis of the deep veins and pulmonary embolism may occur.

Treatment usually requires hospitalization and an attempt to control infection by chemotherapy. If necrosis is widespread and deep or if infection is spreading rapidly amputation should be carried out immediately. The author favors the local use of streptomycin solution with systemic chemotherapy. If enough thrombosis present the femoral canal should be ligated if a present dicumol or heparin should be given. Lumbar sympathectomy should be considered if there is a good skin temperature response to proximal anesthesia and if there appears to be no chance of saving the leg. If varicose veins are the cause of local infection they should be treated by high ligation of the saphenous vein. A decision as to the need of amputation should be made as soon as possible. ROSE, M. Y. and TAYLOR, M. D.

Fibrinolysis: Its Mechanism and Significance. R. C. MCGILL and ROSEMARY BLOOM. *Blood* 9:48, 5-6.

The authors define fibrinolysis as the septic dissolution of fibrin brought about by the direct action of a mechanism existing in normal blood. Although fibrin in tissue blood clots usually remain intact for days or weeks, a rapid lysis of fibrin may occur following the direct action of fibrinolytic organisms. Fibrinolysis is probably the result of proteolytic digestion by enzymes.

Previous experimental work has shown that proteolytic enzymes present in serum (plasmin) are activated by fibrin which destroy some substrate, creating a fibrinolytic (antiplasmin). Fibrinolysis of plasma proteins may also result in proteolytic activity by separating enzymes and inhibitors. Recent studies have shown that streptococcal fibrinolysinase causes liberation of a proteolytic enzyme (plasmin) from serum by activating its precursor (plasminogen). Thus fibrinolysis which is induced by streptokinase, chloroform, fractionation, or dilution is in the living subject is the active plasmin which will also digest plasma protein, casein, and gelatin.

Antiplasmin is associated with the albumin fraction of the plasma, whereas plasmin and plasminogen are associated with the globulin fraction. Enzymes resembling plasmin have been found in various tissues especially of the lung and urine and inhibitors resembling plasmin have also been found in various tissues particularly in the spleen and liver.

Observations in the living subject indicate that fibrinolysis may occur following stimulation of the plasma by severe exercise or the injection of adrenalin. The mechanism of plasmin activation in these cases is obscure and can be obtained in the absence of a normal function of the liver, pancreas, adrenals and suprarenal cortex. Cumulative evidence

suggests that the plasmin-antiplasmin complex plays a fundamental part in several essential physiological processes such as shock, protein breakdown, synthesis equilibrium, blood coagulation, and other reactions. S. LLOYD TITCHELHAM, M.D.

Energy Mechanisms in Malignant Tumors in Relation to Chemotherapy. MATTHEW M. RUSSELL, ISRAEL S. KLEINER, and HERMAN BOLKER. *Cancer Res.* 9:48, 7-8:13.

The differences in metabolism between normal and malignant tissues have been the basis for many attempts to develop chemotherapeutic measures.

A new approach toward a rational chemotherapy of malignant tumors seems indicated in terms of energy rich phosphate bonds. Thus if malignant cells are particularly dependent on the glycolytic mechanism for their energy requirements, it might be possible to inhibit their activity if one could selectively limit the formation or utilization of these bonds.

Based on this concept, an hypothesis of biochemical function in malignant tissue as compared to normal was formulated as follows: with the abnormal malignancy there is a significant alteration in energy mechanism of tissue. The preferred pathway involves the glycolytic mechanisms while the respiratory enzyme reactions are diminished as compared with their role in normal tissue. The respiratory functional potentiality is not absent but merely residual. The glycolytic mechanism itself may be divided into (a) the primary portion from triphospholactic acid, and (b) the tricarboxylic acid cycle which is a secondary mechanism for energy production.

To obtain maximum destruction of energy-producing reactions in malignant tissue, inhibition of the primary glycolytic mechanism would occur at the points of creation of the high energy phosphate bonds. Such reactions are inhibited by iodoacetic acid and sodium fluoride. Adaptation of malignant tissue to these inhibitors occurs and is associated with utilization of a secondary mechanism for energy production. The tricarboxylic acid cycle is a secondary pathway. Inhibition of the cycle can be accomplished by the use of malonic acid which inhibits the succinate dehydrogenase system. Finally, adaptation after initial sensitivity of the malignant tissue to the glycolytic inhibitors would occur might well be accomplished over the dynamic metabolic pathways that is, those using the respiratory enzyme chains, particularly cytochrome oxidase. Such reactions might be inhibited by the use of cyanide which blocks oxidase activity.

This report gives the results of preliminary experiments based on the concepts mentioned. The various inhibitors were administered in divided doses to patients with the following diseases: acute myeloblastic leukemia in 10 patients; lymphatic leukemia in 4; acute monoblastic leukemia in 1; gastric carcinoma in 3; lymphosarcoma in 1; carcinoma of the colon in 3; carcinoma of the prostate in 4; carcinoma of the testis in 2; and Hodgkin's disease in 3.

The temperature observed, as well as the striking relation between the calculated dose and the actual dose needed to produce the temperature rise is in support of the validity of the original ideas upon which these studies were undertaken.

It is also significant that the observations reported here prove that the mechanism of adaptation by cutaneous cells, although the phenomenon of adaptation still constitutes a major limitation in this and other thermotempore modalities, it appears that it does not involve the creation of regulatory mechanisms *de novo* but rather the utilization of previously existing secondary pathways.

There were no deleterious effects observed, particularly as regards the retina and intestinal mucosa. These tissues have been reported as having metabolic activity similar to neoplastic tissue, particularly with regard to a high glycolytic activity.

DENNIS H. LEXS, M.D.

Review of the Problem of Air Contamination in Operating Rooms and of the Diverse Procedures of Air Sterilization (Revue sur le problème de la contamination de l'air des locaux opératoires et sur les divers procédés de stérilisation de l'air) FERNAND L. GONZALEZ and MARIE FLAUGNOT. *Rev. chir.*, Paris, 1946, 1: 164.

The particles containing bacilli may travel in the air in dry form or as minute droplets of about 0.5 to 1.0 microns in diameter. A number of physical factors have been used to purify the air from bacterial contamination, and have been used in attempts to purify the air. Rise of the temperature causes evaporation and lowering of the temperature causes condensation and precipitation of these droplets. Air is not brought into a warmer room causes condensation of droplets on its surface. Therefore, air is brought to a tray with sterile instrument with temperature of the tray is lower than that of the air—droplets containing bacteria will precipitate on the tray.

Physical factors that have been used for sterilization are lowering of the air pressure, raising of the air pressure, precipitation, ultraviolet light, and electric ionization and filtration of the air through different absorbing materials. The use of chemical substances have been used for sterilization, especially oxidizing agents like formalin, glycol propylene and formaldehyde. They are inconvenient because of their irritation of the respiratory passages and they are not effective or both. Various methods of the different methods in use have been devised. They have devised a method of passing the air of the operating room through a tray of water vapor until a dense mist is formed. The very small droplets of this mist fix the very small dust particles containing bacteria. These are then condensed on the surfaces of the tray which is cooled by water.

Biologic Studies of Surgical Shock. Paroxysmal Arterial Hypertension Following Any Tissue Trauma Is Due to Adrenalin Secretion by the Suprarenal Gland (Étude biologique du choc chirurgical. L'hypertension artérielle paroxysmique secondaire à tout traumatisme tissulaire est due à un écoulement adrénalinique des surrénales) J. DUBREUIL. *Rev. chir.*, Paris, 1946, 67: 1-10.

In an earlier publication the author showed that the drop of the blood pressure in surgical shock is always preceded by a very short period of marked hypertension. By systematic continuous registration of the pressure inside of the carotid artery it could be demonstrated that this hypertensive period consists of a sequence of momentary very transitory shocks which are of too brief duration to be observed with the usual sphygmomanometer.

In the present article the author reports a series of experiments on the curarized dog to prove that the hypertension preceding the hypotension of shock is due to the secretion of adrenalin which is caused by traumatism of the tissue.

The hypertension lasts only a few seconds the blood pressure rising about 25 to 30 seconds above the normal level. It can be repeated any number of times by a new trauma in the same animal (cutting of the skin, manipulation of the intestine, or severing of a portion of muscle). Parallel to the hypertension there occurs hyperglycemia a further proof of the adrenogenic nature of the hypertension. By the intravenous injection of adrenalin the same characteristic curve of the elevated blood pressure and hyperglycemia can be brought about.

Furthermore the volume of the spleen was measured in a plethysmograph and it was shown that the volume decreased considerably with each trauma exerted on the curarized animal.

When the lumbodrenal vein was ligated proximally and distally to the gland subsequent traumatism failed to produce hypertension and hyperglycemia. When the splanchnic nerves were paralyzed by cocaine infiltration, subsequent trauma produced only a very slight elevation of the blood pressure.

EXPERIMENTAL SURGERY

Attempts at the Production of Experimental Neoplasms by the Injection of Thorotrast (Tierexperimentelle Untersuchungen zur Frage der Geschwulstentstehung durch Intravenöse Thorotrast-Injektionen) LUDWIG RULAND. *Chirurgia* 1947, 17: 18-540.

The author states that several writers have remarked that a tumor forming process may require a latent period of from 10 to 25 years in the human before the neoplasm comes into being. In certain animals latent periods have been accurately worked out for carcinogenic agents. Thus the author decided to observe a series of animals beyond the maximum of the latent period to observe the carcinogenic properties of a 25 per cent colloidal suspension of thorium dioxide.

Three factors demanded consideration (1) the continued action of the thorium as an irritating foreign body in the tissues, (2) the radioactivity of the thorium and (3) the susceptibility of the animal to carcinogenesis. In these experiments both rats and guinea pigs were employed. A point of lessened resistance was produced by fracturing the tibia at the epiphysis, a point of active growth.

The animals were given an autopsy examination if death occurred from an intercurrent disease, or they were sacrificed at 26 months. Although active thorium dioxide was found in the areas of the trauma, and although an active chronic inflammatory reaction was often present no tumors were found in any of the animals. The author believes that the processes which were observed may be interpreted as precancerous manifestations.

He concludes that these experiments are equivocal, and should not be used for an interpretation of what may occur in man. The latent period for the observance of cancer in patients who have received injections of thorium has not yet been reached as this material did not become available for general use until 1934. Also the changes which he saw in his animals might be more progressive in man.

WILLIAM C. BECK, M.D.

Amputation of the Canine Atrial Appendages.
H. K. HELLERSTEIN, E. SWEINCO, and M. DOLGIN.
Surgery 94:5, 24-79.

The left atrial appendage is frequently the site of thrombus formation and the source of the multiple arterial emboli which often complicate rheumatic mitral disease. Since there is no effective treatment for this condition, surgical excision of the involved atrial appendage is suggested as a possible solution.

To test the feasibility of such a procedure, the left atrial appendage was surgically removed from 5 dogs; the right atrial appendage was excised in 1 dog, and in 1 dog both appendages were removed. The procedure generally used was simple clamping at the base of the appendage, ligation, amputation, and a reinforcing transfixion suture. An anterior intercostal approach was used, with or without rib resection. Each dog received 200,000 units of penicillin daily for 2 weeks postoperatively and serial electrocardiograms were taken.

One dog died 15 minutes after the closure of the incision. The other seven dogs recovered successfully and were active and normal in appearance within 7 days. Follow-up electrocardiograms showed no changes indicative of myocardial damage or abnormal atrial rhythm, except that one dog had a transient intra-atrial block. Autopsies, performed 4 to 12 weeks postoperatively, revealed excellent healing of the atrial incisions in all dogs, with complete endothelialization of the endocardial surface. No mural thrombi were found. Firm adhesions were present between the visceral and parietal pericardium at the stump of the atrial appendage. There was no evidence of emboli or infarction in any other organs. The histologic report verified the gross observation of firm healing of the atrial incisions.

It is concluded that one or both atrial appendages may be surgically excised in the normal dog without significantly altering the normal physiology of the heart. The feasibility of this procedure in patients with atrial appendages containing mural thrombi deserves further consideration. The atrial appendages may provide a more convenient approach in intracardiac surgery than the ventricular approach.

METHODS FOR PRESERVATION AND TRANSPLANTATION OF ARTERIAL GRAFTS

Observations on Arterial Grafts in Dogs Report of Transplantation of Preserved Arterial Grafts in 9 Human Cases

ROBERT E. GROSS M.D., F.A.C.S. ALEXANDER H. BILL, Jr. M.D. and
E. CONVERSE PEIRCE, 2nd M.D., Boston, Massachusetts

IN certain operative procedures it would be of great value to be able to bridge an arterial defect with a graft provided the method of grafting is reliable and is not cumbersome. Vein grafts (from the same individual and from other humans) have been used with some success and are reasonably satisfactory if one is repairing arteries which are not of great size. There has been no safe method for permanently replacing a segment of a very large artery especially the aorta and it is to this problem that we have turned our attention.

Veins and arteries have been grafted into animals from the same animal (autografts) from the same species (homografts) and from other species (heterografts) (1 3 4 5 6 8 9 13 14 18 26 31 32 33). It has been generally reported that autografts or homografts are more satisfactory than heterografts (5 6 8 9 14 15). Many substitutes for blood vessels have been suggested. Various inert substances have been suggested or tried for bridging blood vessel defects (10 11 23) including tubes of glass of aluminum of gold plate and

of silver lined with paraffin. All of these substances have led to thrombosis. Recently, lucite channels for intubation of vessels (19) has led to more promising results. Rigid rings (vein lined) for the nonsuture method of joining vessels have been made from ivory (25) magnesium (28) and vitallium (1).

A wholly satisfactory solution to the problem of bridging a gap in large arteries or in the aorta would seem to lie in the direction of providing a vascular graft which is viable which would resemble the normal vessel after implantation which could withstand intra arterial pressures which would not cause thrombosis and which would not set up serious reaction in the regional tissues. Knowing that transplantation of fresh arterial grafts from one animal to another had shown varying degrees of survival in the hands of Carrel and Guthrie (6 8 14) and others (3 18 31) we undertook to repeat and extend some of their work, and to investigate extensively methods for preservation and storage of arterial grafts. As a preliminary part of our investigations a study was made of the effects of transplantation of fresh aorta from one dog to another this is being reported elsewhere by Gross and Hurwitt (13).

From the Department of Surgery, (The Harvard Medical School and the Medical Services of The Children's Hospital and the Peter Bent Brigham Hospital.

Three factors demanded consideration (1) the continued action of the thorium as an irritating foreign body in the tissues, (2) the radioactivity of the thorium and (3) the susceptibility of the animal to carcinogenesis. In these experiments both rats and guinea pigs were employed. A point of lessened resistance was produced by fracturing the tibia at the epiphysis a point of active growth.

The animals were given an autopsy examination if death occurred from an intercurrent disease or they were sacrificed at 26 months. Although active thorium dioxide was found in the areas of the trauma, and although an active chronic inflammatory reaction was often present no tumors were found in any of the animals. TABLE I. RESULTS OF IMPLANTATION OF HOMOGRAFTS (PRESERVED BY QUICK FREEZING TO -72 DEGREES C.) INTO DOG AORTAS

Recipient dog No.	Atmosphere in storage tube	Length of time used preserved	Length of life of dog post-operatively	Cause of death	Fate of graft
1-7	Air	days	da	Hemorrhage	Graft broke down
16	Air	8 da	da	Hemorrhage	Graft broke down and completely thrombosed
	Air	days	60 days	Hemorrhage	Graft broke down
26	Air	da	da	Hemorrhage	Graft broke down and completely thrombosed
	Air	days	6 months	Sacrificed	Intimal sclerosis
	Air	days	8 da	Hemorrhage	Graft broke down
	Air	60 da	da	Hemorrhage	Graft broke down. Two thrombi
7	Helium	da	20 da	Hemorrhage	Graft broke down. Some thrombus
1	Helium	days	da	Peritonitis	Tubular aortal thrombus, non thick
66	Helium	da	8 da	Hemorrhage	Graft broke down and completely thrombosed
	Helium	8 da	days	Hemorrhage	Graft broke down
126-7	Helium	days	months	(Still alive)	Considerable aortal thrombus by aortotomy

Preservation of blood vessels has been studied previously by other surgeons. Carrel (7-9) preserved arteries by storage in a refrigerator at temperatures above freezing in various media, including vaseline salt solution defibrinated blood and humid air. With these methods he had some degree of success in survival of the grafts following their implantation into other dogs. His results are rather difficult to evaluate because of the relatively few experiments in each method of study. Recently Blakemore and Lord (1) and also Hufnagel (20) have reported the successful preservation of arteries and veins by quick freezing and storage at temperatures well below freezing. The successful transplantation of an artery after preservation in formalin was reported by Levin and Larkin (21-22) but they were apparently unable to repeat this in later experiments. This was later successfully repeated by Guthrie (16).

The third series was designed to investigate the preservation and use of homografts (from an animal of the same species) storing the grafts at temperatures just above freezing in appropriate media, the constituents of which were based on formulas developed by others interested in the field of tissue culture techniques and which were suggested to us by J. H. Hanks (17) of the Department of Bacteriology of the Harvard Medical School. We thought that it would be of interest to determine whether various methods of preservation would allow the tissues of a vessel to remain alive; hence it was decided to parallel our animal experimentations with tissue culture studies of specimens of the preserved vessels (29). Microscopic studies of implanted grafts were also planned; these were conducted (and will be reported) by Alan R. Moritz.

EXPERIMENTAL GRAFTS IN ANIMALS

branches were tied with fine silk. It was cut into 30 centimeter lengths.

When a segment of aorta was to be implanted into a recipient animal the technique used was as follows. The dog was anesthetized with intravenous nembutal and the abdomen was opened through a left rectus incision. The abdominal aorta, between the renal arteries and the inferior mesenteric artery was exposed and freed of branches for a distance of about 50 centimeters. It was then occluded in two places either by the use of aortic clamps such as described by Gross and Hufnagel (12) or by the use of tape tourniquets and severed between the two occluded points. A generous cuff was left beyond each clamp or tourniquet. After an aorta was thus divided its cut ends retracted for a distance of approximately 30 centimeters the graft to be tested was sutured into place between those ends (Fig. 4). The anastomoses were made by a single, continuous everting mattress stitch using 5-0 Deknatel silk on an atraumatic needle. The insertion of such a graft took an average of 45 minutes following which the clamps or tourniquets were removed. The peritoneum was then brought together over the aorta and the abdomen was closed. No chemotherapy or anticoagulants were used. No damage to the spinal cord or hind limbs was observed as a result of the occlusion of the aorta during these operations.

Series A implantation of aortic homografts (preserved at -70 degrees centigrade) Twelve grafts were carried out with vessels which had been preserved at -70 degrees centigrade. The segments of aorta were obtained from donor dogs and placed in sterile test tubes which were hermetically sealed. Seven of these contained room air. In the five remaining tubes the air in the tube was replaced by an atmosphere of helium under pressure of 20 to 40 millimeters of mercury above atmospheric level. This was done in an attempt to repeat the work of Hufnagel (20) who felt that helium (particularly under pressure) was a better conductor of heat than was air and hence would allow quicker freezing of the vessel.

When sealed the test tube containing an aortic segment was immersed in a beaker con-

Fig. 1. Blood vessel in Erlenmeyer flask containing nutrient medium, ready for storage in refrigerator.

taining 300 cubic centimeters of 95 per cent alcohol in which was floating one-half its volume of carbon-dioxide ice. The temperature of this mixture was -72 degrees centigrade. The tubes were kept in this for 15 minutes and were then stored in a carbon-dioxide ice refrigerator at a temperature of about -70 degrees centigrade. The vessels were stored in this manner for lengths of time varying between 2 and 35 days. When a vessel was to be implanted into a recipient dog it was thawed by immersing its test tube for 10 minutes in a bath of water at 35 degrees centigrade after which it was removed from the tube and placed in a bowl of Ringer's solution at the operating table. It was then sutured into the abdominal aorta of a recipient dog as described previously. Table I shows the results.

It will be seen that of 12 dogs 1 dog died of pneumonia in 19 days. 2 dogs survived for at least 6 months with fairly good arterial pathways and 9 died of breakdown of one of the anastomoses. The grafts which broke down did so between 2 and 12 days in 7 cases and at 20 and 30 days in the other 2. Examination of these 9 autopsy specimens showed that the grafts themselves were friable and necrotic to the point of allowing the sutures to pull out

TABLE I—RESULTS OF IMPLANTATION OF HOMOGRAFTS (PRESERVED BY QUICK FREEZING TO - 2 DEGREES C.) INTO DOG AORTAS

Recipient dog No.	Atmosphere in storage tube	Length of time vessel preserved	Length of life of dog post operation	Cause of death	Fate of graft

	Formalin	24	24	Pyemia	Tubular mural thrombus seen thick
65	Formalin	24	8 days	Hemorrhage	Graft broke down and completely thrombosed
66	Formalin	24	24	Hemorrhage	Graft broke down
67	Formalin	24	3 months	(Still alive)	Considerable mural thrombus by aortostomy

Preservation of blood vessels has been studied previously by other surgeons. Carrel (7-9) preserved arteries by storage in a refrigerator at temperatures above freezing in various media including vaseline salt solution defibrinated blood and humid air. With these methods he had some degree of success in survival of the grafts following their implantation into other dogs. His results are rather difficult to evaluate because of the relatively few experiments in each method of study. Recently Blakemore and Lord (1) and also Hufnagel (20) have reported the successful preservation of arteries and veins by quick freezing and storage at temperatures well below freezing. The successful transplantation of an artery after preservation in formalin was reported by Levin and Larkin (21-22) but they were apparently unable to repeat this in later experiments. This was later successfully repeated by Guthrie (16).

Based on knowledge of the above previously published data, we outlined and completed three sets of animal experiments. In the first series of experiments an attempt was made to duplicate the work of Blakemore and Lord and of Hufnagel in quick freezing the grafts and storing them at about -70 degrees centigrade. The second series was to investigate further the feasibility of preservation and use of heterografts (from one species to another).

The third series was designed to investigate the preservation and use of homografts (from an animal of the same species) storing the grafts at temperatures just above freezing in appropriate media, the constituents of which were based on formulas developed by others interested in the field of tissue culture techniques and which were suggested to us by J. H. Hanks (17) of the Department of Bacteriology of the Harvard Medical School. We thought that it would be of interest to determine whether various methods of preservation would allow the tissues of a vessel to remain alive; hence, it was decided to parallel our animal experiments with tissue culture studies of specimens of the preserved vessels (29). Microscopic studies of implanted grafts were also planned; these were conducted (and will be reported) by Alan R. Moritz.

EXPERIMENTAL GRAFTS IN ANIMALS

Grafting into the abdominal aortas of dogs was selected as the method for the operative work. In such a large vessel anastomoses are easily performed and it is possible to evaluate the grafts without being hampered by thromboses which are apt to be troublesome when working with small vessels. The arteries to be preserved and tested were taken under sterile conditions from animals which had been sacrificed. The aorta was removed and its

branches were tied with fine silk. It was cut into 3.0 centimeter lengths.

When a segment of aorta was to be implanted into a recipient animal the technique used was as follows. The dog was anesthetized with intravenous nembutal and the abdomen was opened through a left rectus incision. The abdominal aorta between the renal arteries and the inferior mesenteric artery was exposed and freed of branches for a distance of about 5.0 centimeters. It was then occluded in two places either by the use of aortic clamps such as described by Hufnagel (12) or by the use of rubber tourniquets and severed between the two occluded points. A generous cuff was left on each side of the clamp or tourniquet. After an aortic segment was divided the cut ends retracted proximally 3.0 centimeters. The graft to be tested was sutured into the aorta between those ends (Fig. 4). The anastomosis was made by a continuous suture stitch using 5-0 Deknatel silk thread and a automatic needle. The insertion of the needle took an average of 45 minutes in which the clamps or tourniquets were removed. The peritoneum was then sutured together over the aorta and the abdominal wall was closed. No chemotherapy or antibiotics were used. No damage to the spinal cord or hind limbs was observed as a result of the occlusion of the aorta during these operations.

Series A: Implantation of aortic homografts (preserved at -70 degrees centigrade). Twelve grafts were carried out with vessels which had been preserved at -70 degrees centigrade. The segments of aorta were obtained from donor dogs and placed in sterile test tubes which were hermetically sealed. Seven of these contained room air. In the five remaining tubes the air in the tube was replaced by an atmosphere of helium under pressure of 20 to 40 millimeters of mercury above atmospheric level. This was done in an attempt to repeat the work of Hufnagel (10) who felt that helium (particularly under pressure) was a better conductor of heat than was air and hence would allow quicker freezing of the vessel.

When sealed the test tube containing an aortic segment was immersed in a beaker con-

FIG. 1. Erlenmeyer flask containing nutrient medium, ready for storage in refrigerator.

taining 500 cubic centimeters of 95 per cent alcohol in which was floating one-half its volume of carbon-dioxide ice. The temperature of this mixture was -70 degrees centigrade. The tubes were kept in this for 15 minutes and were then stored in a carbon-dioxide ice refrigerator at a temperature of about -70 degrees centigrade. The vessels were stored in this manner for lengths of time varying between 1 and 12 days. When a vessel was to be implanted into a recipient dog it was thawed by immersing its test tube for 10 minutes in a bath of water at $+5$ degrees centigrade, after which it was removed from the tube and placed in a bowl of Ringer's solution at the operating table. It was then sutured into the abdominal aorta of a recipient dog as described previously. Table I shows the results.

It will be seen that of 12 dogs 1 dog died of pneumonia in 10 days, 2 dogs survived for at least 6 months with fairly good arterial pathways and 0 died of breakdown of one of the anastomoses. The grafts which broke down did so between 1 and 12 days in 7 cases and at 70 and 90 days in the other 2. Examination of these 9 autopsy specimens showed that the grafts themselves were viable and necrotic to the point of allowing the sutures to pull out

branches were tied with fine silk. It was cut into 3.0 centimeter lengths.

The abdominal aorta, between the renal arteries and the inferior mesenteric artery was exposed and freed of branches for a distance of about 5.0 centimeters. It was then occluded in two places, either by the use of aortic clamps such as described by Gross and Hufnagel (12), or by the use of tape tourniquets and severed between the two occluded points. A generous cuff was left beyond each clamp or tourniquet. After an aorta was thus divided, its cut ends retracted for a distance of approximately 3.0 centimeters the graft to be tested was sutured into place between those ends (Fig. 4). The anastomoses were made by a single continuous everting mattress stitch, using 5-0 Deknatel silk on an atraumatic needle. The insertion of such a graft took an average of 45 minutes, following which the clamps or tourniquets were removed. The peritoneum was then brought together over the aorta and the abdomen was closed. No chemotherapy or anticoagulants were used. No damage to the spinal cord or hind limbs was observed as a result of the occlusion of the aorta during these operations.

Series A: implantation of aortic homografts (preserved at -70 degrees centigrade). Twelve grafts were carried out with vessels which had been preserved at -70 degrees centigrade. The segments of aorta were obtained from donor dogs and placed in sterile test tubes which were hermetically sealed. Seven of these contained room air. In the five remaining tubes, the air in the tube was replaced by an atmosphere of helium under pressure of 20 to 40 millimeters of mercury above atmospheric level. This was done in an attempt to repeat the work of Hufnagel (20) who felt that helium (particularly under pressure) was a better conductor of heat than was air and hence would allow quicker freezing of the vessel.

When sealed the test tube containing an aortic segment was immersed in a beaker con-

Fig. 1. Blood vessel in Erlenmeyer flask containing nutrient medium, ready for storage in refrigerator.

taining 300 cubic centimeters of 95 per cent alcohol in which was floating one half its volume of carbon-dioxide ice. The temperature of this mixture was -72 degrees centigrade. The tubes were kept in this for 15 minutes and were then stored in a carbon-dioxide ice refrigerator at a temperature of about -70 degrees centigrade. The vessels were stored in this manner for lengths of time varying between 2 and 35 days. When a vessel was to be implanted into a recipient dog it was thawed by immersing its test tube for 10 minutes in a bath of water at 35 degrees centigrade after which it was removed from the tube and placed in a bowl of Ringer's solution at the operating table. It was then sutured into the abdominal aorta of a recipient dog as described previously. Table I shows the results.

It will be seen that of 12 dogs 1 dog died of pneumonia in 19 days. 2 dogs survived for at least 6 months with fairly good arterial pathways and 9 died of breakdown of one of the anastomoses. The grafts which broke down did so between 2 and 12 days in 7 cases, and at 20 and 30 days in the other 2. Examination of these 9 autopsy specimens showed that the grafts themselves were friable and necrotic to the point of allowing the sutures to pull out

TABLE II—RESULTS OF IMPLANTATION OF HETEROGRAFTS (PRESERVED IN 10 PER CENT DOX SERUM IN BALANCED SALT SOLUTION AT 1 TO 4 DEGREES C.) INTO DOG VORTAS

No.	Series of graft	Length of time (days) preserved	Length of life of dog post-operatively	Cause of death	Fate of graft
1	16x	hours	3 months	(Still alive)	Aneurysmal dilatation of graft by aortogram
2	11	day	40 days	Sacrificed	Completely thrombosed
3	15	days	6 months	Sacrificed	Excellent
4	14	day	30 days	Peritonitis	Excellent
5	14x15	day	months	Sacrificed	Marked intimal sclerosis
6	14x15	day	day	Hemorrhage	Dismembered
7	15	day	months	(Still alive)	Completely thrombosed as shown by aortogram
8	20x	day	months	(Still alive)	Great dilatation of graft as shown by aortogram

before filtration had taken place. In our hands this method of preservation by freezing gave highly unsatisfactory results.

Series B: implantation of aortic heterografts (preserved in balanced salt solution and 10 per cent dog serum at 1 to 4 degrees centigrade). A small number of heterografts were transplanted into dogs to study the effects of transfer of arteries from one species to another. Four vessels from a hog, from a baboon, and 1 vessel from a human were grafted into abdominal aortas of dogs. These vessels were obtained within 2 to 3 hours of death and were stored at from 1 to 4 degrees centigrade in a balanced salt solution to which 10 per cent dog serum was added. (The method of preservation is fully described in Series C.) The vessels were stored for varying periods of time before being implanted into recipient animals as recorded in Table II.

Examination of Table II shows that the use of baboon aorta was uniformly unsatisfactory, while 3 of the hog vessels and the one piece of human vessel were partially successful in carrying blood for protracted periods of time. This small series of experiments in transplanting vessels from one species to another would seem to indicate that success or failure will depend upon the immunological reaction between the two species involved in the transfer. In some combinations, heterografts seem to live whereas other combinations of heterografts cause an intense reaction which leads to rapid degeneration or thrombosis of the implanted vessels.

Series C implantation of aortic homografts (preserved in balanced salt solution and 10 per

cent dog serum at 1 to 4 degrees centigrade). Twenty five experiments were carried out with segments of aorta which had been stored in a medium which would supply minerals and nutrient elements to keep the tissue of the vessel alive. Each segment was obtained in a sterile manner and was then placed in a sterile 25 or 50 cubic centimeter Erlenmeyer flask which contained enough of the nutrient medium to just cover the graft. The medium was composed of 10 per cent homologous (dog) serum in balanced salt solution¹ which was maintained at a fairly constant pH by means of a buffer. To this medium was added enough of the salts of penicillin and streptomycin to give a concentration of 50 units of each drug per cubic centimeter of fluid. The flask was closed with a sterile cotton stopper and placed in an electric refrigerator of the hospital's blood bank which is maintained with great care between the temperatures of 1 and 4 degrees centigrade. (A cotton stopper was used originally to allow free diffusion of carbon dioxide and oxygen but subsequent studies show that a rubber cap is equally satisfactory and is probably more efficient in maintaining a suitable pH range in the flask contents.) After

The balanced salt solution is a modification of T rode solution prepared and supplied to us by J. H. Hanks. It is made as follows:

Stock solution, content per 50 ml: NaCl 30 gms., KCl 5 gms., MgSO_4 7 gms., MgCl_2 6 gms., CaCl_2 25 gms. (dissolved separately), Na_2HPO_4 5 gms. (or 38 gms. of $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$), KH_2PO_4 5 gms. glucose 5 gms.; 4 per cent phenol red 5.

The stock solution is stored in room temperature with chloroform.

The final solution is made by diluting the stock 0.5, adding 10% buffer (previously autoclaved) per 20 ml. This is stored in cotton-stoppered containers on the ice box. It has an equilibrium at about pH 7.0.

preservation in this manner and before grafting a segment of vessel has physical qualities very similar to those of a fresh vessel. This is in contrast to the frozen vessels of Series A which were often quite friable when thawed out.

We do not mean to imply that the temperature range of 1 to 4 degrees centigrade is necessarily the most optimum one for storage of blood vessels. Indeed we have not extensively studied the preservation of tissue at many ranges of temperature above freezing because there seems to be little practical value in pursuing such investigations. We believed it to be worth while to study methods of preservation only at the low temperatures of refrigeration which are available to us and to many surgeons such as that commonly used in blood bank storage systems where the range is usually 1 to 4 degrees centigrade.

As we have used it this method has proved extremely satisfactory. It will be seen that among the 25 dogs with implanted grafts we had no deaths from disruption of the graft. There were 3 instances of complete thrombosis. In 1 of these a vessel which had been preserved for 1 day the graft was larger in diameter than the recipient aorta when implanted giving an effect like that of a slight aneurysm. In the 2 others the grafts had been preserved for 56 days and 98 days respectively which is considerably longer than we can now recommend for reliable preservation of grafts. In the remaining 22 dogs the grafts were known to be carrying blood at intervals from 4 days to 10 months after operation (Table III).

When viewed grossly at postmortem examination the vessels were quite satisfactory save for the 3 which were wholly thrombosed. There was very little reaction in the retroperitoneal tissues around the grafts. Inspection of the intima of the grafts in the sacrificed animals has shown 4 which had small insignificant mural thrombi. One animal which died of hepatitis 20 days after implantation of a 34 day preserved graft showed a thickened irregular suture line. One graft sacrificed 3 months after implantation of a 5 day preserved specimen showed considerable intimal sclerosis. All of the remaining grafts which have

Fig. 3. Results of tissue culture studies to test viability of pieces of dog blood vessels which had been stored in 10 per cent homologous serum in balanced salt solution at 1 to 4 degrees C. The number above each column indicates the number of tissue culture tests which were made. Most of the vessels appeared to be viable for 35 to 40 days.

In the first part of this work 8 pieces of tissue were cultured from each of 12 dog aortas the pieces of vessel being obtained within 2 to 5 hours after death of the animals. Of the 96 pieces of vessels which were so planted 91 grew out fibroblastic cells.

Study of portions of dog aorta which had been stored at -70 degrees centigrade (Series A) showed that planting of 34 such specimens led to growth in only 2 instances. The freezing and thawing process doubtless had killed the tissue cells in most instances.

Studies of baboon aorta hog aorta and human aorta each of which had been stored in the cold in balanced salt solution containing 10 per cent dog serum (Series B) showed that most of the vessels were living after more than a month.

Detailed studies were made of dog aorta each of which had been stored at 1 to 4 degrees centigrade in balanced salt solution containing 10 per cent dog serum (Series C). Samples of the vessels were planted at varying times after initial storage of them to determine how long the vessels were in a viable state. Figure 3 summarizes the data which were obtained. It will be seen that most of the vessels were living and could be grown out on tissue culture for as long as a month or more. After 30 or 35 days there was a marked diminution in the number of aortas which were still living. After 55 days all vessels were found to be dead. These studies lead us to believe that arteries can be stored and kept viable for a little more than a month by the technique which is described in detail under Series C.

DISCUSSION

We believe that there are three main factors which might influence the success or failure of an arterial graft: (1) the viability of the vessel at the time of implantation; (2) the degree of the immunological reaction between the host and the graft; and (3) the technique employed in making the anastomoses.

In our work with dogs we have had good results with the transplantation of arterial homografts which had been stored at low temperature in 10 per cent homologous serum in balanced salt solution. We have set certain time limits for obtaining the blood vessel seg-

Fig. 4. Preserved aortic graft being implanted into abdominal aorta of a dog. a, above, Graft in place. b, Completion of anastomoses (everting, continuous, mattress suture employed).

ments after death of the donor: a period of 3 or 4 hours is satisfactory but it probably should not exceed 6 hours. Vessels removed as long as 6 hours after death were found to be still viable by tissue culture studies and successful transplants could be carried out with them. Beyond 6 hours we felt that there was a likelihood of rapid appearance of postmortem change and of bacterial contamination.

From animal experimentation we found that vessels could be stored (at low temperature and in 10 per cent homologous serum in balanced salt solution) and subsequently used for grafting into other animals of the same species. The upper limits of safety for storing vessels under these conditions is probably in the region of 35 or 40 days. We have selected this limit because aortic grafts in dogs were successful up until this time, and thereafter began to fail. Furthermore tissue culture studies also indicated that viability of vascular segments is maintained for approximately 35 or 40 days and then rapidly declines.

If we include the preliminary series of fresh homografts transplanted into dog aortas re-

longer periods of time. In each of these 8 animals the graft has been studied during life by means of aortography, employing roentgen visualization of the abdominal aorta (Fig. 5). In all of these 8 dogs the aortic graft is patent and has the same caliber as the adjacent host aorta. In 3 of them there are one or several tiny irregularities at anastomotic lines which probably are insignificant mural thrombi and which do not diminish the caliber of vessel lumina to any important degree.

Inspection of Table III will show that storage of the grafts for more than 30 days appears to be unsatisfactory. Of the 4 vessels kept for more than 30 days before grafting 1 was not available for study because the animal died on the fourth day from intestinal obstruction. Two vessels were thrombosed and only 1

was wholly satisfactory. Of the 21 grafts stored less than 30 days before implantation, 20 were satisfactory and only 1 was unsatisfactory. It is noteworthy that in this whole series not one animal died from breakdown of a graft.

TISSUE CULTURE EVALUATION OF METHODS OF ARTERIAL PRESERVATION

The vessels which were used in all three experimental series were examined by making tissue cultures of them at appropriate intervals to determine their viability (Fig. 2). These tissue cultures were made under the guidance of J. H. Hanks and John Ender. The work will be described in greater detail elsewhere (20) but the principal results are summarized herewith.

In the first part of this work 8 pieces of tissue were cultured from each of 12 dog aortas the pieces of vessel being obtained within 2 to 5 hours after death of the animals. Of the 96 pieces of vessels which were so planted 91 grew out fibroblastic cells.

Study of portions of dog aorta which had been stored at -70 degrees centigrade (Series A) showed that planting of 34 such specimens led to growth in only 2 instances. The freezing and thawing process doubtless had killed the tissue cells in most instances.

Studies of baboon aortas hog aortas and human aortas each of which had been stored in the cold in balanced salt solution containing 10 per cent dog serum (Series B) showed that most of the vessels were living after more than a month.

Detailed studies were made of dog aortas each of which had been stored at 1 to 4 degrees centigrade in balanced salt solution containing 10 per cent dog serum (Series C). Samples of the vessels were planted at varying times after initial storage of them to determine how long the vessels were in a viable state. Figure 3 summarizes the data which were obtained. It will be seen that most of the vessels were living and could be grown out on tissue culture for as long as a month or more. After 30 or 35 days there was a marked diminution in the number of aortas which were still living. After 55 days all vessels were found to be dead. These studies lead us to believe that arteries can be stored and kept viable for a little more than a month by the technique which is described in detail under Series C.

DISCUSSION

We believe that there are three main factors which might influence the success or failure of an arterial graft: (1) the viability of the vessel at the time of implantation; (2) the degree of the immunological reaction between the host and the graft; and (3) the technique employed in making the anastomoses.

In our work with dogs we have had good results with the transplantation of arterial homografts which had been stored at low temperature in 10 per cent homologous serum in balanced salt solution. We have set certain time limits for obtaining the blood vessel seg-

longer periods of time. In each of these 8 animals the graft has been studied during life by means of aortography employing roentgen visualization of the abdominal aorta (Fig. 5). In all of these 8 dogs the aortic graft is patent and has the same caliber as the adjacent host aorta. In 3 of them there are one or several tiny irregularities at anastomotic lines which probably are insignificant mural thrombi and which do not diminish the caliber of vessel lumina to any important degree.

Inspection of Table III will show that storage of the grafts for more than 50 days appears to be unsatisfactory. Of the 4 vessels kept for more than 50 days before grafting 1 was not available for study because the animal died on the fourth day from intestinal obstruction; 2 vessels were thrombosed, and only 1

was wholly satisfactory. Of the 21 grafts stored less than 50 days before implantation, 20 were satisfactory and only 1 was unsatisfactory. It is noteworthy that in this whole series not one animal died from breakdown of a graft.

TISSUE CULTURE EVALUATION OF METHODS OF ARTERIAL PRESERVATION

The vessels which were used in all three experimental series were examined by making tissue cultures of them at appropriate intervals to determine their viability (Fig. 2). These tissue cultures were made under the guidance of J. H. Hanks and John Enders. The work will be described in greater detail elsewhere (29) but the principal results are summarized herewith.

In the first part of this work 8 pieces of tissue were cultured from each of 12 dog aortas the pieces of vessel being obtained within 2 to 5 hours after death of the animals. Of the 96 pieces of vessels which were so planted 91 grew out fibroblastic cells.

Study of portions of dog aorta which had been stored at -70 degrees centigrade (Series A) showed that planting of 34 such specimens led to growth in only 2 instances. The freezing and thawing process doubtless had killed the tissue cells in most instances.

Studies of baboon aortas, hog aortas and human aortas each of which had been stored in the cold in balanced salt solution containing 10 per cent dog serum (Series B) showed that most of the vessels were living after more than a month.

Detailed studies were made of dog aortas each of which had been stored at 1 to 4 degrees centigrade in balanced salt solution containing 10 per cent dog serum (Series C). Samples of the vessels were planted at varying times after initial storage of them to determine how long the vessels were in a viable state. Figure 3 summarizes the data which were obtained. It will be seen that most of the vessels were living and could be grown out on tissue culture for as long as a month or more. After 30 or 35 days there was a marked diminution in the number of aortas which were still living. After 55 days all vessels were found to be dead. These studies lead us to believe that arteries can be stored and kept viable for a little more than a month by the technique which is described in detail under Series C.

DISCUSSION

We believe that there are three main factors which might influence the success or failure of an arterial graft: (1) the viability of the vessel at the time of implantation, (2) the degree of the immunological reaction between the host and the graft, and (3) the technique employed in making the anastomoses.

In our work with dogs we have had good results with the transplantation of arterial homografts which had been stored at low temperature in 10 per cent homologous serum in balanced salt solution. We have set certain time limits for obtaining the blood vessel seg-

Fig. 4. Preserved aortic graft being implanted into abdominal aorta of a dog a, above Graft in place, b, Completion of anastomoses (everting continuous mattress suture employed).

ments after death of the donor a period of 3 or 4 hours is satisfactory but it probably should not exceed 6 hours. Vessels removed as long as 6 hours after death were found to be still viable by tissue culture studies and successful transplants could be carried out with them. Beyond 6 hours we felt that there was a likelihood of rapid appearance of postmortem change and of bacterial contamination.

From animal experimentation we found that vessels could be stored (at low temperature and in 10 per cent homologous serum in balanced salt solution) and subsequently used for grafting into other animals of the same species. The upper limits of safety for storing vessels under these conditions is probably in the region of 35 or 40 days. We have selected this limit because aortic grafts in dogs were successful up until this time and thereafter began to fail. Furthermore tissue culture studies also indicated that viability of vascular segments is maintained for approximately 35 or 40 days and then rapidly declines.

If we include the preliminary series of fresh homografts transplanted into dog aortas, re-

Fig. 5. Aortograms of homografts (abdominal aortas) of dogs, made during life by diodrast injection through catheter which had been threaded up from the femoral artery. All of the grafts had been previously stored in 10 per cent dog serum in balanced salt solution at -70°C . The graft is the segment between the two arrows. *a*, Dog 70-47. Graft stored for 30 days. Aortogram made 6 months after insertion of graft. *b*, Dog 44-48. Graft stored for 43 days. Aortogram made 6 months after insertion of graft. *c*, Dog 67-48. Graft stored for 70 days. Aortogram made 1 month after insertion of graft.

ported by Gross and Hurwitt (12) we have now observed in this laboratory the results of four categories of aortic grafts. They are (1) fresh homografts (2) homografts from tissue preserved by quick freezing to about -70°C degrees centigrade (3) heterografts (hog to dog, baboon to dog, and human to dog) from tissue preserved in 10 per cent dog serum in balanced salt solution and (4) homografts from tissue preserved in 10 per cent dog serum in balanced salt solution. In our hands, the three series in which the grafts could be shown to be viable up to the time of implantation

were much more successful than the series of homografts preserved by quick freezing in which life could seldom be demonstrated by tissue culture. It is important to note that the homoplastic tissue preserved in a living state (up to 43 days) in the balanced salt and 10 per cent serum mixture was as satisfactory as fresh tissue for grafting. From our various observations we believe that a graft is more apt to be successful if it is viable when implanted.

The factor of immunological reaction between graft and host is exceedingly difficult to evaluate. Our series of heterografts is small and no conclusions can be drawn therefrom. However it was a distinct surprise to find that any of the grafts from one species to another would survive. Indeed the microscopic structure of the grafts which were transferred from hog to dog showed better preservation of the media than was the case in any of the dog to dog homografts. The grafts from baboon to dog on the other hand were very poor both grossly and microscopically. This raises the interesting possibility that the transplantation of heterografts between certain species may be practical. If it could be proved for example, that vessels of sheep, dog or hog could be used successfully in human beings, we could have available a relatively convenient source of blood vessel grafts. The successful transplantation of fresh dog arteries to the femoral artery in 3 human beings is being reported by Oudet (26) from Paris. He stated in a personal communication (27) that dog vessels were used rather than human arteries because French law prohibits autopsy (and any chance of procuring vessels from a dead body) until 24 hours postmortem. He was able to demonstrate by arteriography that the dog vessel grafts were patent but he did not state how long after operation these roentgenographic studies were made.

While our laboratory experiences convinced us of the dependability of homografts—as far as dog to dog is concerned—there is, of course

We have had some measure of success with small series of 3 grafts, both are definitely known to be nonviable. These grafts were stored in a 4 per cent neutral formalin for from 10 to 35 days, were then rinsed thoroughly in buffered salt solution, and implanted into recipient animals. All grafts carried blood at several months, but roentgenograms of some of these show calcification in the graft walls.

considerable doubt regarding the possibility of safely transferring arteries from one human to another. While it is true that there might be no correlation between what occurred in dogs and what might happen to homografts in humans, our laboratory experiences did give us some courage to attempt grafts in patients for bridging gaps in large arteries or in the aorta when the circumstances at the operating table demanded such therapy.

ARTERIAL GRAFTS IN HUMAN CASES

Segments of large arteries or aorta have been accumulated from human subjects who have died in automobile accidents and from whom we were able to get the material by the courtesy and co-operation of the medical examiner. In all instances the vessels were removed within a few hours after death of the individual and in no instance was the time lapse greater than 5 hours. The body was always opened under aseptic conditions (operator with cap, mask, sterile gown and gloves, skin preparation with tincture of iodine, sterile drapes, instruments, etc.). The acquired segments of vessel—iliac, carotid, subclavian and aortic—were preserved in individual flasks and just covered with the balanced salt solution described previously under Series C, except that the 10 per cent serum was human in origin. These flasks were then stored in a carefully regulated refrigerator (of the hospital's blood bank) at 1 to 4 degrees centigrade.

Eight of these human grafts have been implanted into patients who had a cyanotic type of congenital heart disease and in whom it was desirable to make some sort of a shunt of blood (the Blalock-Taussig principle) from the aorta or one of its branches into the pulmonary artery. Ordinarily it is possible to bring such vessels together for a direct anastomosis by the Blalock (2) or the Potts (30) techniques but under some circumstances it is very difficult to establish such shunts without excessive tension on the suture lines. While we hasten to express the opinion that direct anastomoses will in the majority of cases prove to be superior to any method which employs an interposed vessel, it is also probably true that the use of a graft in an occasional case (which will

Fig. 6. Photographs of homografts in abdominal aortas of dogs. Prior to their implantation all grafts had been preserved in 10 per cent dog serum in balanced salt solution at 1 to 4 degrees C. a, Dog 150-47. Graft stored 4 days; animal sacrificed 3 months after implantation. b, Dog 187-47. Graft stored 14 days; animal sacrificed 12 days after implantation. c, Dog 183-47. Graft stored 7 days; animal sacrificed 6 months after implantation. d, Dog 170-47. Graft stored 20 days; animal sacrificed 6 months after implantation.

allow arterial junctions to be made without the slightest tension) will give a result which is better than that which would have been obtained from a poor direct anastomosis. These same general principles also will probably hold true for treatment of coarctation of the aorta. Excision of a constricted segment and anastomosis of the remaining ends of aorta give a very satisfactory result in most cases but in some instances a very long portion of aorta must be excised or else the remaining aortic ends are inelastic and cannot be easily apposed. Under either set of circumstances the use of an interposed graft may prove to be the most satisfactory method of re-establishing an aortic pathway of normal size. The validity of this statement is suggested by the pleasing result obtained in Case 9 wherein a graft was

Fig. 5. Aortograms of homografts. (b) Abdominal aortas of dogs, made during life. (c) Rhodrast injection through catheter, each has been threaded up from the femoral artery. All of the grafts had been previously stored in per cent dog serum in balanced salt solution at $+4$ degrees C. The graft is the segment between the \downarrow arrows. In each instance the graft is patent. Dog 70 47. Graft stored for 30 days. Aortogram made 6 months after insertion of graft. (b) Dog 44 48. Graft stored for 4 days. Aortogram made 6 months after insertion of graft. (c) Dog 67 48. Graft stored for 70 days. Aortogram made 1 month after insertion of graft.

ported by Gross and Hurwitt (12) we have now observed in this laboratory the results of four categories of aortic grafts. They are (1) fresh homografts, (2) homografts from tissue preserved by quick freezing to about -70 degrees centigrade, (3) heterografts (hog to dog, baboon to dog, and human to dog) from tissue preserved in 10 per cent dog serum in balanced salt solution and (4) homografts from tissue preserved in 10 per cent dog serum in balanced salt solution. In our hands, the three series in which the grafts could be shown to be viable up to the time of implantation

were much more successful than the series of homografts preserved by quick freezing in which life could seldom be demonstrated by tissue culture. It is important to note that the homoplastic tissue preserved in a living state (up to 42 days) in the balanced salt and 10 per cent serum mixture was as satisfactory as fresh tissue for grafting. From our various observations we believe that a graft is more apt to be successful if it is viable when implanted.

The factor of immunological reaction between graft and host is exceedingly difficult to evaluate. Our series of heterografts is small and no conclusions can be drawn therefrom. However it was a distinct surprise to find that any of the grafts from one species to another would survive. Indeed the microscopic structure of the grafts which were transferred from hog to dog showed better preservation of the media than was the case in any of the dog to dog homografts. The grafts from baboon to dog on the other hand were very poor both grossly and microscopically. This raises the interesting possibility that the transplantation of heterografts between certain species may be practical. If it could be proved, for example, that vessels of sheep, dog or hog could be used successfully in human beings, we could have available a relatively convenient source of blood vessel grafts. The successful transplantation of fresh dog arteries to the femoral artery in 3 human beings is being reported by Oudot (26) from Paris. He stated in a personal communication (27) that dog vessels were used rather than human arteries because French law prohibits autopsy (and any chance of procuring vessels from a dead body) until 24 hours postmortem. He was able to demonstrate, by arteriography, that the dog vessel grafts were patent, but he did not state how long after operation these roentgenographic studies were made.

While our laboratory experiences convinced us of the dependability of homografts—as far as dog to dog is concerned—there is, of course,

we have had some measure of success with small series of 11 grafts which were definitely known to be nonviable. These grafts were stored in 4 per cent neutral formalin for from 10 to 15 days, were then rinsed thoroughly in buffered salt solution, and were implanted into recipient animals. All grafts carried blood well for several months, but roentgenograms of some of these show calcification in the graft walls.

Fig. 8. Treatment of coarctation of the aorta (Case 9) by removal of narrowed segment of aorta and insertion of a human aortic graft. The graft had been procured from a human who had died in an automobile accident, it had been preserved for 38 days in 10 per cent human serum in balanced salt solution at 1 to 4 degrees C before insertion into the recipient patient. The graft was 5 centimeters in length.

graft, which had been preserved 1 day was placed between the right subclavian artery and the side of the right pulmonary artery. Dicumarol therapy was given postoperatively on the tenth day bleeding began from the nose, mouth gastrointestinal tract into the right pleural cavity and manifestations of intracranial neurological disturbances appeared. Because the blood in the right side of the chest could not be satisfactorily aspirated a thoracotomy was performed on March 16, 1948 to remove clots. The child died the following day largely from the neurological complications of the anticoagulation therapy. Postmortem examination showed the graft and shunt to be patent and in good condition without evidence of leakage or thrombosis. The thoracic bleeding had apparently come from the musculature of the chest wall.

CASE 4. L. B. a 12 year old girl had been cyanotic since the age of 3 to 4 months. She was barely able to climb one flight of stairs. On physical examination there was marked cyanosis, advanced clubbing

and a systolic murmur of considerable intensity in the pulmonic area. Roentgenograms and electrocardiograms were consistent with a tetralogy of Fallot. The red blood count was 8.7 million. At operation on May 1, 1948 a graft which had been preserved for 4 days, was implanted between the proximal end of the left subclavian artery and the side of the left pulmonary artery. The child's color was greatly improved for about 24 hours but she then developed congestive heart failure and died on the second postoperative day. A continuous murmur was heard until death occurred. At autopsy the graft was found to be intact and also to be free of thrombosis.

CASE 5. H. B. a 13 year old boy was first noted to have persistent cyanosis at the age of 6 years. He was forced to squat and rest after short periods of walking. Physical examination showed moderate cyanosis, well marked clubbing of the fingers and toes and a loud systolic murmur over the pulmonic area. Roentgenograms of the chest and electrocardiograms

Fig. 7. Treatment of tetralogy of Fallot (Case 3) by insertion of human arterial graft between the left pulmonary artery and the proximal end of the left subclavian artery. (Patient had right aortic arch and an innominate artery on the left.) The graft had been secured from another human and had been preserved for 14 days before insertion into the recipient patient.

used to repair an aortic defect after excision of a coarctation. A brief summary of each case follows.

CASE 1. D. E. a 5 year old boy had been cyanotic since birth and had great limitation of physical activity. On physical examination there was marked cyanosis of the fingers and toes and a harsh systolic murmur in the pulmonary area. Roentgenograms of the chest gave findings typical of a tetralogy of Fallot. Electrocardiograms showed right axis deviation. The red blood count was 7.6 million. At operation on February 6, 1948 a 3 centimeter segment of (adult) iliac artery which had been preserved for 3 weeks, was sutured into place between the left pulmonary artery and the proximal end of the left subclavian artery. During the 5 months since operation the child has had great alleviation of his cyanosis and has had a marked increase in his tolerance for exercise. The red blood count has fallen to 5.5 million. There is a continuous murmur in the pulmonary area of the precordium.

CASE 2. W. P. a 4½ year old child, deeply cyanotic since birth, had had a right-sided hemiplegia since the age of 2, this neurological damage being presumably on the basis of thrombosis of intracranial

vessels. A faint systolic murmur was audible in the pulmonary area. The red blood count was 9.8 million and the hematocrit was 87 per cent. He had insufficient strength to do more than sit in bed. Roentgenograms and electrocardiograms were typical of a tetralogy of Fallot; the aortic arch was on the right. At operation on February 11, 1948, a human arterial graft 3.5 centimeters long which had been preserved for 14 days, was sutured in place between the proximal end of the left subclavian artery and the side of the left pulmonary artery (Fig. 7). During the 5 months that the boy has been followed since operation his general condition has been dramatically improved. The red count has fallen to 5.8 million. He can now walk considerable distances and has a marked alleviation of his cyanosis. A continuous murmur is audible in the left second intercostal space anteriorly.

CASE 3. S. F. a 10½ year old girl, had been cyanotic since birth, and was able to walk only 75 yards at a time. Auscultation revealed a pulmonary systolic murmur of moderate intensity. Roentgenograms, electrocardiograms and cardiac catheterization all gave findings which were compatible with a tetralogy of Fallot. The aortic arch was on the right. At operation on March 2, 1948 a human arterial

Fig. 8. Treatment of coarctation of the aorta (Case 9) by removal of narrowed segment of aorta and insertion of a human aortic graft. The graft had been procured from a human who had died in an automobile accident. It had been preserved for 28 days in 10 per cent human serum in balanced salt solution at 1 to 4 degrees C. before insertion into the recipient patient. The graft was 5 centimeters in length.

graft, which had been preserved 1 day, was placed between the right subclavian artery and the side of the right pulmonary artery. Dicumarol therapy was given postoperatively. On the tenth day bleeding began from the nose, mouth, gastrointestinal tract, into the right pleural cavity, and manifestations of intracranial neurological disturbances appeared. Because the blood in the right side of the chest could not be satisfactorily aspirated, a thoracotomy was performed on March 16, 1948, to remove clots. The child died the following day, largely from the neurological complications of the anticoagulation therapy. Postmortem examination showed the graft and shunt to be patent and in good condition without evidence of leakage or thrombosis. The thoracic bleeding had apparently come from the musculature of the chest wall.

CASE 4. L. B., a 12 year old girl, had been cyanotic since the age of 3 to 4 months. She was barely able to climb one flight of stairs. On physical examination there was marked cyanosis, advanced clubbing

and a systolic murmur of considerable intensity in the pulmonary area. Roentgenograms and electrocardiograms were consistent with a tetralogy of Fallot. The red blood count was 8 million. At operation on May 1, 1948, a graft, which had been preserved for 4 days, was implanted between the proximal end of the left subclavian artery and the side of the left pulmonary artery. The child's color was greatly improved for about 24 hours but she then developed congestive heart failure and died on the second postoperative day. A continuous murmur was heard until death occurred. At autopsy the graft was found to be intact and also to be free of thrombosis.

CASE 5. H. B., a 13 year old boy, was known to have persistent cyanosis at the age of 6 years. He was forced to squat and rest after short periods of walking. Physical examination showed marked cyanosis, well marked clubbing of the fingers, and a loud systolic murmur over the pulmonary area. Roentgenograms of the chest showed a large heart and

ere consistent with a diagnosis of tetralogy of Fallot. The red blood count was 6.2 million. At operation on May 3, 1948, a segment of human aorta 3 centimeters long (from a 5 year old child) which had been preserved 6 days was sutured in place between the distal end of the descending aorta and the side of the left pulmonary artery. Postoperatively a continuous murmur is audible over the pulmonary area. In the months since operation was performed this boy has progressed extremely well; his color is greatly improved, his physical activity is strikingly increased and the red blood count has fallen to 5.2 million.

CASE 6. R. D. is a 1 year old boy who had been intensely cyanotic since birth. His activity had been so severely limited that he was barely able to ascend on slight flights. Physical examination showed marked cyanosis and mild clubbing of the fingers and toes. A loud systolic murmur over the pulmonary area. Roentgenogram, electrocardiograms, and cardiac catheterization were interpreted as indicating that the patient had a stenosis of the tricuspid valve with a associated large interauricular septal defect. The pulmonary blood flow was believed to be insufficient. At operation on May 6, 1948, a segment of human aorta (from a 5 year old child) which had been preserved 9 days was interposed as a bridge between the side of the descending aorta and the side of the left pulmonary artery. Postoperatively there is a continuous murmur in the pulmonary area. In the months since operation the boy has had an excellent improvement in color and in tolerance for physical activity.

CASE 7. A. H. was a 7 year old boy who had exhibited rather constant cyanosis since birth and had had frequent spells of fainting without definite evidence of cerebral thrombosis. He had a low tolerance for exercise and frequently assumed a squatting position. On examination there was marked cyanosis, clubbing of a thrill and a loud systolic murmur in the third left interspace. Electrocardiograms showed a marked right axis deviation and fluoroscopic findings were not those consistently found with tetralogy of Fallot. At operation on May 17, 1948, the pressure in the left pulmonary artery—although not actually measured—was obviously much greater than in most cases of tetralogy and was very doubtful if an aorta-pulmonary artery shunt would be of value. However it was decided to attempt such an anastomosis. Because the vessels lay in positions which precluded direct anastomosis, a graft 3 centimeters in length (which had been preserved 20 days) was sutured into the side of the descending aorta and its opposite end sewed end-to-side into the pulmonary artery. Only a questionable thrill could be felt in the graft when the clamps were removed, the pulmonary artery pressure was so high that probably little if any blood flowed through the graft. Following operation the boy showed no important changes in color or activity; only a systolic murmur could be heard in the pulmonary area. He was discharged home unimproved. We believe that the

failure to produce beneficial changes in this case was due not to thrombosis of the graft, but to the fact that the child has some sort of a cyanotic state (such as an Eisenmenger complex) which is not benefited by an aorta pulmonary shunt.

CASE 8. R. A. was a 12 year old boy who had been cyanotic since birth. There had been moderate limitation of activities, spells of weakness and frequent squatting on his haunches. On examination there was moderate cyanosis, a very loud systolic murmur in the pulmonary area and mild clubbing. The hemoglobin was 25.8 grams and the hematocrit was 71 per cent. The electrocardiogram showed a right axis shift. Cardiac catheterization and fluoroscopic findings indicated the existence of a tetralogy of Fallot. At operation on May 19, 1948 the left subclavian artery was turned downward but in spite of the fact that the left pulmonary artery was divided (and its distal end turned upward) these two ends of vessel could not be brought together for anastomosis. Therefore, a graft 4 centimeters long (which had been preserved 32 days) was inserted end-to-end between the left subclavian artery and the distal end of the left pulmonary artery. Following operation the boy made an excellent recovery by the time of hospital discharge the hemoglobin had fallen to 16 grams. Since the operation was carried out there has been a loud, continuous murmur in the pulmonary area, the boy's color has greatly improved and even though the period of postoperative observation is only 7 weeks it is already obvious that his exercise tolerance is increased.

CASE 9. D. S. was a 7 year old boy who entered the hospital for treatment of coarctation of the aorta. Examination showed a pressure in the arms varying on multiple readings from 130 to 150 millimeters of mercury systolic. No femoral pulsations could be felt, and no blood pressure readings could be obtained in the legs. A systolic murmur of moderate intensity was heard in the precordium. By fluoroscopy the heart was slightly enlarged. At operation on May 24, 1948 a coarctation of the aorta was found about 1.5 centimeters below the origin of the left subclavian artery. The narrowed portion was excised and it was found to have a lumen of only 2 millimeters in diameter. The remaining ends of the aorta could be brought together only with great tension. It was therefore decided to insert a graft. This graft was a segment of aorta removed from a human 28 days previously; it measured 5 centimeters in length. The anastomoses to the aorta above and to the aorta below were made with continuous mattress stitches of silk, piercing the entire thickness of the vessel walls and evertting the ends of the vessels (Fig. 8). The anastomoses could be made without the slightest tension. The patient had an uninterrupted convalescence. Following operation there was an excellent pulsation in the arteries of the legs. By the end of the second postoperative week the arm pressures had fallen to 103 millimeters of mercury systolic and the leg pressures had risen to 135 millimeters of mercury systolic.

SUMMARY

A method for the preservation of arterial segments is described. This consists in the storage of vessels at temperatures just above freezing and immersed in a mixture of 10 per cent homologous serum in a balanced salt solution to which are added a buffer a pH color indicator, and streptomycin and penicillin. Vessels to be stored in this manner have been removed from donor animals between 1 and 6 hours after death and have been kept for periods of as long as 42 days before they were successfully transplanted into other dogs. Tissue culture studies have shown that viability is maintained for 35 to 40 days in blood vessels stored in this way.

On the basis of these laboratory investigations segments of arteries or aortas have been secured from humans who have died suddenly and without sepsis. These vessels have been stored in the manner described and have subsequently been used for human patients when the need arose to bridge gaps in large arteries. Segments of such preserved arteries or aortas have been grafted into 9 human subjects with results which are very promising and which certainly merit further trial and study.

Since completion of this manuscript, 6 more grafts have been inserted into humans. One of these has been used in the treatment of a tetralogy of Fallot and the other 5 were inserted into the aorta after removal of coarctations. These have been in place from 3 to 9 months and all are still patent.

TESTOSTERONE PROPIONATE IN THE TREATMENT OF ADVANCED CARCINOMA OF THE BREAST

JAMES R. WATSON, M.D., F.A.C.S. and GEORGE H. FETTERMAN, M.D.
Pittsburgh, Pennsylvania

RADICAL amputation of the breast is the only known method of treatment which offers the prospect of cure for carcinoma of this organ and is followed by excellent results when the operation is well done and the lesion is still limited to the breast. That it fails in many instances due primarily to the extent of the lesion when the patient is first seen is a common experience in every surgeon's practice and has led to the employment of certain therapeutic adjuncts to radical amputation, the most frequently used of which is x-ray therapy. An other adjunct of a more controversial nature which has found intermittent favor over the last fifty years is the production of hormonal imbalance. This has been produced by surgical castration, by irradiation of the ovaries, and more recently by the administration of the male sex hormone, testosterone propionate.

There is considerable laboratory evidence to support the theory that both the estrogens and androgens influence the course of mammary cancer. The administration of estrogenic substances frequently has been shown to result in the formation of mammary cancers in both male and female animals while Nathanson and Andervont reported that administration of the androgen testosterone propionate prevented the development of spontaneous breast tumors in cancer bearing strains of mice. Loeser found that the implantation of testosterone propionate pellets in cancer strains of mice reduced the mortality due to spontaneous cancer from 75 per cent in the controls to 40 per cent in the treated animals.

There has been little clinical evidence to prove that the administration of estrogens, in spite of their widespread and often indiscriminate use, ever results in the production of cancer of the human breast or that the adminis-

tration of androgens to patients who have cancer of the breast results in any permanent benefit.

REVIEW OF THE LITERATURE

In 1941 Loeser first reported the use of testosterone propionate in the treatment of cancer of the human breast. He reported 5 cases. Three of these were said to be free of the disease at the time the pellets were implanted and remained well for 4 years. In 2 cases where the disease was present no regression was noted although there was systemic improvement and relief from pain.

In 1939 Farrow treated a series of 33 cases with skeletal metastases seen on the breast service at Memorial Hospital in the city of New York. Testosterone propionate was given in doses of from 5 to 25 milligrams for a total of from 6 to 12 injections. Temporary relief from pain with general improvement in the patient was noted in about half the cases. No patient showed clinical or radiographic evidence of control of the disease and all patients were dead at the time of the report made in 1944.

In 1946 Adair and Herrmann reported their studies on the treatment of 11 cases of advanced carcinoma of the breast. Four of these, one with soft part and three with osseous metastases, manifested remarkable improvement which consisted in regression of the primary lesion and soft part metastases in the one and an increase in calcification in areas of osseous metastases in the other three. Four other cases did not respond to treatment while the remaining cases were still under treatment without clinical evidence of improvement. Each of these patients received from 2000 to 4100 milligrams over a period of 2 to 3 months. None of the patients had been observed for longer than 3 months.

Boger reported the case of a 27 year old woman who was bedridden with extensive me-

From the Tumor Clinic and the John C. Oller Memorial Research Foundation of the St. Margaret Memorial Hospital.

tastases from a cancer of the breast. Surgical castration followed by the administration of 1440 milligrams of methyl testosterone orally resulted in relief from pain and partial recalcification of extensive bone lesions of the spine and pelvis. The relief persisted for 8 months but death occurred 4 months later.

Schwander and Marvin used testosterone in 5 cases with soft tissue metastases in doses up to 1425 milligrams and noted symptomatic relief of pain and an increased sense of well being. Moderate doses had no beneficial effect on the primary lesion or on soft tissue metastases although the results suggested

that recalcification of osteolytic metastases occurred with adequate therapy.

Herrmann, Adair, and Woodard subsequently reported 11 additional cases with osseous metastases. Three of these had received prior irradiation of the lesions without relief from pain. The others were treated solely with testosterone. Symptomatic improvement occurred in 8 patients within 2 weeks after the onset of therapy. The favorable results were obtained with smaller amounts of testosterone than were used in the cases they had previously reported, dosages of 100 milligrams triweekly being found effective.

Fig 3. Case 3. J. J. Roentgenogram showing metastasis to right humerus with pathological fracture at time of first admission to the hospital.

Fig 4. Case 3. J. J. Calcification and bony union in pathological fracture following 2400 milligrams of testosterone.

Fig. 5. Case 4. F. S. Roentgenogram showing metastasis to shaft of right radius which appeared after patient had received 3150 milligrams of testosterone.

Herrman and Adair (8) reported 10 cases with soft tissue metastases. One patient showed marked regression of the primary lesion with disappearance of axillary and supraclavicular metastases after the administration of 3150 milligrams over a period of 2 months. She died of the disease 9 months after the start of treatment. Three others showed cytologic alterations of hydropic changes in cytoplasm and pyknosis of nuclei. There was no gross evidence of regression of the lesions, and all died. The 6 remaining patients showed no response to treatment.

The most optimistic report was that of Prudente from Sao Paulo, Brazil. In 1945 he reported a series of 63 patients with carcinoma of the breast treated since 1939 by radical amputation followed by prolonged prophylactic administration of testosterone propionate in doses of 175 milligrams per week. Comparing them with a series of 64 patients treated prior to 1939 without the use of testosterone, he concluded that there was an improvement in the survival rate among the testosterone-treated patients of approximately 100 per cent.

REPORT OF CASES

CASE 1. In the fall of 1946, one of us (J.R.W.) was asked to see a white female, A. McC., aged 50 years, who had cutaneous metastases of the chest wall secondary to a carcinoma of the breast. Five years previous to this, she had had a radical amputation of the left breast performed in another city for a carcinoma. Operation was followed by a course of x-ray therapy, and a year later by the intrauterine use of radium to induce an artificial menopause. Four years after her original operation, she had had a second course of x-ray therapy for cutaneous metastases, and a year later, rather extensive excision and plastic repair of the involved area, which was preceded and followed by a course of Goldblatt's serum. Physical examination 3 months after her last operation revealed a modified left radical mastectomy scar with presence of several cutaneous metastases over the left anterior and scapular regions. The chest wall bilateral metastatic invasion of the supraclavicular lymph nodes and lymphatics secondary to radiation therapy. One of the cutaneous metastases had broken down and as a result an indolent ulcer about 2 centimeters in diameter had

Fig. 7. Case 1. Chest wall after metastasis to lymph node of testosterone. $\times 80$.

formed. The patient knew the nature of her disease and both she and her husband were desperate in their search for help.

Testosterone propionate therapy was discussed with them and finally started at their insistence and with their full knowledge as to the uncertainty of the results as well as to the expense involved. She received 400 milligrams per week for a period of 8 weeks after which the dosage was reduced to 50 milligrams every other week. Two weeks after the institution of therapy she stated that she felt better and thereafter for nearly 3 months the improvement was rapid and sustained. Her appetite improved, she gained weight and strength and had almost complete relief from pain not only from the pain of the metastases but interestingly enough relief from the arthritic pain in her knees and right shoulder which she had had for years. She discarded the cane which she frequently used and changed from an invalid to an energetic woman even taking a thousand mile auto trip every minute of which she enjoyed. The skin metastases also appeared to be altered having taken on a dull cyanotic cast and apparently having diminished somewhat in size although there was no tendency of the ulcer to heal. The greatest change of all was in her mental attitude for she was convinced that she was going to get well.

Three months after the institution of treatment she began to fail. Histologic sections of cutaneous metastases before and after testosterone therapy showed no change (Figs. 1 and 2). There was a gradual increase in the size as well as number of the cutaneous metastases some of which broke down to the form of other ulcers. A tumor clinically typical of a rapidly growing carcinoma appeared in the other breast and she died with extensive cutaneous and visceral carcinomatosis 8 months after the start of treatment.

Stimulated by the early changes which occurred in this patient the problem was submitted to the Tumor Clinic at St. Margaret Memorial Hospital where it was agreed to carry out further investigation on the use of testosterone propionate in the treatment of cases of advanced carcinoma of the breast. This is a report of the above case plus 6 additional cases followed in the Tumor Clinic. The expenses of the investigation were born by the John C. Oliver Research Foundation of the hospital.

In all 7 cases were studied. Four of these were patients who had operable carcinoma of the breast with proved axillary metastases and were treated by radical amputation of the breast and the administration of testosterone. Two had inoperable carcinoma with skeletal metastases while the seventh case

was the one here described with recurrent carcinoma following prior radical amputation.

Testosterone propionate (perandren) was administered intramuscularly in doses of 200 to 250 milligrams twice a week for a total of 3000 milligrams. It was then reduced to 50 milligrams every other week and continued until the condition of the patient indicated that the disease was progressing in spite of its use or until the patient died. Exceptions to this were 2 patients in whom treatment was stopped approximately 6 months following radical amputation and who appeared to be well. One patient died early in the course of treatment having received 1200 milligrams. The 6 other patients received a total amount of the drug which ranged from 3000 to 3900 milligrams. Where possible cutaneous or lymph node metastases were removed after the administration of at least 2000 milligrams of testosterone for microscopic comparison with the original lesions.

CASE 2. E. K., a white female aged 37 years was presented to the Tumor Clinic because of a mass in the right breast of unknown duration. Her chief complaint was pain in her joints and back which had been present for about 2 years. On physical examination she was found to have a large tumor in the breast with palpable axillary lymph nodes. There was x-ray evidence of metastases to the lumbar spine, pelvis and left femur. There was a moderate secondary anemia. An axillary lymph node was removed for microscopic examination and was reported as a metastatic adenocarcinoma. Broders grade four. Testosterone propionate was started in doses of 200 milligrams twice a week. This was followed by an apparent decrease in the size of the remaining axillary lymph nodes and a gain of 4 pounds in weight and sufficient relief from pain to permit her to walk into the out-patient department instead of being brought in in a wheel chair. She died 1 month after the start of treatment with the clinical signs and symptoms of a cerebral metastasis. She had received 1200 milligrams of the drug.

CASE 3. J. J., a white female aged 63 years was admitted to the hospital as an emergency case with a fracture of the right humerus as a result of a minor trauma. On physical examination she was found to have in addition to the fracture a tumor in the left breast which measured approximately 6 centimeters in diameter together with enlargement of the axillary lymph nodes. She stated that she had known of the presence of the tumor for at least 3 years but had consulted no one about it because it was not producing any symptoms. A ray examination of the skeletal system showed osteolytic lesions in the head and neck of the left femur, the left ilium

Fig. 4. Case 4. L. S. Roentgenogram showing metastases in shaft of right radius which appeared after patient had received 1350 milligrams of testosterone.

Herrman and Adair (b) reported 10 cases with soft tissue metastases. One patient showed marked regression of the primary lesion with disappearance of axillary and supraclavicular metastases after the administration of 3150 milligrams over a period of 2 months. She died of the disease 9 months after the start of treatment. Three others showed cytologic alterations of hydropic changes in cytoplasm and pyknosis of nuclei. There was no gross evidence of regression of the lesions, and all died. The 6 remaining patients showed no response to treatment.

Fig. 5. Case 5. S. D. Photomicrograph of axillary metastasis removed at time of radical operation. $\times 80$.

The most optimistic report was that of Irudente from Sao Paulo, Brazil. In 1945 he reported a series of 63 patients with carcinoma of the breast treated since 1939 by radical amputation followed by prolonged prophylactic administration of testosterone propionate in doses of 175 milligrams per week. Comparing them with a series of 64 patients treated prior to 1939 without the use of testosterone, he concluded that there was an improvement in the survival rate among the testosterone treated patients of approximately 100 per cent.

REPORT OF CASES

CASE 1. In the fall of 1946 one of us (J.R.W.) was asked to see a white female A. McC., aged 39 years, who had cutaneous metastases of the chest wall secondary to a carcinoma of the breast. Five years previously she had had a radical amputation of the left breast performed in another city for a carcinoma. Operation was followed by a course of x-ray therapy, and a year later by the intrauterine use of radium to induce an artificial menopause. Four years after her original operation she had had a second course of x-ray therapy for cutaneous metastases, and a year later a rather extensive excision and plastic repair of the involved area which was preceded and followed by a course of Goldblatt's serum. Physical examination 3 months after her latest operation revealed a modified left radical mastectomy scar, the presence of several cutaneous metastases over the left anterior and scapular regions of the chest wall, bilateral metastatic invasion of the supraclavicular lymph nodes and skin changes secondary to radiation therapy. One of the cutaneous metastases had broken down and as a result an indolent ulcer about 2 centimeters in diameter had

Fig. 6. Case 5. S. D. Metastatic lymph node of chest wall after 2000 milligrams of testosterone. $\times 80$.

milligrams given twice a week until the patient had received 3000 milligrams and then reduced to 50 milligrams every other week. This was carried out under the supervision of her family physician and was finally stopped after a total of 3500 milligrams had been given, and the patient was apparently well. She remained well for 11 months when cutaneous metastases began to appear in large numbers over the chest wall. She refused any further therapy and died 16 months after operation.

CASE 7. E. G. a white female aged 45 years had known of the presence of a gradually enlarging tumor in the left breast for 18 months. Highly intelligent in all other respects she had consulted no one about it because she feared it might be a cancer. Her physical examination was entirely negative save for the breast lesion which measured 3 centimeters in diameter and for the presence of palpable axillary lymph nodes. Laboratory studies including blood calcium, phosphorus and alkaline phosphatase determinations were all within normal limits. Radical amputation of the breast was carried out the lesion being reported to be a Broders grade three adenocarcinoma with axillary metastases. This was followed by the administration of 250 milligrams of testosterone propionate twice a week for a total of 3000 milligrams and then 50 milligrams every other week until she had received 3400 milligrams. Menstruation ceased shortly after the beginning of treatment and did not reappear until a month after the last injection. She felt well and had no disturbing reactions except for a slight deepening of her voice which was somewhat embarrassing to her in her occupation as a store executive. Medication was discontinued 6 months after operation. She is apparently well with out evidence of recurrence 18 months after operation.

RESULTS

In this series of cases the administration of testosterone appears to have had no curative and little inhibitory effect on the disease or its course. Six of the 7 patients treated have died of the disease within 16 months of the institution of treatment. Four of the 7 patients had radical mastectomy for operable carcinoma of the breast with axillary metastases. Three of these are now dead and one is living and apparently well. This is too small a group to have any statistical significance, although the result is no better than that obtained by radical amputation alone. In 2 inoperable cases with bone metastases, there was prompt relief from the pain of such lesions while in 1 of these union of a pathological fracture occurred within 6 weeks. No permanent effect was noted on soft tissue metastases. In 3 patients there appeared to

be a slight decrease in the size of metastatic lesions to the skin or axillary nodes but this was a best of temporary duration and the observation is subject to question. In one instance this apparent decrease was associated with a change in the color of several skin metastases from flesh color to a dusky red but they soon faded again and ultimately broke down to form ulcers. Microscopic examination of soft tissue lesions before and after treatment in 2 cases failed to show any unusual changes in the appearance of the tumor cells which could be attributed to testosterone. Distant metastases to the liver and brain occurred during treatment while 1 patient developed a rapidly growing carcinoma in the remaining breast.

Laboratory tests carried out before and during the course of treatment revealed no significant alterations in blood counts, urinalysis, blood calcium, phosphorus or alkaline phosphatase studies.

All patients noted an improved sense of well being so marked in several instances that they volunteered the information that they felt better than they had for years and that their friends remarked on how much better they looked. This improvement appeared within 2 to 3 weeks of the institution of treatment was most pronounced in those patients showing the greatest debility and persisted for a variable period of from 2 to 5 months. There was an increase in body weight, appetite and strength and a marked improvement in the mental attitude of those

and the upper portion of the right humerus with a pathological fracture in the latter. Laboratory studies were as follows: red blood cells 5,120,000; hemoglobin 95 per cent; blood calcium 10.3 milligrams phosphorus 3.0 milligrams alkaline phosphatase 4.8 Bodanski units urine, normal. An axillary lymph node was removed for pathologic examination and was reported as a Broders grade three adenocarcinoma of breast origin. The fracture was immobilized by means of an abduction splint and testosterone propionate was started in doses of 25 milligrams twice a week. Six weeks after the institution of treatment, the patient returned to the hospital for examination. She had discarded the orthopedic appliance and was using her right arm to feed herself and to comb her hair. She stated that she felt better than she had for the last 5 years and that her friends all commented on how well she appeared. X-ray studies revealed evidence of calcification (Figs. 3 and 4) of the bony lesions with union of the fracture of the right humerus. The dosage of testosterone was reduced to 50 milligrams every other week. As the patient lived in a distant town she was not seen again although periodic reports indicated that the improvement was maintained until 3 weeks before death when she became jaundiced as a result of liver metastases, and lapsed into coma. She had had very little pain even in the terminal phase of the disease. Her death occurred 6 months after the institution of treatment. She had received 3500 milligrams of testosterone.

CASE 4. E. S. a white female aged 41 years was seen in the Tumor Clinic because of the presence of a tumor in the left breast which she had had for 14 months, having first noticed it during the second month of a pregnancy. She went through the pregnancy and was delivered of a normal healthy infant at term. The breast tumor had not been noted by her obstetrician nor did she call any attention to it until 7 months after delivery when she became alarmed because of its increase in size. On examination the tumor was found to measure approximately 5 centimeters in diameter. The lymph nodes in the axilla were enlarged. A blood count and urinalysis were normal. Radical amputation of the breast was performed, the pathologist reporting the lesion to be a Broders grade two adenocarcinoma in a lactating breast with involvement of the axillary lymph nodes. Two hundred milligrams of testosterone were given 1 week after operation and this dosage was continued twice a week for a total of 3000 milligrams. It was then reduced to 50 milligrams every other week. Menstruation ceased after the second injection. The patient repeatedly volunteered the information that she felt fine and her sole complaints were that her voice seemed to have deepened a little and that she occasionally had vague pain in the region of the lower dorsal spine. X-ray studies of the chest, ribs, and spine were negative. Three months after the beginning of treatment she complained of pain and swelling (Fig. 5) in the right forearm just below the elbow and x-ray examination of the area

revealed a bone metastasis to the shaft of the radius. Because it had appeared while she was still receiving testosterone x-ray therapy was used with prompt relief from pain and with evidence of recalcification of the lesion. Ten months after operation she was readmitted to the hospital because of failing vision. An x-ray of the skull was negative but there was clinical evidence of a cerebral lesion, probably of metastatic origin. She died 3 months later. She had received testosterone for the entire year the total dosage being 3000 milligrams.

CASE 5. S. D. a white female aged 53 years, was sent to the Tumor Clinic because of a tumor of the left breast which had been present for a year. She had passed through the menopause at the age of 31 years. Physical examination revealed an inflammatory carcinoma involving the entire left breast with palpable axillary lymph nodes. There was no other evidence of extension of the disease, either on physical examination or on x-ray examination of the chest. The lesion was considered to be operable. Laboratory studies showed 4,000,000 red blood cells and 91 per cent hemoglobin. Urinalysis was negative. The blood calcium was 7.3 milligrams and the phosphorus 88 milligrams. The alkaline phosphatase was recorded as 3.68 Bodanski units. Radical amputation of the breast was performed for a Broders grade four adenocarcinoma with axillary metastases and was followed by the administration of testosterone propionate in dosages of 500 milligrams twice a week.

There was a gain in weight and a sense of well-being. A macular rash appeared on her body but lasted for only a week and disappeared without local treatment and without stopping the drug. After the patient had received 2000 milligrams of testosterone, it was noted that there was an enlargement of the left supraclavicular lymph node together with skin metastases on the chest wall (Figs. 6 and 7) one of the latter of which was removed for microscopic examination. Histologic examination of this tumor showed considerable change in the appearance of the tumor chiefly fibrous but with some degeneration of essential cells. This change was not considered specific for testosterone therapy. Testosterone therapy was continued until the patient had had a total of 3150 milligrams. She ultimately developed metastases to the liver associated with severe pain and died 8 months after operation.

CASE 6. A. F. a white female aged 64 years, was admitted to the hospital because of diabetes mellitus and the presence of a tumor in the right breast. Physical examination was essentially negative save for generalized arteriosclerosis, the presence of a tumor in the breast which measured 3 centimeters in diameter and palpable lymph nodes in the right axilla. There was three plus sugar in the urine and a blood sugar level of 338 milligrams. After adequate control of the diabetes had been obtained radical amputation of the breast was performed. The pathologist reported the tumor to be a Broders grade three adenocarcinoma with axillary metastases. Testosterone propionate was started in doses of 250

be accelerated by three types of stimuli stresses and strains diet and hormones and other chemical and enzymatic substances that both estrin and testosterone are effective stimulants and that their administration resulted in an increased rate of bone repair. Gardner and his associates think that testosterone may find a practical application in the prevention or alleviation of the symptoms of senile osteoporosis and in the acceleration of the rate of healing of fractures.

The recent observations that testosterone may be effective in some instances in the treatment of bone metastases from carcinoma of the breast may possibly be explained by the stimulation of bone repair at the site of the metastases rather than to any specific effect on the tumor. It is not logical to assume that cancer cells would be altered when they reside in bone but not when they occur in soft tissue. The relief from the pain of bone metastases in 2 patients in this series as well as the rapid union of a pathological fracture in one of these was thus possibly due to the hormonal stimulation of bone repair.

The temporary duration of the bodily changes which occur following the administration of testosterone has been noted by many observers and apparently is due to the interrelationship between the adrenals, pituitary, and ovaries. Farrow states that any natural or artificial imbalance caused by either the menopause or castration will be followed by compensatory changes in other endocrine organs and a partial replacement by hormones or compounds having a biologic effect similar to that of those which have become deficient and consequently that any imbalance due to excesses or deficiencies of sex hormones may be of a temporary nature. Although our clinical observations would tend to indicate a beneficial effect of many weeks' duration, Kenyon states that the drug may lose its effect in as short a period as 10 days. The appearance of a metastatic bone lesion in 1 patient of this series while under testosterone therapy would tend to indicate the inability of the drug to maintain its effect for any prolonged period of time.

It is possible that the systemic improvement noted following the treatment of 7 pa-

tients with advanced carcinoma of the breast with testosterone propionate was due not to any effect on the tumor cells but rather to the anabolic action of the drug on all the body tissues. It is our belief that it has no place in the management of carcinoma of the breast except as a palliative agent.

SUMMARY AND CONCLUSIONS

1 Testosterone propionate in amounts up to 3900 milligrams was used to treat 7 patients with carcinoma of the breast.

2 In 3 patients with inoperable or recurrent carcinoma it failed to alter the course of the disease and all 3 patients are dead.

3 In 4 patients with operable carcinoma with axillary metastases administration following radical amputation failed to improve the results ordinarily obtained by radical amputation alone. Three of the 4 patients are now dead.

4 There was no evidence of any specific alteration in tumor cytology in 2 patients in whom metastatic lesions were removed after the administration of 2000 and 3000 milligrams of testosterone respectively.

5 Systemic improvement consisting of a gain in weight and strength occurred in all cases, being most marked in those with the greatest debility. It appeared within 2 to 3 weeks of treatment but was of temporary duration, usually lasting for about 3 months.

6 The pain of bone metastases was relieved in the 2 patients who had such lesions when treatment was started, while union occurred in the 1 patient with a pathological fracture. One patient developed a painful bone metastasis while under treatment.

7 There is evidence to show that systemic improvement, relief from pain and calcification of bone metastases are due to the anabolic effect of the drug on the entire body rather than to any specific effect on tumor cells that similar improvement occurs when the drug is administered in the presence of other diseases and that it can be explained entirely by the known action of the drug on the normal subject.

8 No evidence was obtained in this series of 7 cases to indicate that testosterone propionate had any specific inhibitory effect on

patients who knew the nature and the prognosis of their disease. Those patients who had pain were relieved during treatment, although they all required narcotics during the terminal stages of the disease.

There were no adverse reactions to the use of testosterone. In those patients in the younger age group menstruation ceased shortly after the institution of treatment. Deepening of the voice occurred but was not marked enough to be annoying or particularly embarrassing. It was not noted in those patients who had passed the menopause. There was no evidence of hirsutism. One patient had a transient acne which persisted for only a short time and disappeared without altering the course of treatment and was accordingly thought not to be due to the testosterone.

DISCUSSION

The results obtained in this series of cases have not been encouraging and do not seem to warrant the enthusiasm found in some of the other reports. All 7 cases were examples of carcinoma of the breast with metastases. Three were in an advanced stage of the disease when treatment was begun while the remaining 4 had operable tumors with axillary metastases. In 3 of the operable cases the patients possessed complicating factors such as pregnancy diabetes mellitus or an inflammatory type of tumor all of which are known to give an unfavorable prognosis in this disease. The only operable case in which one of these complicating factors did not exist was Case 7. This is the only patient who is still living. Were testosterone propionate effective in the treatment of carcinoma of the breast some improvement in results should have been apparent regardless of the stage of the disease. This was not the case in spite of the fact that large doses were given and that 5 of the 6 patients who died were still receiving the drug at the time of death. Not only was the ultimate outcome unaffected but microscopic examination of metastatic lesions removed from 3 patients after the administration of 2000 and 3000 milligrams, respectively failed to reveal any alteration in tumor cytology which could be attributed to testosterone.

Three beneficial effects were noted there was a gain in weight and strength with a sense of well-being there was a decrease in pain and there was evidence of calcification of bony metastases. All of these were of temporary duration. It is our impression that they were all due to the action of testosterone propionate on the metabolic processes of the body rather than to any specific effect on tumor cells. There is evidence to support this impression.

Kenyon states that testosterone has an anabolic effect on the body causing a decrease in the urinary excretion of nitrogen, inorganic phosphorus and sulfate, potassium sodium and creatine and that its administration results in an increase in the basal metabolic rate and gain in body weight. He found that 25 milligrams daily is an effective dose if the patient is maintained on a constant diet. Butler and his associates found that a reduction in urinary nitrogen occurred even in the presence of a starvation diet with inadequate caloric intake although a positive nitrogen balance could not be obtained unless the patient was on a diet adequate in calories and protein. Abbott, studying a series of burn cases and noting the effects of diet and testosterone on recovery stated that patients receiving testosterone and an adequate caloric intake did better than those without testosterone or those on an inadequate diet with or without testosterone. He further stated that a reduction in the amount of urinary nitrogen and a gain in body weight occurs following its administration to normal subjects of both sexes and referred to similar observations having been made on patients with carcinoma of the stomach hyperthyroidism Cushing's disease Simmonds disease, pernicious anemia hypogonadism and nephrosis. The amount of nitrogen excreted in the urine could be reduced effectively by giving 12.6 milligrams daily.

Interest has been shown in the effect of hormones on the healing processes of bone. According to Allbright the healing of a fracture is a special form of bone metabolism which is dependent on the formation of an organic matrix through the activity of the osteoblasts. He found that this activity could

be accelerated by three types of stimuli: stresses and strains, diet and hormones and other chemical and enzymatic substances that both estrin and testosterone are effective stimulants and that their administration resulted in an increased rate of bone repair. Gardner and his associates think that testosterone may find a practical application in the prevention or alleviation of the symptoms of senile osteoporosis and in the acceleration of the rate of healing of fractures.

The recent observations that testosterone may be effective in some instances in the treatment of bone metastases from carcinoma of the breast may possibly be explained by the stimulation of bone repair at the site of the metastases rather than to any specific effect on the tumor. It is not logical to assume that cancer cells would be altered when they reside in bone but not when they occur in soft tissue. The relief from the pain of bone metastases in 2 patients in this series as well as the rapid union of a pathological fracture in one of these was thus possibly due to the hormonal stimulation of bone repair.

The temporary duration of the bodily changes which occur following the administration of testosterone has been noted by many observers and apparently is due to the interrelationship between the adrenals, pituitary, and ovaries. Larrow states that any natural or artificial imbalance caused by either the menopause or castration will be followed by compensatory changes in other endocrine organs and a partial replacement by hormones or compounds having a biologic effect similar to that of those which have become deficient, and consequently that any imbalance due to excesses or deficiencies of sex hormones may be of a temporary nature. Although our clinical observations would tend to indicate a beneficial effect of many weeks' duration, Kenyon states that the drug may lose its effect in as short a period as 10 days. The appearance of a metastatic bone lesion in 1 patient of this series while under testosterone therapy would tend to indicate the inability of the drug to maintain its effect for any prolonged period of time.

It is possible that the systemic improvement noted following the treatment of 7 pa-

tients with advanced carcinoma of the breast with testosterone propionate was due not to any effect on the tumor cells but rather to the anabolic action of the drug on all the body tissues. It is our belief that it has no place in the management of carcinoma of the breast except as a palliative agent.

SUMMARY AND CONCLUSIONS

1. Testosterone propionate in amounts up to 3900 milligrams was used to treat 7 patients with carcinoma of the breast.

2. In 3 patients with inoperable or recurrent carcinoma it failed to alter the course of the disease and all 3 patients are dead.

3. In 4 patients with operable carcinoma with axillary metastases administration following radical amputation failed to improve the results ordinarily obtained by radical amputation alone. Three of the 4 patients are now dead.

4. There was no evidence of any specific alteration in tumor cytology in 2 patients in whom metastatic lesions were removed after the administration of 2000 and 3000 milligrams of testosterone respectively.

5. Systemic improvement consisting of a gain in weight and strength occurred in all cases, being most marked in those with the greatest debility. It appeared within 2 to 3 weeks of treatment but was of temporary duration usually lasting for about 3 months.

6. The pain of bone metastases was relieved in the 2 patients who had such lesions when treatment was started, while union occurred in the 1 patient with a pathological fracture. One patient developed a painful bone metastasis while under treatment.

7. There is evidence to show that systemic improvement, relief from pain, and calcification of bone metastases are due to the anabolic effect of the drug on the entire body rather than to any specific effect on tumor cells that similar improvement occurs when the drug is administered in the presence of other diseases and that it can be explained entirely by the known action of the drug on the normal subject.

8. No evidence was obtained in this series of 7 cases to indicate that testosterone propionate had any specific inhibitory effect on

patients who knew the nature and the prognosis of their disease. Those patients who had pain were relieved during treatment although they all required narcotics during the terminal stages of the disease.

There were no adverse reactions to the use of testosterone. In those patients in the younger age group menstruation ceased shortly after the institution of treatment. Deepening of the voice occurred but was not marked enough to be annoying or particularly embarrassing. It was not noted in those patients who had passed the menopause. There was no evidence of hirsutism. One patient had a transient acne which persisted for only a short time and disappeared without altering the course of treatment and was accordingly thought not to be due to the testosterone.

DISCUSSION

The results obtained in this series of cases have not been encouraging and do not seem to warrant the enthusiasm found in some of the other reports. All 7 cases were examples of carcinoma of the breast with metastases. Three were in an advanced stage of the disease when treatment was begun while the remaining 4 had operable tumors with axillary metastases. In 3 of the operable cases the patients possessed complicating factors such as pregnancy, diabetes mellitus, or an inflammatory type of tumor all of which are known to give an unfavorable prognosis in this disease. The only operable case in which one of these complicating factors did not exist was Case 7. This is the only patient who is still living. Were testosterone propionate effective in the treatment of carcinoma of the breast some improvement in results should have been apparent regardless of the stage of the disease. This was not the case in spite of the fact that large doses were given and that 5 of the 6 patients who died were still receiving the drug at the time of death. Not only was the ultimate outcome unaffected but microscopic examination of metastatic lesions removed from 2 patients after the administration of 2000 and 3000 milligrams, respectively, failed to reveal any alteration in tumor cytology which could be attributed to testosterone.

Three beneficial effects were noted there was a gain in weight and strength with a sense of well-being there was a decrease in pain and there was evidence of calcification of bony metastases. All of these were of temporary duration. It is our impression that they were all due to the action of testosterone propionate on the metabolic processes of the body rather than to any specific effect on tumor cells. There is evidence to support this impression.

Kenyon states that testosterone has an anabolic effect on the body causing a decrease in the urinary excretion of nitrogen, inorganic phosphorus and sulfate potassium sodium and creatine and that its administration results in an increase in the basal metabolic rate and gain in body weight. He found that 25 milligrams daily is an effective dose if the patient is maintained on a constant diet. Butler and his associates found that a reduction in urinary nitrogen occurred even in the presence of a starvation diet with inadequate caloric intake although a positive nitrogen balance could not be obtained unless the patient was on a diet adequate in calories and protein. Abbott studying a series of burn cases and noting the effects of diet and testosterone on recovery stated that patients receiving testosterone and an adequate caloric intake did better than those without testosterone or those on an inadequate diet with or without testosterone. He further stated that a reduction in the amount of urinary nitrogen and a gain in body weight occurs following its administration to normal subjects of both sexes and referred to similar observations having been made on patients with carcinoma of the stomach, hyperthyroidism, Cushing's disease, Simmonds' disease, pernicious anemia, hypogonadism and nephrosis. The amount of nitrogen excreted in the urine could be reduced effectively by giving 12.6 milligrams daily.

Interest has been shown in the effect of hormones on the healing processes of bone. According to Albright the healing of a fracture is a special form of bone metabolism which is dependent on the formation of an organic matrix through the activity of the osteoblasts. He found that this activity could

be accelerated by three types of stimuli stresses and strains diet and hormones and other chemical and enzymatic substances that both estrin and testosterone are effective stimulants and that their administration resulted in an increased rate of bone repair. Gardner and his associates think that testosterone may find a practical application in the prevention or alleviation of the symptoms of senile osteoporosis and in the acceleration of the rate of healing of fractures.

The recent observations that testosterone may be effective in some instances in the treatment of bone metastases from carcinoma of the breast may possibly be explained by the stimulation of bone repair at the site of the metastases rather than to any specific effect on the tumor. It is not logical to assume that cancer cells would be altered when they reside in bone but not when they occur in soft tissue. The relief from the pain of bone metastases in 2 patients in this series as well as the rapid union of a pathological fracture in one of these was thus possibly due to the hormonal stimulation of bone repair.

The temporary duration of the bodily changes which occur following the administration of testosterone has been noted by many observers and apparently is due to the interrelationship between the adrenals, pituitary and ovaries. Farrow states that 'any natural or artificial imbalance caused by either the menopause or castration will be followed by compensatory changes in other endocrine organs and a partial replacement by hormones or compounds having a biologic effect similar to that of those which have become deficient and consequently that 'any imbalance due to excesses or deficiencies of sex hormones may be of a temporary nature'. Although our clinical observations would tend to indicate a beneficial effect of many weeks duration, Kenyon states that the drug may lose its effect in as short a period as 10 days. The appearance of a metastatic bone lesion in 1 patient of this series while under testosterone therapy would tend to indicate the inability of the drug to maintain its effect for any prolonged period of time.

It is possible that the systemic improvement noted following the treatment of 7 pa-

tients with advanced carcinoma of the breast with testosterone propionate was due not to any effect on the tumor cells but rather to the anabolic action of the drug on all the body tissues. It is our belief that it has no place in the management of carcinoma of the breast except as a palliative agent.

SUMMARY AND CONCLUSIONS

1 Testosterone propionate in amounts up to 3900 milligrams was used to treat 7 patients with carcinoma of the breast.

2 In 3 patients with inoperable or recurrent carcinoma it failed to alter the course of the disease and all 3 patients are dead.

3 In 4 patients with operable carcinoma with axillary metastases administration following radical amputation failed to improve the results ordinarily obtained by radical amputation alone. Three of the 4 patients are now dead.

4 There was no evidence of any specific alteration in tumor cytology in 2 patients in whom metastatic lesions were removed after the administration of 2000 and 3000 milligrams of testosterone respectively.

5 Systemic improvement consisting of a gain in weight and strength occurred in all cases being most marked in those with the greatest debility. It appeared within 2 to 3 weeks of treatment but was of temporary duration usually lasting for about 3 months.

6 The pain of bone metastases was relieved in the 2 patients who had such lesions when treatment was started while union occurred in the 1 patient with a pathological fracture. One patient developed a painful bone metastasis while under treatment.

7 There is evidence to show that systemic improvement, relief from pain and calcification of bone metastases are due to the anabolic effect of the drug on the entire body rather than to any specific effect on tumor cells; that similar improvement occurs when the drug is administered in the presence of other diseases and that it can be explained entirely by the known action of the drug on the normal subject.

8 No evidence was obtained in this series of 7 cases to indicate that testosterone propionate had any specific inhibitory effect on

patients who know the nature and the prognosis of their disease. Those patients who had pain were relieved during treatment, although they all required narcotics during the terminal stages of the disease.

There were no adverse reactions to the use of testosterone. In those patients in the younger age group menstruation ceased shortly after the institution of treatment. Deepening of the voice occurred but was not marked enough to be annoying or particularly embarrassing. It was not noted in those patients who had passed the menopause. There was no evidence of hirsutism. One patient had a transient acne which persisted for only a short time and disappeared without altering the course of treatment and was accordingly thought not to be due to the testosterone.

THE STUDY OF PERIPHERAL VASCULAR DISEASE WITH RADIOACTIVE ISOTOPES

Part II

F W COOPER Jr., M D F.A.C.S., DANIEL C ELKIN M D F.A.C.S.
PATRICK C SHEA, Jr., M D., and E. W DENNIS B.S Atlanta, Georgia

THE introduction of the use of radioactive isotopes in the study of peripheral vascular disease has made possible the critical evaluation of the circulation in the tissues of the extremities. Although all methods of instrumental investigation have certain inherent weaknesses they contribute a valuable addition to the clinical evaluation of vascular disorders. Studies on the circulation in the muscles of the extremities in normal individuals and those with vascular diseases have made possible a more objective evaluation of the patient.

In a previous report Part I (1) two methods for the use of radioactive sodium 24 in the investigation of circulatory physiology of the extremities were compared and discussed. The electronic apparatus used for these studies was described in detail and the results of one of the study methods were evaluated. This paper is concerned with an evaluation of the results of the second method.

In brief a sterile solution of radioactive sodium chloride consisting of 10 microcuries of the radioactive substance in approximately 0.2 cubic centimeter of solution is injected into the muscle of the extremity to be studied. The radiation effect on the individual from this quantity of radioactive material is negligible and frequent repeated observations can be made without danger to the patient. The radioactive sodium emits strong gamma rays which are readily detected by electronic equipment placed outside the body.

The presence of the sodium chloride in the muscle is recorded automatically by an electromechanical device built for these studies.

(3) As the radioactive salt solution is mobilized into the vascular channels and is removed from the part the decrease in the amount of sodium chloride in the muscle is similarly detected. Since the amount of radioactive salt solution originally injected is small after its mobilization into vascular system and subsequent dilution the amount of radioactive salt returning to the extremity is not significant.

The technique of the procedure consists of placing the patient on a tilt table with the extremities elevated at 35 degrees. A detecting unit (Geiger Mueller tube) is placed posterior to each gastrocnemius muscle. The radioactive sodium chloride is injected into the muscle and its rate of disappearance is measured for a period of 10 minutes. The patient may then be placed in a horizontal position, and a similar determination of the rate of disappearance made. In certain instances drugs have been administered or other measures have been carried out which are believed to enhance the circulation and their influence on the mobilization of the sodium determined. These findings are to be reported later.

Fifty seven normal individuals have been studied by this method. It has been found that under basal conditions the disappearance of sodium from the muscle in a given individual is constant. If the rate of disappearance of the sodium is plotted on semilogarithmic paper a linear expression of the rate of disappearance is obtained. For comparison of results, this linear expression can be converted into numerical terms by an equation first employed by Kety (2).

$$K = \frac{\log C_1 - \log C_2}{-4.343 (T_1 - T_2)}$$

C = counting rate at time T
C₁ = counting rate at time T₁

Fig 1 Graph representing the rate of removal of sodium in a normal person and in a patient with hyperthyroidism.

In all individuals, many factors control the rate and volume of blood flow to the extremities, for example, the emotional tone of the patient, excitement or apprehension, the activity of the part, the temperature of the environment, and the presence of edema, infection, or metabolic disturbances. Even though a constantly controlled temperature room is used and the patient is observed under basal conditions, only a few of the variables can be eliminated.

It has been found that if the individual is unduly apprehensive the mobilization of sodium will be increased above normal during the initial portion of the examination period and will fall below normal after the apprehension subsides. Consequently it has been found necessary in all individuals to delay the determination of the rate of disappearance for at least 2 or 3 minutes following the injection of

Fig 2 Distribution curve of the results in the study of 4 normal extremities.

the sodium. The patient must be cautioned to remain completely motionless as exercise of the muscle greatly expedites the removal of the sodium and will thus render the determination inaccurate.

From the observation of 114 normal extremities, a disappearance pattern was obtained which varied only within slight limits (Fig 1). The factors, previously mentioned, which produce variations in the disappearance rate of the sodium are included. On plotting these determinations as a distribution curve, the pattern becomes statistically significant (Fig 2).

In individuals of high emotional tone with hypertension or patients with hyperthyroidism, the mobilization of sodium from the muscle has been found to be uniformly increased. Similarly, if hyperemia of the extremity is produced by application and removal of a tourniquet, the mobilization of the sodium can be initially inhibited and then precipitously and abnormally increased in rate. Follow

Fig. 3 Graph representing rate of removal of sodium in patient S.A.G. with hypertension blood pressure of 188/126.

ing the application of a venous tourniquet inflated to diastolic pressure the removal of the sodium is prevented.

Patients with obliterative arterial disease and with lesser degrees of vasospastic phenomena will repeatedly produce the most constant pattern of sodium removal. In such individuals the variable factors influencing the blood flow in the extremities are apparently minimized. It is believed that in this group particularly less error would be encountered in the evaluation of specific measures of therapy or operative procedures. Individuals with vascular diseases in which vasospastic phenomena are of more significance demonstrate greater variations during a single period of observation, but they too mobilize sodium at below normal levels seemingly in proportion to the degree of arterial insufficiency.

One hundred and two patients with various vascular changes have been studied. An effort was made to include patients with all types of circulatory abnormalities. Similar curves were obtained on patients with the same vascular disorder. Representative results obtained in individuals with vascular disturbances are presented here.

Hyperthyroidism. In the 5 patients with hyperthyroidism the mobilization of the sodium from the extremity was greatly increased (Fig. 1). This might also be expected in patients with increased cardiac output, increased pulse pressure and peripheral vasodilatation.

Fig. 4 Graph representing rate of removal of sodium in patient O.D.K. with thrombosis of bifurcation of aorta.

Hypertension. Five patients with essential hypertension without congestive failure were studied. These individuals were of high emotional tone, gave an exaggerated response to the Hines and Brown cold pressor test and exhibited marked decline in blood pressure upon sedation. They showed an increased rate of removal of the sodium. Sympathectomy and splanchnicectomy were subsequently performed in each case in an attempt to alleviate the hypertension. Following operation there was no significant change in the rate of sodium removal.

S.A.G. (Fig. 3). Hypertension was discovered in this 30-year-old white male during a routine examination for admission to the Air Corps 8 years previous to this examination. For 18 months previous to admission he noticed increasingly severe headaches.

Physical examination revealed an elevation of blood pressure to 188/126 in both arms. No cardiac or kidney changes were present. Only slight response to the Hines and Brown cold pressor test was noted. Sympathectomy and splanchnicectomy were performed for the hypertension.

Arteriosclerosis obliterans. Twenty patients with varying degrees of arteriosclerotic ob-

Fig. 1. Graph representing the rate of removal of sodium in normal person and in patient with hyperthyroidism.

In all individuals, many factors control the rate and volume of blood flow to the extremities, for example, the emotional tone of the patient, excitement or apprehension, the activity of the part, the temperature of the environment and the presence of edema, infection or metabolic disturbances. Even though a constantly controlled temperature room is used and the patient is observed under basal conditions, only a few of the variables can be eliminated.

It has been found that if the individual is unduly apprehensive the mobilization of sodium will be increased above normal during the initial portion of the examination period and will fall below normal after the apprehension subsides. Consequently it has been found necessary in all individuals to delay the determination of the rate of disappearance for at least 2 or 3 minutes following the injection of

Fig. 2. Distribution curve of the results in the study of 4 normal extremities.

the sodium. The patient must be cautioned to remain completely motionless as exercise of the muscle greatly expedites the removal of the sodium and will thus render the determination inaccurate.

From the observation of 114 normal extremities a disappearance pattern was obtained which varied only within slight limits (Fig. 1). The factors previously mentioned, which produce variations in the disappearance rate of the sodium are included. On plotting these determinations as a distribution curve the pattern becomes statistically significant (Fig. 2).

In individuals of high emotional tone with hypertension or patients with hyperthyroidism the mobilization of sodium from the muscle has been found to be uniformly increased. Similarly if hyperemia of the extremity is produced by application and removal of a tourniquet, the mobilization of the sodium can be initially inhibited and then precipitously and abnormally increased in rate. Follow

Fig. 3. Graph representing rate of removal of sodium in patient S.A.G. with hypertension blood pressure of 188/126

ing the application of a venous tourniquet inflated to diastolic pressure the removal of the sodium is prevented

Patients with obliterative arterial disease and with lesser degrees of vasospastic phenomena will repeatedly produce the most constant pattern of sodium removal. In such individuals the variable factors influencing the blood flow in the extremities are apparently minimized. It is believed that in this group particularly less error would be encountered in the evaluation of specific measures of therapy or operative procedures. Individuals with vascular diseases in which vasospastic phenomena are of more significance demonstrate greater variations during a single period of observation but they too mobilize sodium at below normal levels seemingly in proportion to the degree of arterial insufficiency.

One hundred and two patients with various vascular changes have been studied. An effort was made to include patients with all types of circulatory abnormalities. Similar curves were obtained on patients with the same vascular disorder. Representative results obtained in individuals with vascular disturbances are presented here.

Hypertension In the 5 patients with hypertension the mobilization of the sodium from the extremity was greatly increased (Fig. 1). This might also be expected in patients with increased cardiac output, increased pulse pressure and peripheral vasodilatation.

Fig. 4. Graph representing rate of removal of sodium in patient O.D.K. with thrombosis of bifurcation of aorta

Hypertension Five patients with essential hypertension without congestive failure were studied. These individuals were of high emotional tone, gave an exaggerated response to the Hines and Brown cold pressor test, and exhibited marked decline in blood pressure upon sedation. They showed an increased rate of removal of the sodium. Sympathectomy and splanchnicectomy were subsequently performed in each case in an attempt to alleviate the hypertension. Following operation there was no significant change in the rate of sodium removal.

S.A.G. (Fig. 3) Hypertension was discovered in this 30-year-old white male during a routine examination for admission to the Air Corps 8 years previous to this examination. For 18 months previous to admission he noticed increasingly severe headaches. Physical examination revealed an elevation of blood pressure to 188/126 in both arms. No cardiac or kidney changes were present. Only slight response to the Hines and Brown cold pressor test was noted. Sympathectomy and splanchnicectomy were performed for the hypertension.

Arteriosclerosis obliterans Twenty patients with varying degrees of arteriosclerotic ob-

Fig. 5A.

literation of the vascular tree in the lower extremities were studied. It was found that this group of individuals had less variation in the rate of sodium disappearance even in the presence of emotional and psychic factors. However the degree of elevation of the extremity was found to be important in this group. With moderate degrees of vascular obliteration in which the extremity retained a normal color in the horizontal position the rate of sodium disappearance was frequently within normal ranges. If the extremity was elevated at an angle of 35 degrees, the rate of the removal of sodium was greatly retarded. With the extremity in this position the administration of drugs which cause a decrease

in blood pressure or generalized vasodilatation resulted in a decrease in rate of mobilization of the sodium.

O.D.K. (Fig. 4) a 40 year old male physician, first noticed an indefinite fatigability of the lower extremities 5 years previous to this examination. Three years ago following 2 days of strenuous hunting and walking there was a precipitous increase in the fatigability. Since that time there has been progressive weakness of the extremities, characterized by a feeling of tiredness, aching and claudication. Occasional numbness of the great toes was noted.

Examination revealed no abnormal color changes in either lower extremity, both became ruborous on dependency following elevation but a pallor was present on elevation. There was slight trophic change in the skin and nails of the lower extremities. All arterial pulsations were absent in the extremities.

Fig. 5. Patient C.R.J. with arteriosclerosis, popliteal aneurysm and gangrene. a, Graph showing skin temperatures b, graph representing rate of removal of sodium, c, arteriogram showing obstruction of femoropopliteal junction

and no pulsation could be felt in the abdominal aorta below the umbilicus. Skin surface temperatures were normal. Oscillometry revealed greatly diminished pulsations at all levels in the lower extremities.

A diagnosis of thrombosis of the abdominal aorta was made.

C.R.J. (Fig. 5a, b, c.) This 86 year old white male stated that he had been active until 3 weeks prior to admission. An accurate history could not be obtained because of his mental confusion. He was awakened at 2 a.m. at the onset of his present condition with severe pain in the right lower extremity. Shortly thereafter he noticed that his entire foot was cool and that a rubor was present. Cyanosis was present.

Examination of the extremities revealed marked pallor of the right lower extremity on elevation. Both lower extremities became ruborous on dependency. There were trophic changes in the skin and its derivatives in both lower extremities. A small gangrenous plaque was present on the lateral aspect of the right foot at the head of the 5th metatarsal. An area of cyanosis was persistent on the dorsolateral aspect of the right foot when in the horizontal position. The dorsalis pedis and posterior tibial pulses were absent bilaterally. The right popliteal pulse was absent. A popliteal aneurysm was present on the left.

Oscillometric examination revealed pulsations to be absent distal from the knee inferiorly on the right, increased in the left knee region over the aneurysm and diminished at the left ankle. Skin surface temperatures were elevated on the left and normal on the right. An arteriogram (Fig. 5c) was made revealing an obstruction of the femoropopliteal junction.

A diagnosis of arteriosclerosis obliterans and aneurysm popliteal left was made.

E.H. (Fig. 6) a 76 year old white male had a history of a cerebral accident 7 years previous to this examination. Since that time he had suffered from claudications in his legs. There was no history of

Fig. 5c

trophic changes in the extremities nor did physical examination reveal any such changes. Pallor of the feet was present on elevation. Femoral pulses were palpable but oscillometry did not reveal any pulsations from the knees distally. Skin surface temperatures were diminished bilaterally.

A diagnosis of arteriosclerosis obliterans was made.

Thrombophlebitis Twenty-eight patients with thrombophlebitis were studied. This group was by far the most difficult to evaluate. The sodium was found to mobilize more rapidly with the extremity in the elevated position if no arterial insufficiency was present. In this position however the removal rate of the sodium was usually below normal in the edematous extremity and was always less in the affected extremity than in the opposite or normal extremity. The greater the degree of edema of the calf muscle the greater was the retention of the salt solution. It was found also that in general the higher the skin surface temperature the greater was the rapidity of removal. In individuals with high skin surface temperatures the rate of sodium removal was frequently within normal limits.

Even if the extremity had become elephantine in proportion due to an old chronic venous and lymphatic obstruction with extensive fibrosis in the subcutaneous region the mobilization of sodium chloride from the muscle was frequently equal to the rate of mobilization in the uninvolved extremity. This was interpreted as indicating that the

Fig 32

literation of the vascular tree in the lower extremities were studied. It was found that this group of individual had less variation in the rate of sodium disappearance even in the presence of emotional and psychic factors. However the degree of elevation of the extremity was found to be important in this group. With moderate degrees of vascular obliteration in which the extremity retained a normal color in the horizontal position the rate of sodium disappearance was frequently within normal ranges. If the extremity was elevated at an angle of 35 degrees the rate of the removal of sodium was greatly retarded. With the extremity in this position the administration of drugs which cause a decrease

in blood pressure or generalized vasodilatation resulted in a decrease in rate of mobilization of the sodium.

O. D. K. (Fig 4) a 40 year old male physician first noticed an insidious fatigability of the lower extremities 5 years previous to this examination. Three years ago following 2 days of strenuous hunting and walking there was a precipitous increase in the fatigability. Since that time there has been progressive atrophy of the extremities characterized by feeling of tiredness, aching and claudication. Occasional numbness of the great toes was noted.

Examination revealed no abnormal color changes in either lower extremity, both became ruborous on dependency following elevation but no pallor is present on elevation. There was slight trophic change in the skin and nail of the lower extremities. All arterial pulsations were absent in the extremities.

and no pulsation could be felt in the abdominal aorta below the umbilicus. Skin surface temperatures were normal. Oscillometry revealed greatly diminished pulsations at all levels in the lower extremities.

A diagnosis of thrombosis of the abdominal aorta was made.

C.R.J. (Fig. 5a, b, c). This 86 year old white male stated that he had been active until 3 weeks prior to admission. An accurate history could not be obtained because of his mental confusion. He was awakened at 2 a.m. at the onset of his present condition with severe pain in the right lower extremity. Shortly thereafter he noticed that his entire foot was cool and that a ruborous cyanosis was present.

Examination of the extremities revealed marked pallor of the right lower extremity on elevation. Both lower extremities became ruborous on dependency. There were trophic changes in the skin and its derivatives in both lower extremities. A small gangrenous plaque was present on the lateral aspect of the right foot at the head of the 5th metatarsal. An area of cyanosis was persistent on the dorsolateral aspect of the right foot when in the horizontal position. The dorsalis pedis and posterior tibial pulses were absent bilaterally. The right popliteal pulse was absent. A popliteal aneurysm was present on the left.

Oscillometric examination revealed pulsations to be absent distal from the knee inferiorly on the right, increased in the left knee region over the aneurysm and diminished at the left ankle. Skin surface temperatures were elevated on the left and normal on the right. An arteriogram (Fig. 5c) was made revealing an obstruction of the femoropopliteal junction.

A diagnosis of arteriosclerosis obliterans and aneurysm popliteal left was made.

E.H. (Fig. 6) a 76 year old white male had a history of a cerebral accident 7 years previous to this examination. Since that time he had suffered from claudications in his legs. There was no history of

trophic changes in the extremities nor did physical examination reveal any such changes. Pallor of the feet was present on elevation. Femoral pulses were palpable but oscillometry did not reveal any pulsations from the knees distally. Skin surface temperatures were diminished bilaterally.

A diagnosis of arteriosclerosis obliterans was made.

Thrombophlebitis Twenty-eight patients with thrombophlebitis were studied. This group was by far the most difficult to evaluate. The sodium was found to mobilize more rapidly with the extremity in the elevated position if no arterial insufficiency was present. In this position however the removal rate of the sodium was usually below normal in the edematous extremity and was always less in the affected extremity than in the opposite or normal extremity. The greater the degree of edema of the calf muscle the greater was the retention of the salt solution. It was found also that in general the higher the skin surface temperature the greater was the rapidity of removal. In individuals with high skin surface temperatures the rate of sodium removal was frequently within normal limits.

Even if the extremity had become elephantine in proportion due to an old chronic venous and lymphatic obstruction with extensive fibrosis in the subcutaneous region, the mobilization of sodium chloride from the muscle was frequently equal to the rate of mobilization in the uninvolved extremity. This was interpreted as indicating that the

Fig. 6a

Fig. 6. Patient F.H. with arteriosclerosis bilateralis
a, Graph showing skin temperatures, b, graph representing
rate of removal of sodium.

edema was confined largely to the subcutaneous tissues (Fig. 7)

Thromboangitis obliterans (Buerger's disease) Five patients with thromboangitis obliterans were studied. There was a variation in the degree and extent of the obliterative process in these individuals. In patients with symptoms confined largely to distal ulcerations on the toes and with good major arterial pulsations the sodium disappeared rapidly from the gastrocnemius muscle. Patients with advanced disease demonstrated a slow removal of sodium chloride.

B.J.F. (Fig. 8) One year prior to admission, this 53 year old white male developed intermittent claudications in the legs, which gradually increased in

Fig. 7 Graph representing rate of removal of sodium in patient with chronic thrombophlebitis

severity. Five months later this was followed by lesions of migratory phlebitis on the left forearm and the lower extremities. Six weeks prior to admission he developed pain and discoloration in the right great toe and a small ulcer formed just beneath the great toenail.

Examination revealed cyanosis of the right great toe with a small painful ulcer on the terminal phalanx. Areas of migratory phlebitis were present on the left lower extremity and on the left forearm. Pallor of the right foot developed on elevation. Skin surface temperatures were normal. Oscillometry revealed essentially normal pulsations in the knee and ankle region. The dorsalis pedis pulsation were faint bilaterally. The posterior tibial pulsation was moderate on the left and absent on the right. There was a loss of hair over the toes on the right foot.

A diagnosis of thromboangitis obliterans was made.

A right lumbar sympathectomy was performed with removal of the sympathetic chain from the first to the third lumbar vertebra. There was immediate relief of pain in the foot and improvement in the appearance of the ulcer.

DISCUSSION

To obtain constant results by this method of studying the mobilization of radioactive sodium chloride in the muscle certain precautions must be carefully observed. The temperature and humidity in which the patient is studied should be constantly controlled. The procedure should be explained to the patient and his fears allayed regarding the discomfort associated with the procedure and the absence of danger from the use of radioactive materials. At the beginning of the study extremities should be elevated for at

Fig. 8 Graph representing rate of removal of sodium in patient B J F with thromboangitis obliterans, before and after right lumbar sympathectomy

least 10 minutes prior to the injection. The added strain imposed upon the circulation by the position of the extremity will thus become more completely manifest.

The extremity must be carefully placed over the Ciger Mueller tube and the position of the patient must be such that there will be no shifting of the body during the examination. It is obvious that variations in the distance of the injected deposit of sodium into the muscle from the Ciger Mueller tube will in itself change the rate of count and will therefore produce artifacts in the determination. The patient must be constantly observed and reminded that the extremities should remain motionless; this is particularly important in elderly patients who unconsciously change the position of their legs. In individuals whose extremities become painful in the elevated position these determinations must be carried out with the extremities horizontal.

More accurate determinations are obtained if small amounts of fluid are injected. It is necessary that the solution of sodium chloride be carefully prepared and be neutral in reaction.

SUMMARY AND CONCLUSIONS

By measuring the rate of disappearance of radioactive sodium chloride from the muscles of an extremity, an additional method of evaluating the circulatory physiology of the extremities has been made possible.

In the study of 57 normal individuals and 102 patients with peripheral vascular disturbances, curves representing the rate of disap-

pearance of the sodium from the muscle form statistically accurate patterns.

It is believed that this method of study may offer a valuable aid in the evaluation of certain forms of therapy which are believed to enhance the circulation.

SUTURE OF PERIPHERAL NERVES

Factors Affecting Prognosis

JOHN W. KIRKLIN, M.D., Rochester, Minnesota, FRANCIS MURPHEY, M.D.
Memphis, Tennessee, and JOSEPH BERKSON, M.D., Rochester, Minnesota

ALL who have cared for patients in whose case a peripheral nerve has required suture know that complete recovery of function of the involved nerve does not always occur. Yet it also is known that under the proper circumstances an extremely gratifying recovery can ensue.

Careful selection of cases for neurorrhaphy, accurate operative technique, and good attention to the postoperative care of the patient all tend to produce conditions favorable for recovery. It would seem also that an understanding of the factors of importance in the prognosis of such injuries would lead to better treatment and thus ultimately to more nearly complete return of function than would otherwise be possible.

Because of this, we are recording an analysis of these factors obtained from a group of patients with peripheral nerve injuries during World War II. The literature in recent years has contained numerous reports on peripheral nerve injuries but it is felt that no useful purpose will be served by complete review of these. Instead, we are merely recording experience in one hospital in the hope that the data obtained from such a group of cases may be of value to others.

MATERIAL

Patients with peripheral nerve injuries, admitted to this army installation from September 14, 1942 to October 1, 1945 form the basis of this study. This group comprised 2,849 patients who had 3,276 injuries to peripheral nerves. For these nerve injuries, 957 neurorrhaphies were carried out of which 673 were done by the members of the neurosurgical service at this hospital. The remainder were done at other army installations prior to ad-

mission of the patients to our hospital and the postoperative course was followed by us. Two hundred and seventy-nine neurolyses and 115 explorations without suture or neurolysis comprise the other operative procedures performed during this period at our installation.

The 957 neurorrhaphies were not all available for careful analysis and inclusion in this series. Cases were excluded if the neurorrhaphy was only partial if we had no definite record or knowledge of the function present in the muscles innervated by the nerve in question prior to neurorrhaphy and if the follow-up period was less than 6 months. After these cases were discarded, 755 neurorrhaphies remained for careful analysis and comprise the material analyzed for this study (Table I).

In each case, a record of the operative procedures and of the preoperative function present was available. Each patient was examined in so far as possible every 3 months during the follow-up period. The majority of patients were followed for 15 months although some were followed for as long as 28 months. Because the majority of patients were under observation for about 15 months, the graphic presentation of the data includes the recovery occurring in the first 15 months after suture. Yet certain definite impressions of the recovery after 15 months were obtained and these will be recorded in the discussion as impressions.

In testing these patients for recovery of motor power, accurate palpation was employed to determine the extent of contraction of the muscle or of movement of its tendon. Due regard was paid to trick movements, substitution, anomalous innervation and the like. Motor power was graded arbitrarily in the following manner: grade 1 consists of a palpable degree of contraction or movement of sufficient strength to produce movement of the part against gravity; grade 2, of a contrac-

months after suture) From this group one is able to determine by examination the number who have recovered function during this latter period and thus the specific recovery rate for the interval can be calculated. The application of such rates calculated for each interval in an appropriate manner gives the desired accumulated recovery rate.

The essentials of the method are basically very simple. As an example they will be presented here briefly in terms of the experience with radial neurorrhaphy analyzed according to the interval between wounding and suture. For purposes of illustration the calculations necessary for construction of the curve for those cases sutured from 4 to 6 months after injury when recovery of the extensor carpi radialis longus muscle only is considered are presented.

These calculations are given in Table II. Fifty-one individuals were examined 6 months after suture who were known not to have recovered at 3 months after suture of these 20 were found to have recovered. The recovery rate for the interval 3 to 6 months therefore was 39.2 per cent. Twenty-seven individuals were examined 9 months after suture who had not recovered at the 6 months point¹ and of these 14 had recovered this gives a rate of 51.8 per cent for the interval 6 to 9 months. Similarly the interval recovery rates for the 9 to 12 and 12 to 15 month periods were found to be 70 per cent and 80 per cent respectively.

With the interval recovery rates so ascertained we proceeded with the calculation as shown in columns 4 to 7 of Table II. We begin with a hypothetical 1,000 individuals who had not recovered at the end of the zero to 3 month period. Of these 39.2 per cent recovered during the interval of 3 to 6 months (column 5) obtained from column 3 or 392 have recovered in the interval (column 6) leaving 608 (column 4) who had not recovered at the beginning of the 6 to 9 month interval so that 39.2 per cent (column 7) have recovered by the beginning of that interval. Of the 608 individuals who had not recovered at the beginning of the 6 to 9 month interval 51.8 per cent

TABLE II — EXAMPLE OF CALCULATION OF TIME RECOVERY CURVE FOR RADIAL NEURORRHAPHY PERFORMED 4 TO 6 MONTHS AFTER INJURY. RESULTS OBTAINED IN EXTENSOR CARPI RADIALIS LONGUS MUSCLE

From observations			Calculation of curve

recovered during the interval that is 315 leaving 293 (column 4) who had not recovered at the beginning of the 9 to 12 month interval therefore 70.7 or 70.7 per cent (column 7) have recovered by then. The continuation of this process completes Table II. In this manner are determined the percentage of persons recovered at various periods after suture as given in column 7. The course of recovery then can be shown graphically by plotting the accumulative percentage of persons recovered (column 7) against time (Fig. 1).

The construction of each curve of recovery necessitated such a calculation and table. In order to conserve space however none of the other tables are included in this paper.

An attempt was made when studying a given factor such as the wrapping of the suture line with tantalum foil to utilize a homogeneous group of cases. Thus when using the cases of radial neurorrhaphy to study this factor individuals were selected whose nerves were sutured within 9 months after injury and whose lesions were located from 0 to 12 centimeters proximal to the lateral epicondyle. This group was then divided into those in which the nerves had been wrapped in tantalum foil and those in which they had not been wrapped in tantalum foil. The legend for each graph will indicate the method of selection of cases.

In the remainder of the paper the data are presented in their entirety in the graphs. No

¹Note that this is the number of patients examined 9 months after suture who had not recovered 6 months after suture, and the total number of patients examined 9 months after operation.

months after suture) From this group one is able to determine by examination the number who have recovered function during this latter period and thus the specific recovery rate for the interval can be calculated. The application of such rates calculated for each interval in an appropriate manner gives the desired accumulated recovery rate.

The essentials of the method are basically very simple. As an example they will be presented here briefly in terms of the experience with radial neurorrhaphy analyzed according to the interval between wounding and suture. For purposes of illustration the calculations necessary for construction of the curve for those cases sutured from 4 to 6 months after injury when recovery of the extensor carpi radialis longus muscle only is considered, are presented.

These calculations are given in Table II. Fifty-one individuals were examined 6 months after suture who were known not to have recovered at 3 months after suture; of these 20 were found to have recovered. The recovery rate for the interval 3 to 6 months therefore was 39.2 per cent. Twenty-seven individuals were examined 9 months after suture who had not recovered at the 6 months' point¹ and of these 14 had recovered; this gives a rate of 51.8 per cent for the interval 6 to 9 months. Similarly the interval recovery rates for the 9 to 12 and 12 to 15 month periods were found to be 10 per cent and 80 per cent respectively.

With the interval recovery rates so ascertained we proceeded with the calculation as shown in columns 4 to 7 of Table II. We began with a hypothetical 1,000 individuals who had not recovered at the end of the zero to 3 month period. Of these 39.2 per cent recovered during the interval of 3 to 6 months (column 5) obtained from column 3, or 392 have recovered in the interval (column 6), leaving 608 (column 4) who had not recovered at the beginning of the 6 to 9 month interval, so that 51.8 per cent (column 7) have recovered by the beginning of that interval. Of the 608 individuals who had not recovered at the beginning of the 6 to 9 month interval 51.8 per cent

TABLE II — EXAMPLE OF CALCULATION OF TIME RECOVERY CURVE FOR RADIAL NEURORRHAPHY PERFORMED 4 TO 6 MONTHS AFTER INJURY. RESULTS OBTAINED IN EXTENSOR CARPI RADIALIS LONGUS MUSCLE

Fig. 3. Effect of the interval between wounding and suturing on the recovery of sensory function after median neurotaphy. Only cases in which the lesion was located 5 centimeters or more distal to the medial epicondyle were included.

Fig. 4. Effect of the interval between wounding and suturing on the recovery of sensory function after sciatic neurotaphy. All cases. There were no instances of recovery of sensory function of grade 3.

When the divided nerve is sutured 10 to 15 months after injury the results are distinctly inferior. Nonetheless, since 20 per cent of the patients were able to regain active extension of the wrist even when 10 to 15 months had elapsed between injury and suture of the radial nerve suture is worth while in this situation even at that late date. However, when it is done as late as 10 months after severance of the nerve, it must be realized that a certain

portion of the motor deficit most probably will have to be compensated for later by an appropriate transference of tendons.

Sensory function. In the median nerve (Fig. 3) and also in the ulnar nerve although the data are not presented, a sensory return of grade 1 can nearly always be expected if the nerve is sutured within 9 months after injury. As a matter of fact 90 per cent of the patients obtained this much return of function when

Fig. 5. Effect of the level of the lesion on the recovery of function after sciatic neurotomy. Only cases in which the nerve was sutured within 3 months after injury are included.

the nerve was sutured as late as 15 months after injury. Sensory return of grade 2 like wise ensued in nearly all instances when the nerve was sutured within 9 months of its severance. In more than half of the cases in which the nerve was sutured from 10 to 15 months after injury such a return occurred. There is no doubt, however, that suture within 3 months of injury is of unquestioned superiority in obtaining a return of sensory function to grade 3 in the median and ulnar nerves. Yet the return of nearly normal sensation with stereognosis and two point discrimination is uncommon even under these favorable circumstances.

In the sciatic nerve (Fig. 4) return of sensory function in general was disappointing in our experience. There were no instances of sensory return of grade 3. Suture within 3 months gave slightly less than 20 per cent of the patients so treated return of sensory function to grade 2 which is indeed disappointing. Suture at any time within 9 months gave just about this same result. The postponement of suturing beyond this date gave uniformly unsatisfactory results. It might further be added that the long term follow-up in some cases for 28 months after suture of the nerve has sub-

stantiated these observations that a return of sensory function to grade 3 in the sciatic nerve, even under the best of circumstances, is indeed rare.

EFFECT OF THE LEVEL OF THE INJURY

Motor function. The data for the sciatic nerve are presented in Figure 5. The conclusions drawn from these data were substantiated by data calculated for the other nerves, which we are not presenting.

It is obvious that in general a higher percentage of patients with distally placed lesions, than of those with more proximally located injuries recover. However even lesions high in the sciatic nerve did allow some motor recovery in many instances. The same is true of lesions high in the nerves of the arm, that is lesions of the brachial plexus and cervical nerve roots.

Thus, in patients with high-lying lesions, a special effort should be made to obtain end-to-end anastomosis within a few months after injury so that the best possible recovery under the circumstances will ensue.

Sensory function. The data with regard to sensory recovery are obtained from a comparison of two groups of median nerve in-

Fig. 6 Effect of the level of the lesion on the recovery of sensory function after median neurorrhaphy. Only cases in which the nerve was sutured within 6 months after injury were included.

juries both sutured within 6 months after injury (Fig. 6). One group comprises patients with lesions at certain levels in the forearm while the other comprises those with lesions at certain levels in the arm.

Return of sensory function of grade 1 and grade 2 was slightly superior for the low-lying lesions to that for high lying lesions. It would appear also that the low lying lesions have a superior return of sensory function to grade 3. However since both curves were continuing to rise at the last period plotted, these data are not entirely convincing. The patients whom we have seen as long as 28 months after injury however have given us the impression that this is a true difference.

Mention has been made of the poor prognosis for return of sensory function in cases of injury to the sciatic nerve. Thus the prognosis is unusually poor for recovery of sensory appreciation in high lying lesions of this nerve.

EFFECT OF GAP BETWEEN NERVE ENDS AFTER RESECTION OF NEUROMA AND GLIOMA

These data are presented only with regard to return of motor function. Two groups of cases, namely those in which median neuror-

rhaphies (Fig. 7) and sciatic neurorrhaphies (Fig. 8) were performed will be considered. Without belaboring the differences that do occur it can certainly be stated without hesitation that the presence of a large gap between the nerve ends is no barrier to at least partial recovery of function if careful suturing has been carried out. Thus we feel strongly that large gaps should never deter the surgeon from carrying out an end-to-end anastomosis if such is at all feasible for in such cases he will frequently be rewarded by a gratifying recovery of motor function.

EFFECT OF THE WRAPPING OF THE SUTURE LINE WITH TANTALUM FOIL

Motor function. A difference of opinion occurred among the surgeons caring for these patients concerning the value of the wrapping of the suture line with tantalum foil. Consequently two fairly comparable groups of cases are available in one of which wrapping of the suture line was employed and in the other of which it was not employed. The data obtained from an analysis of radial neurorrhaphies are given in Figure 9 and those from an analysis of sciatic neurorrhaphies in Figure 10.

Fig. 6 Effect of the level of the lesion on the recovery of sensory function after median neurography. Only cases in which the nerve was sutured within 6 months after injury were included.

juries, both sutured within 6 months after injury (Fig. 6). One group comprises patients with lesions at certain levels in the forearm while the other comprises those with lesions at certain levels in the arm.

Return of sensory function of grade 1 and grade 2 was slightly superior for the low lying lesions to that for high lying lesions. It would appear also that the low lying lesions have a superior return of sensory function to grade 3. However, since both curves were continuing to rise at the last period plotted, these data are not entirely convincing. The patients whom we have seen as long as 28 months after injury, however, have given us the impression that this is a true difference.

Mention has been made of the poor prognosis for return of sensory function in cases of injury to the sciatic nerve. Thus the prognosis is unusually poor for recovery of sensory appreciation in high lying lesions of this nerve.

EFFECT OF GAP BETWEEN NERVE ENDS AFTER RESECTION OF NEUROMA AND GLIOMA

These data are presented only with regard to return of motor function. Two groups of cases, namely those in which median neuro-

raphies (Fig. 7) and sciatic neurotaphies (Fig. 8) were performed will be considered. Without belaboring the differences that do occur, it can certainly be stated without hesitation that the presence of a large gap between the nerve ends is no barrier to *at least* partial recovery of function, if careful suturing has been carried out. Thus we feel strongly that large gaps should never deter the surgeon from carrying out an end-to-end anastomosis if such is at all feasible, for in such cases he will frequently be rewarded by a gratifying recovery of motor function.

EFFECT OF THE WRAPPING OF THE SUTURE LINE WITH TANTALUM FOIL

Motor function. A difference of opinion occurred among the surgeons caring for these patients concerning the value of the wrapping of the suture line with tantalum foil. Consequently, two fairly comparable groups of cases are available, in one of which wrapping of the suture line was employed and in the other of which it was not employed. The data obtained from an analysis of radial neurotaphies are given in Figure 9 and those from an analysis of sciatic neurotaphies in Figure 10.

Fig. 4. Effect of the level of the lesion on the recovery of function after sciatic neurotomy. Only cases in which the nerve was sutured within 5 months after injury are included.

the nerve was sutured as late as 15 months after injury. Sensory return of grade 2 likewise ensued in nearly all instances when the nerve was sutured within 9 months of its severance. In more than half of the cases in which the nerve was sutured from 10 to 15 months after injury such a return occurred. There is no doubt, however, that suture within 3 months of injury is of unquestioned superiority in obtaining a return of sensory function to grade 3 in the median and ulnar nerves. Yet the return of nearly normal sensation with stereognosis and two point discrimination is uncommon even under these favorable circumstances.

In the sciatic nerve (Fig. 4) return of sensory function in general was disappointing in our experience. There were no instances of sensory return of grade 3. Suture within 3 months gave slightly less than 20 per cent of the patients so treated return of sensory function to grade 2 which is indeed disappointing. Suture at any time within 9 months gave just about this same result. The postponement of suturing beyond this date gave uniformly unsatisfactory results. It might further be added that the long term follow up in some cases for 28 months after suture of the nerve has sub-

stantiated these observations that a return of sensory function to grade 3 in the sciatic nerve, even under the best of circumstances, is indeed rare.

EFFECT OF THE LEVEL OF THE INJURY

Motor function. The data for the sciatic nerve are presented in Figure 5. The conclusions drawn from these data were substantiated by data calculated for the other nerves, which we are not presenting.

It is obvious that in general a higher percentage of patients with distally placed lesions than of those with more proximally located injuries recover. However even lesions high in the sciatic nerve did allow some motor recovery in many instances. The same is true of lesions high in the nerves of the arm that is lesions of the brachial plexus and cervical nerve roots.

Thus in patients with high lying lesions, a special effort should be made to obtain end-to-end anastomosis within a few months after injury so that the best possible recovery under the circumstances will ensue.

Sensory function. The data with regard to sensory recovery are obtained from a comparison of two groups of median nerve in-

Fig. 6. Effect of the level of the lesion on the recovery of sensory function after median neurography. Only cases in which the nerve was sutured within 6 months after injury were included.

junes, both sutured within 6 months after injury (Fig. 6). One group comprises patients with lesions at certain levels in the forearm while the other comprises those with lesions at certain levels in the arm.

Return of sensory function of grade 1 and grade 2 was slightly superior for the low lying lesions to that for high-lying lesions. It would appear also that the low lying lesions have a superior return of sensory function to grade 3. However since both curves were continuing to rise at the last period plotted, these data are not entirely convincing. The patients whom we have seen as long as 28 months after injury, however have given us the impression that this is a true difference.

Mention has been made of the poor prognosis for return of sensory function in cases of injury to the sciatic nerve. Thus the prognosis is unusually poor for recovery of sensory appreciation in high lying lesions of this nerve.

EFFECT OF GAP BETWEEN NERVE ENDS AFTER RESECTION OF NEUROMA AND GLIOMA

These data are presented only with regard to return of motor function. Two groups of cases, namely those in which median neuro-

raphies (Fig. 7) and sciatic neurotaphies (Fig. 8) were performed will be considered. Without belaboring the differences that do occur, it can certainly be stated without hesitation that the presence of a large gap between the nerve ends is no barrier to at least partial recovery of function if careful suturing has been carried out. Thus we feel strongly that large gaps should never deter the surgeon from carrying out an end-to-end anastomosis if such is at all feasible for in such cases he will frequently be rewarded by a gratifying recovery of motor function.

EFFECT OF THE WRAPPING OF THE SUTURE LINE WITH TANTALUM FOIL

Motor function. A difference of opinion occurred among the surgeons caring for these patients concerning the value of the wrapping of the suture line with tantalum foil. Consequently, two fairly comparable groups of cases are available, in one of which wrapping of the suture line was employed and in the other of which it was not employed. The data obtained from an analysis of radial neurotaphies are given in Figure 9 and those from an analysis of sciatic neurotaphies in Figure 10.

Fig. 6. Effect of the level of the lesion on the recovery of sensory function after median neurotomy. Only cases in which the nerve was sutured within 6 months after injury were included.

juries both sutured within 6 months after injury (Fig. 6). One group comprises patients with lesions at certain levels in the forearm while the other comprises those with lesions at certain levels in the arm.

Return of sensory function of grade 1 and grade 2 was slightly superior for the low-lying lesions to that for high lying lesions. It would appear also that the low lying lesions have a superior return of sensory function to grade 3. The patients whom we have seen as long as 28 months after injury however have given us the impression that this is a true difference.

Mention has been made of the poor prognosis for return of sensory function in cases of injury to the sciatic nerve. Thus the prognosis is unusually poor for recovery of sensory appreciation in high lying lesions of this nerve.

EFFECT OF GAP BETWEEN NERVE ENDS AFTER RESECTION OF NEUROMA AND GLIOMA

These data are presented only with regard to return of motor function. Two groups of cases, namely those in which median neuror-

raphies (Fig. 7) and sciatic neurorraphies (Fig. 8) were performed will be considered. Without belaboring the differences that do occur it can certainly be stated without hesitation that the presence of a large gap between the nerve ends is no barrier to at least partial recovery of function, if careful suturing has been carried out. Thus we feel strongly that large gaps should never deter the surgeon from carrying out an end-to-end anastomosis if such is at all feasible for in such cases he will frequently be rewarded by a gratifying recovery of motor function.

EFFECT OF THE WRAPPING OF THE SUTURE LINE WITH TANTALUM FOIL

Motor function. A difference of opinion occurred among the surgeons caring for these patients concerning the value of the wrapping of the suture line with tantalum foil. Consequently two fairly comparable groups of cases are available, in one of which wrapping of the suture line was employed and in the other which it was not employed. The data obtained from an analysis of radial neurorraphies are given in Figure 9 and those from an analysis of sciatic neurorraphies in Figure 10.

Fig. 1. Effect of the wrapping of the line of suture with tantalum foil on the recovery of sensory function after median neuroorthophy. Only cases in which the lesion was located from 5 to 30 centimeters distal to the medial epicondyle and in which the nerve was sutured within 9 months after injury were included.

sensory function. These data suggest no great difference in recovery between the cases in which wrapping had been employed and those in which it had not been employed. There would appear to be a slight superiority of return to sensory function of grade 3 in the median nerve when wrapping is employed but it is doubtful if this is of significance.

Comment: It can thus be concluded that wrapping of the suture line with tantalum foil has no discernible advantages. In addition to the absence of any demonstrable effect on end results, the use of tantalum foil in this manner seems of doubtful value on the basis of the appearance of the suture line in the nerve at re-exploration. Many surgeons have commented on the fact that such anastomoses in nerves of ten appear attenuated and compressed by a constricting cuff of tantalum foil.

EFFECT OF THE MICROSCOPIC APPEARANCE OF THE RESECTED ENDS OF THE NERVES

It was the practice at this neurosurgical center to examine microscopically the cut ends of segments removed from the nerves prior to anastomosis. In this manner examination of

the mirror image of the approximated nerve ends was made. The presence of any neuroma in the proximal end of the nerve or of any glioma in the distal end was ascertained. Further note was made of the presence of shrinkage of the tubules of Schwann's cells, of edema of the funiculi and of fibrosis and cellular infiltration of the nerve trunks.

Because it was also our practice to obtain frozen sections at the time of operation on all questionable nerve ends, we fortunately had a very small number 24 in this series of cases in which operation was performed in this installation and in which the permanent sections showed 'unsatisfactory' nerve ends. In 17 cases a neuroma occupied half or slightly more of the proximal end of the nerve. In 7 cases glioma occupied half or more of the distal end. In 1 of these 7 cases the glioma occupied almost all of the end of the nerve.

A statistical analysis of such a small group is of course impossible. A study of the recovery in these cases does allow a few statements however. In the cases in which half or slightly more of the end of the nerve consisted of neuroma a definite return of function oc-

Fig. 12. Effect of the wrapping of the suture line with tantalum foil on the recovery of sensory function after sciatic neurorrhaphy. Only cases in which the lesion was located from 0 to 25 centimeters proximal to the head of the fibula and in which the nerve was sutured within 6 months after injury were included. There were no instances of recovery of sensory function of grade 3.

curred, but in only 3 did a really good recovery occur. Thus it may be fairly concluded that in cases such as this some, although incomplete, return of function may be expected. In only 1 of the 6 cases in which half of the end of the nerve was glioma could the recovery of function be classified as of good quality. In the 1 case in which the distal end was nearly all glioma no return of function occurred.

We thus feel that it is essential to obtain good funiculi both proximally and distally even if this entails the production of a considerable gap between the ends of the nerve. Such a gap of course usually can be overcome by careful and extensive mobilization of the nerve. If it becomes apparent that despite these measures sufficient nerve cannot be resected to give two healthy ends an occasion which should be unusual then the distal end should be resected until good funiculi are seen, the proximal end then should be resected back as far as possible. When on such occasions good funiculi cannot be obtained on the proximal end of the nerve some recovery, although usually incomplete, can be expected.

EFFECT OF OTHER FACTORS

Tension on completed anastomosis. We were not able to obtain statistical data on this factor. Nonetheless it is our distinct impression gained during the experience of operating on and caring for these patients and substantiated by a careful review of all of their records that some tension on the suture line does not

endanger the functional result. As a matter of fact we have frequently seen cases in which the suture line was under much tension and yet a good recovery of function ensued.

It is obvious that extreme tension on a suture line is not desirable primarily because it imposes the risk of disruption. In certain instances in which considerable nerve is either lost or damaged however it is impossible despite all efforts to effect neurorrhaphy without such tension. If the mobilization has been extensive if sutures are accurately placed in the tough epineurium and if the postoperative immobilization has been properly done disruption of the anastomosis even when under considerable tension is rare. We are of the opinion that it is preferable to resect the nerve back to good nerve ends and to have the anastomosis under considerable tension than it is to resect less nerve in order to have the anastomosis only under slight tension but then to have neuroma or glioma in the sutured nerve ends.

Whenever possible of course the operation should consist of resection of the nerve back to good ends, and the establishment of an accurate anastomosis under only slight tension.

Suture material. It was not possible to analyze the data in such a way that the influence of one or another type of suture material could be ascertained. However we wish to record a few impressions.

It is highly probable that any fine nonabsorbable suture material such as silk, cotton

tantalum wire or steel wire will yield excellent results. It is important however to use at least a few radiopaque sutures in some manner on the ends of the nerve so that a subsequent roentgenogram will yield information concerning the presence or absence of disruption of the suture line. The importance of a careful check of this in each case cannot be overemphasized.

It did not seem possible to ascertain from our data the effect of the use of a stay suture. On theoretic grounds, however we believe such a suture is not advisable and we have rarely employed it.

COMMENT

These data lend factual confirmation to the results of many previous studies, and also the impressions of many who have managed peripheral nerve injuries. Complete recovery of function to a degree comparable to the normal state is indeed rare after nerve suture. Emphatically satisfactory recoveries, however can be obtained in many instances.

The patient's interests are best served by accurate end-to-end anastomosis of the nerve within 3 months after injury and preferably in the first month after injury. High lying injuries such as those of the brachial plexus should be an especial stimulus to early repair. However repair is of value though limited when done as long as 15 months after injury. Beyond this period motor recovery will rarely result but some return of crude sensory function may occur.

Large gaps between the healthy portions of a divided nerve offer a temptation to the surgeon to deem the lesion inoperable, or to per-

form bulb suture with the hope of subsequent resection and suture. Such extensive injuries do undoubtedly influence unfavorably the end-results even if an anastomosis is obtained. Nonetheless, good results can frequently be obtained in these cases if the surgeon is prepared and willing to undertake an extensive dissection of the nerve in order to make union of healthy ends possible. Despite some encouraging results (2) the superiority of the use of autogenous nerve grafts over end-to-end anastomosis of the divided nerve in such situations has not been conclusively demonstrated.

No advantage is served by the wrapping of the line of anastomosis in tantalum foil. A few metallic sutures at appropriate points in the nerve ends are of value in that they allow the surgeon to assure himself that the anastomosis is still intact at any time in the post-operative period.

The surgeon must not be discouraged at any time during operative procedures on peripheral nerves, for it is usually possible to effect a satisfactory neurorrhaphy. At the same time, he should not be overoptimistic during the months which follow since certain factors may preclude a nearly complete recovery in a given instance. He should recognize these factors and be ready to recommend or perform suitable reconstructive procedures at an appropriate time. This broad view makes available to the patient the best that surgery can offer.

STRATIFICATION OF BILE IN THE GALL BLADDER AND CHOLELITHIASIS

B A CAMPBELL, M.Sc. M.D., and A C BURTON B.Sc., M.A., Ph.D., London, Ontario

THERE is a voluminous literature on the composition of bile in the gall bladder and on the concentration function of that organ which can be found from recent reviews (8). In these reviews it is implied though not stated that the contents of the gall bladder at any one time, can be thought of as homogeneous so that a sample of bile from any part of the bladder would be representative of the whole.

Yet roentgenological evidence from several investigators (2, 3, 4, 5, 6, 9) has long been published, which indicates, to the contrary, that a high degree of inhomogeneity of bile may exist in the human gall bladder in normal subjects as well as in cholecystitis. Roentgenograms show that the bile in lowest part of the bladder often has a markedly greater radio-opacity than that above with one or more sharp lines of demarcation between.

When floating gallstones are present these are often found to lie in this region of apparent separation between two layers. It is necessary to roentgenograph the patient in an upright, rather than in the usual horizontal position to reveal these phenomena (Fig. 9). Bernstein (2) has put forward a theory of the origin of this stratification and suggested its connection with the formation of gallstones. A review on the roentgenological evidence by Bernstein is in course of publication.

However there have been critics (Akerlund) who have maintained that the introduction of iodized oil needed to visualize the layers leads to artefacts which are wholly responsible for the phenomena observed. It is of obvious importance that our concept of the state of the bile in the gall bladder should include 'stratification' if this is physiologically present so that the suggestion of Dr Bernstein it was decided to seek evidence other than roentgenological on the point.

METHODS

The obvious line of attack was to secure samples of bile from different levels in the gall bladders of animals and if possible from those of patients at cholecystectomy and to examine them to see if differences existed at different levels. Measurements of specific gravity of the samples which can easily be made with only a few drops, offered the best starting point. Measurements of viscosity, indicative mainly of the amount of mucoid material of hydrogen ion concentration and of a color index were later added.

Technique of obtaining samples As far as the choice of an animal was concerned it was felt that one in which gallstones occurred naturally would be most suitable. In answer to a request for information the Ontario Agricultural College replied that among the common experimental animals gallstones occurred so infrequently as to be practically nonexistent though among the domestic animals beef cattle had such stones more frequently than other species. It is of interest that in such animal a cholesterol stone was found in the gall bladder during this research.

Preliminary experiments were made upon the gall bladders of cats which became available. These cats had been used in acute experiments in which various convulsive drugs were given. As soon as the animal had been killed the gall bladder was removed from the body and suspended with the fundus hanging down in order that samples might be taken. Five tenths cubic centimeter samples of bile were then drawn off by means of a hypodermic needle, at intervals of 1 centimeter from one another from the neck down to the fundus of the gall bladder. The uniformity of the distance between the levels of the samples was gauged by suspending the bladder beside a ruler and steadying it there. When possible samples were also drawn from the hepatic ducts.

From the Department of Anatomy and of Biophysics, Medical School, University of Western Ontario.

The results in the cat series given in detail later were by no means conclusive due to the small size of the bladder and the consequent difficulty in obtaining accurately spaced samples of adequate size.

Gall bladders of cattle proved to be more suitable for the purposes of this experiment. In length from neck to fundus they average about 12 centimeters (7 to 19 cm). Because of their large size it is possible to draw off relatively large samples (2 c.c.) accurately spaced without interfering greatly with any stratification which may be present. The gall bladders were obtained at a local abattoir from beef cattle which were to be killed and the meat dressed for sale. A 48 hour period of fasting preceded the death of the beasts which were 2, 3, and 4 year old heifers for the most part with the occasional bull and cow. It was subsequently appeared that sex and parity in no significant way affected the results obtained. The method of killing is worthy of note. The beast was first driven into a small pen just large enough to hold it, the floor of which was a trap door. It was stunned with a blow on the forehead where upon the trap door was opened and the animal dropped or rather rolled to the killing floor 3 feet below. During this drop the animal was completely turned over so that the gall bladder presumably experienced a considerable amount of disturbance. The actual killing was accomplished by severing the aorta and allowing the animal to bleed to death. A certain amount of struggling marked the death of most of the animals. The animals used in the experiment were completely unselected being taken as they came in order to obtain a representative series on essentially normal beasts. From the time the animal was killed until samples were drawn was, on the average about 15 minutes (7 to 25). As soon as the bladder was freed from the body it was suspended beside the ruler fundus down and samples were withdrawn at centimeter intervals. The needle of the syringe was introduced through the wall bevel upward as close to the vertical axis of the bladder as possible.

In addition a small series of cases in humans was investigated. These were all patients with clinical cholecystitis and cholelithiasis. The

method of obtaining samples will be discussed in a separate section.

Technique of measurements made on samples

The specific gravities were measured by testing whether a drop of the bile floated or sank in solutions of known specific gravity. The known solutions, in this case were mixtures of bromobenzene and xylene the relative proportions of which were varied to give a series of solutions of known specific gravity ranging from 1.000 to 1.080 in steps of .005 that is to say 1.000 1.005 1.010 and so on. By mixing two of these solutions in equal quantities solutions of intermediate specific gravities were obtained (i.e. measurement was made in steps of .0025 in specific gravity).

The viscosity of the samples was measured by a microviscosimeter of the Ostwald type in which the capillary tube and bulb of a white blood cell pipette was used. The measurement consisted of placing a known quantity of bile, 0.5 cubic centimeter in the viscosimeter and, by means of a stop watch measuring the length of time it took to pass through the capillary tube. Results are relative rather than absolute.

In a small series of bladders the color index of the bile was measured as well as the specific gravity. The measurement was made by comparison in a visual comparison colorimeter (Hellige) of the unknown with a standard solution. Two-tenths cubic centimeter of bile was diluted to 10 cubic centimeters and the comparison was made of this solution with the standard which was 1 to 1000 potassium dichromate solution.

The hydrogen ion concentration was also determined by means of a standard electro-metric apparatus.

Alternative method of investigating stratification. A gall bladder obtained in the usual way was suspended over a large graduated cylinder. A small bore hypodermic needle was introduced through the lowest part of the bladder and the bile was allowed to drip out through the needle and run slowly down the side of the graduate. When the bladder had been completely emptied, samples were taken at regular intervals with a pipette introduced to different depths. Specific gravity determinations were made after a period of 4 hours, and

TABLE I—RESULTS

Amount of difference in specific gravity	No. of bladders	Percentage
No change (Less than .0025)	1	17
.0025	15	1
.0050		5
.0075	1	8

.0175	5	8
.0200	4	6
.0225		3
Greater than .0225	0	
Total	65	100

on samples taken each succeeding 24 hours for 1 week

RESULTS

Gall bladders of cats The results obtained in these experiments were suggestive but the series is too small to have any statistical significance. In all 8 cat gall bladders were investigated by the technique previously described. It was possible to draw off at least 4 samples at centimeter intervals for examination.

Figure 1 shows the results of the specific gravity measurements in 1 of these cat gall bladders. Of the 8 bladders 4 showed changes in specific gravity from the neck to the fundus of the bladder larger than could be accounted for by experimental error. Three of these 4 bladders gave evidence of stratification that is to say, abrupt changes of specific gravity as in Figure 1. In the cases in which it was possible to obtain a large enough sample of bile from the hepatic duct to examine it was found to be much less concentrated (specific gravity 1.015-1.020) than the bile of the bladder (specific gravity as high as 1.045).

Gall bladders of cattle In Table I the results in a series of 65 animals are analyzed according to the difference found in specific gravity between samples drawn from the uppermost and the lowest levels. It will be seen that in 54 of the 65 bladders there was a difference between top and bottom certainly greater

Fig. 1. Specific gravity at different levels in the gall bladder of a cat indicating two "strata."

than the least difference measurable and in a large number of bladders the difference was much greater. From this table it is concluded that a considerable degree of inhomogeneity of the contents of the gall bladder of cattle is the rule rather than the exception.

Table I makes no distinction between those cases in which the change from top to bottom was gradual or at least in steps so small as to be within the error of measurement, and those in which a sudden sharp increase in specific gravity between adjacent samples was found (as in the cat gall bladder of Fig. 1). There were 8 cases in which a sharp increase of .0050 in specific gravity was present, 1 of .0075, and 4 of .0100, as well as 6 more cases in which stratification was probably present. An example in which stratification undoubtedly exists is shown in Figure 2. Moreover there were cases in which there was more than one

Fig. 2. Stratification in specific gravity in the gall bladder of a bovine.

The results in the cat series, given in detail later, were by no means conclusive due to the small size of the bladder and the consequent difficulty in obtaining accurately spaced samples of adequate size.

Gall bladders of cattle proved to be more suitable for the purposes of this experiment. In length from neck to fundus they average about 12 centimeters (7 to 19 cm.) Because of their large size it is possible to draw off relatively large samples (2 c.c.) accurately spaced without interfering greatly with any stratification which may be present. The gall bladders were obtained at a local abattoir from beef cattle which were to be killed and the meat dressed for sale. A 48 hour period of fasting preceded the death of the beasts which were 2, 3 and 4 year old heifers for the most part, with the occasional bull and cow. It was subsequently appeared that sex and parity in no significant way affected the results obtained. The method of killing is worthy of note. The beast was first driven into a small pen just large enough to hold it, the floor of which was a trap door. It was stunned with a blow on the forehead whereupon the trap door was opened and the animal dropped or rather rolled to the killing floor 3 feet below. During this drop the animal was completely turned over so that the gall bladder presumably experienced a considerable amount of disturbance. The actual killing was accomplished by severing the aorta and allowing the animal to bleed to death. A certain amount of struggling marked the death of most of the animals. The animals used in the experiment were completely unselected, being taken as they came in order to obtain a representative series on essentially normal beasts. From the time the animal was killed until samples were drawn was, on the average, about 15 minutes (7 to 25). As soon as the bladder was freed from the body it was suspended beside the ruler, fundus down, and samples were withdrawn at centimeter intervals. The needle of the syringe was introduced through the wall, bevel upward as close to the vertical axis of the bladder as possible.

In addition a small series of cases in humans was investigated. These were all patients with clinical cholecystitis and cholelithiasis. The

method of obtaining samples will be discussed in a separate section.

Technique of measurements made on samples. The specific gravities were measured by testing whether a drop of the bile floated or sank in solutions of known specific gravity. The known solutions, in this case, were mixtures of bromobenzene and xylene, the relative proportions of which were varied to give a series of solutions of known specific gravity ranging from 1.000 to 1.080 in steps of .005, that is to say 1.000 1.005 1.010 and so on. By mixing two of these solutions in equal quantities solutions of intermediate specific gravities were obtained (i.e. measurement was made in steps of .0025 in specific gravity).

The viscosity of the samples was measured by a microviscosimeter of the Ostwald type in which the capillary tube and bulb of a white blood cell pipette was used. The measurement consisted of placing a known quantity of bile, 0.5 cubic centimeter in the viscosimeter and, by means of a stop watch measuring the length of time it took to pass through the capillary tube. Results are relative rather than absolute.

In a small series of bladders the color index of the bile was measured as well as the specific gravity. The measurement was made by comparison in a visual comparison colorimeter (Hellige) of the unknown with a standard solution. Two-tenths cubic centimeter of bile was diluted to 10 cubic centimeters and the comparison was made of this solution with the standard which was 1 to 1000 potassium dichromate solution.

The hydrogen ion concentration was also determined by means of a standard electrometric apparatus.

Alternative method of investigating stratification. A gall bladder obtained in the usual way was suspended over a large graduated cylinder. A small bore hypodermic needle was introduced through the lowest part of the bladder and the bile was allowed to drip out through the needle and run slowly down the side of the graduate. When the bladder had been completely emptied, samples were taken at regular intervals, with a pipette introduced to different depths. Specific gravity determinations were made after a period of 4 hours, and

TABLE I—RESULTS

on samples taken each succeeding 24 hours for 1 week

RESULTS

Gall bladders of cats. The results obtained in these experiments were suggestive but the series is too small to have any statistical significance. In all, 8 cat gall bladders were investigated by the technique previously described. It was possible to draw off at least 4 samples at centimeter intervals for examination.

Figure 1 shows the results of the specific gravity measurements in 1 of these cat gall bladders. Of the 8 bladders, 4 showed changes in specific gravity, from the neck to the fundus of the bladder, larger than could be accounted for by experimental error. Three of these 4 bladders gave evidence of stratification, that is to say abrupt changes of specific gravity as in Figure 1. In the cases in which it was possible to obtain a large enough sample of bile from the hepatic duct to examine it was found to be much less concentrated (specific gravity 1.015-1.020) than the bile of the bladder (specific gravity as high as 1.045).

Gall bladders of cattle. In Table I the results in a series of 65 animals are analyzed according to the difference found in specific gravity between samples drawn from the uppermost and the lowest levels. It will be seen that in 54 of the 65 bladders there was a difference between top and bottom certainly greater

Fig. 1. Specific gravity at different levels in the gall bladder of a cat indicating two "strata."

than the least difference measurable, and in a large number of bladders the difference was much greater. From this table it is concluded that a considerable degree of inhomogeneity of the contents of the gall bladder of cattle is the rule rather than the exception.

Table I makes no distinction between those cases in which the change from top to bottom was gradual or at least in steps so small as to be within the error of measurement and those in which a sudden sharp increase in specific gravity between adjacent samples was found (as in the cat gall bladder of Fig. 1). There were 8 cases in which a sharp increase of .0050 in specific gravity was present 1 of .0075 and 4 of .0100 as well as 6 more cases in which 'stratification' was probably present. An example in which stratification undoubtedly exists is shown in Figure 2. Moreover there were cases in which there was more than one

Fig. 2. Stratification in specific gravity in the gall bladder of a heifer.

samples taken each succeeding 24 hours for 12 hrs.

RESULTS

Stratification of bile. The results obtained in experiments were suggestive but the series failed to have any statistical significance. In all 8 cat gall bladders were investigated by the technique previously described. It was possible to draw off at least 4 cc. of bile in intervals for examination.

The average range of the specific gravities in 10 of these cat gall bladders (in 4 bladders 4 showed changes in specific gravity from the neck to the fundus in which stratification could be accounted for) was .0015 to .0055. Three of these bladders showed stratification that is, the specific gravity of the bile was not uniform. In 10 of these bladders it was possible to draw off bile from the fundus. In 10 of these bladders it was found to be uniform (specific gravity .0015 to .0055) in the bile of the bladder (see table next).

In the 10 bladders in Table I, the results are analyzed and in specific gravity .0015 to .0055 and in specific gravity .0015 to .0055. It will be seen that in 10 of these bladders there was a difference in specific gravity greater

Fig. 1. Specific gravity at different levels in the gall bladder of a cat, indicating two "strata."

than the least difference measurable, and in a large number of bladders the difference was much greater. From this table it is concluded that a considerable degree of inhomogeneity of the contents of the gall bladder of cattle is the rule rather than the exception.

Table I makes no distinction between those cases in which the change from one to another was gradual, or at least in steps so small as to be within the error of measurement, and those in which a sudden sharp increase in specific gravity between adjacent samples was noted (as in the cat gall bladder in Fig. 1). There were 8 cases in which a sharp increase of .0020 in specific gravity was present between .0020 and .0040 as well as 5 more cases in which "stratification" was probably present. An example in which stratification was probably present is shown in Figure 2. If there were more cases in which there was stratification

Fig. 2. Stratification of bile in the gall bladder of a cat.

Fig. 3. Results in the gall bladder of a beifer indicating three distinct strata.

sharp increase in specific gravity indicating several strata in the same gall bladder as in Figure 3.

A significant observation was that in all cases in which there was no difference in specific gravity between top and bottom of a gall bladder the specific gravity was throughout very low equal to that usually found in the neck (i.e. less than 1.020).

In the original work of McMaster and Rous (10) on the concentrating ability of the gall bladder the pigment concentration was taken as the criterion of concentration. In view of this, both specific gravity and a color index were measured at different levels in 6 bladders. The results indicated a very close correlation (Fig. 4).

Estimations of the viscosity of the bile were done on 35 bladders. These included 22 immediate samples, 8 twenty-four hour samples, and 5 forty-eight hour samples. Specific gravity determinations were made at the same time. It was found that the viscosity bore little relation to the specific gravity though

Fig. 5. Relation between specific gravity and hydrogen ion concentration in gall bladder of beifer.

Fig. 4. Relation between specific gravity and basicity of color at different levels in gall bladder of a beifer.

generally speaking the viscosity appeared to increase as the fundus of the bladder is approached. This is more noticeable in the later than in the immediate samples. Viscosities were very variable ranging from 1.4 to 5.0 times that of water with a mean of 2.1 times the viscosity of water.

It was expected that the hydrogen ion would be among the most diffusible of substances and that the hydrogen ion concentration of the bile would be constant throughout the gall bladder even when there was a "stratification" in specific gravity and in concentration of pigments.

Contrary to expectation the results of this investigation show that the pH values in a given bladder are closely correlated with the specific gravity. The bile becomes more acid the greater its concentration. This fact has been long known to apply to representative samples from a gall bladder as concentration proceeds (9) but here it is shown that the relation holds for simultaneous layers in the same gall bladders (Fig. 5). Moreover 24 hour specimens showed no essential change from those which had preceded them. The pH values confirm the finding given by the

TABLE II.—CHANGE IN THE DIFFERENCE OF SPECIFIC GRAVITY TOP TO BOTTOM WITH TIME OF STANDING

No. of bladders	Mean of immediate samples	Standard error of mean	Time of later samples	Mean of later samples	Standard error of mean
10	0.005	± 0.004	14 hrs.	0.007	± 0.004
10	0.006	± 0.003	48 hrs.	0.008	± 0.004
4	0.007	± 0.004	7 hrs.	0.009	± 0.003

Fig. 6 Shift in specific gravity in a beef gall bladder after hanging 24 hours.

specific gravity samples that the concentration of bile in the gall bladder is far from homogeneous.

In addition to the specific gravity determinations made as soon as possible after death, determinations were made 24 hours later on the same bladders in 10 cases, 48 hours later in 10 other cases, and 72 hours later in 4 cases. The means with their standard errors are given in Table II.

Except for the difference between the 4 hour and immediate samples, where there is a slightly significant change, there is no evidence of diffusion having significantly decreased the inhomogeneity in the contents of these gall bladders. It is to be noted however that though the gradient had not changed in most cases all the specific gravities were higher in the 24 hour samples than in the corresponding immediate samples (Fig. 6). This is probably due to evaporation and possibly to the absorption of water by the wall of the bladders in the period. The character of the stratification remained the same in spite of evaporation and the removal of the samples. In the case in which the contents of a gall bladder were allowed to drip slowly into a tall graduate the gradient was found to persist even after 1 week (Fig. 7).

Diffusion between the strata is certainly remarkably slow so that once present the stratification persists. To determine whether or not diffusion would be equally slow in a similar system with comparable viscosity and specific gravity, an artificial stratification was made of 18 per cent glycerine in water under distilled water. The results are shown in

Fig. 7 Persistence of gradient of specific gravity in bile dripped into a graduated cylinder.

Figure 8. The diffusion though slow is definitely faster than in the case of stratified bile, so that in the latter some other physicochemical factor than viscosity and specific gravity must play a part. The strongest evidence that mixing of the strata hardly occurs even with mechanical agitation is that stratification was found in the gall bladders of these cattle though in the process of killing and removal of the gall bladders there had been quite violent changes of position.

Human gall bladders. A short series of experiments on human gall bladders obtained at operation is included here. A longer series on human material is being accumulated by one of us and will be presented later elsewhere.

Fig. 8 Change of gradient in specific gravity due to diffusion in a layered sample of distilled water over an 18 per cent glycerine solution.

(Operative procedures were not carried out by the authors.)

In each case an attempt was made to remove samples of bile from the bladder *in situ* that is before it had been disturbed by the manipulations occasioned by its removal. Following removal samples of bile were drawn from the bladder suspended with the fundus down at intervals of 1 centimeter. On these two sets of samples specific gravity and other determinations were made. Of the series of 5 bladders, on 3 both sets of samples were obtained; on 1 it was possible to obtain samples only after removal; and on 1 bladder samples were obtained only before removal. In 1 case it was possible to obtain complete roentgenological investigation, i.e. pictures of the bladder preoperatively as well as postoperatively in both the supine and upright positions.

Figure 9 shows the layer of small floating stones visible when one of the patients was in the erect position. The stones were also visible again floating in a horizontal line when the patient was in the supine position. Roentgenological examination revealed that a good degree of functional contractility and of concentration by the gall bladder was present. Figure 10 shows the results of analysis of samples from this bladder before and after operation. The dotted line represents the level at which the stones floated. There were 19 of these all of specific gravities between 1.040 and 1.0495 so that they were evidently floating in bile of their own specific gravity. This case illustrates the existence of marked stratification of bile in a human gall bladder and the fact that floating stones occur near the region in which the specific gravity changes abruptly. Two other cases of the 5 showed marked differences of specific gravity from top to bottom and evidence of stratification. The series of values of specific gravity in samples from top to bottom ran in the 2 cases

1.020 1.020 1.025 1.0375 1.0375 1.0375
in one case and 1.015 1.015 1.015 1.015
1.0175 1.0175 1.0375 in the other

In these cases, the stones that were present were not floating but at the bottom. This brief series of human cases serves to show that the phenomena of stratification suggested by

the radiological evidence of Bernstein in normal as well as diseased humans, can be found by other methods in humans as well as in cattle and cats.

DISCUSSION OF RESULTS

A series of experiments has been described in which the bile of the gall bladders of cats, cattle and human beings has been investigated for evidence for or against the presence of strata as observed roentgenologically. The results show that the bile of many normal gall bladders is not of a homogeneous composition throughout and that the stratification is remarkably persistent in spite of diffusion. Furthermore the presence of strata has been demonstrated in a sufficiently large number of these bladders to justify the conclusion that stratification occurs as a normal physiological phenomenon in the functioning gall bladder.

The fact of persistent inhomogeneity of the contents of a gall bladder in the normal physiology of these animals, as well as in cholelithiasis, has an important bearing on the interpretation of previous researches. For example, when small samples have been with drawn from gall bladders at successive times to indicate the progress of concentration within the bladder the question must be raised whether such samples were representative of the contents as a whole and so could give reliable information. Some of the reports of astonishingly rapid concentration may have been due to the withdrawal first of more dilute samples from high in the bladder and later of samples of greater concentration from a stratum below.

A simple explanation of the formation of strata of bile in the gall bladder may be suggested. Let us suppose that after filling with dilute hepatic bile the gall bladder has considerably concentrated this before a contraction occurs. Unless this contraction is complete expelling all of the contents, there will be a residue of concentrated bile. Relaxation of the gall bladder will draw in on top of this, a more dilute hepatic bile. If as has been demonstrated the two biles do not readily mix, there will then be two distinct layers of bile in the bladder. A second partial contraction and relaxation might introduce a third

Fig. 9. Roentgenogram of patient with floating gallstones, taken in the erect position.

layer and so on. Thus the presence of stratification would be primarily due to the incompleteness of contraction of a gall bladder which is still able to concentrate.

It has been demonstrated that once established such stratification is remarkably persistent and resists mixing by mechanical agitation. The roentgenological evidence and evidence in humans here reported strongly suggest that the floating gallstones are associated with interfaces between two biles of different concentration. This suggests that the precipitation of cholesterol may be favored at such persistent interfaces by a physicochemical mechanism.

An observation on the population of multiple cholesterol stones in a human case is pertinent which can be explained by the picture

Fig. 10. Results on samples of bile taken from human gall bladder shown in Figure 9.

Fig. 11. Population of multiple stones in a human gall bladder showing distinct families."

of events just described but is difficult on other theories. This gall bladder was full of a very large number of stones of greatly different sizes as well as one large calculus filling the fundus. On inspection the stones could be segregated into what appeared to be three distinct groups (Fig. 11). All were weighed and a statistical population study made. The histogram (Fig. 11) shows that there are as well as the large calculus at least two statistically distinct families of gallstones (corresponding to the maxima in the graph) indicating that there must have been several distinct new beginnings of such families. A new partial contraction and drawing in of a new layer of hepatic bile above the concentrated layers might well be the starting point of each new family of stones.

Theories of cholelithiasis can be grouped under two headings. First there is the metabolic theory in which it is thought that the bile secreted by the liver into the gall bladder is not of normal composition and that this somehow leads to precipitation of calculi. The second theory is that of infection in which

layer, and so on. Thus the presence of stratification would be primarily due to the incompleteness of contraction of a gall bladder which is still able to concentrate.

It has been demonstrated that once established such stratification is remarkably persistent and resists mixing by mechanical agitation. The roentgenological evidence and evidence in humans here reported strongly suggest that the floating gallstones are associated with interfaces between two biles of different concentration. This suggests that the precipitation of cholesterol may be favored at such persistent interfaces by a physicochemical mechanism.

An observation on the population of multiple cholesterol stones in a human case is pertinent which can be explained by the picture

Fig. 10. Results on samples of bile taken from human gall bladder shown in Figure 9.

Fig. 11. Population of multiple stones in a human gall bladder showing distinct "families."

of events just described but is difficult on other theories. This gall bladder was full of a very large number of stones of greatly different sizes as well as one large calculus filling the fundus. On inspection the stones could be segregated into what appeared to be three distinct groups (Fig. 11). All were weighed and a statistical population study made. The histogram (Fig. 11) shows that there are, as well as the large calculus, at least two statistically distinct families of gallstones (corresponding to the maxima in the graph) indicating that there must have been several distinct beginnings of such families. A new partial contraction and drawing in of a new layer of hepatic bile above the concentrated layers might well be the starting point of each new family of stones.

Theories of cholelithiasis can be grouped under two headings. First there is the metabolic theory in which it is thought that the bile secreted by the liver into the gall bladder is not of normal composition and that this somehow leads to precipitation of calculi. The second theory is that of infection in which

infection of the gall bladder wall by altering the absorption of different constituents of the bile is thought to bring about the precipitation. The work here reported suggests that a third factor cannot be neglected. Mere inability of the gall bladder to contract completely leading to infrequent or incomplete emptying of the contents, may itself favor the precipitation of cholesterol stones because of persistent stratification of the bile.

CONCLUSIONS

It is concluded from these experiments that in cats, cattle and in humans the contents of the gall bladder are far from homogeneous as regards specific gravity concentration of bile pigments and hydrogen ion concentration and that this is a physiological rather than a pathological phenomenon. The inhomogeneity is often so abrupt as to suggest that distinct strata of bile of different degrees of concentration coexist. The observations also show that when such stratification exists, it is remarkably persistent and resists the process of diffusion and quite violent mechanical agitation.

The formation of such strata is readily explained in terms of incomplete emptying of a gall bladder which is able to concentrate the bile. The consequences of long persistent stratification have not been demonstrated, but there is suggestive evidence, in cases of floating multiple stones, that it may favor the precipitation of cholesterol stones.

SUMMARY

1. Samples of bile withdrawn at different levels in dependent gall bladders of cats, cattle and of some humans have been examined as

to their specific gravity concentration of pigments, viscosity and hydrogen ion concentration.

2. A lack of homogeneity from top to bottom is the rule rather than the exception. In 65 gall bladders of normal cattle 60 per cent showed an increase in specific gravity from top to bottom of .005 to .023 unit. Changes in hydrogen ion concentration and in color index closely paralleled the changes in specific gravity. Changes in viscosity were not well correlated.

3. The changes were often so abrupt as to show the existence of two or more distinct strata.

4. Neither the process of diffusion for as long as a week nor considerable mechanical agitation was able to mix these strata.

5. In 2 of the 5 human cases, cholesterol stones were floating at the level of the interface between two strata.

6. A theory of the formation of such strata in terms of incomplete emptying of a gall bladder able to concentrate is suggested.

7. The possibility is discussed that persistent stratification of bile may favor the precipitation of cholesterol stones.

VASCULAR CHANGES OF THE SKIN IN PREGNANCY

Vascular Spiders and Palmar Erythema

WILLIAM B BEAN, M D Iowa City Iowa, ROBERT COGSWELL, M D MORRIS DEXTER, M D., Cincinnati Ohio, and JAMES F EMBICK, M D., Iowa City Iowa

ALTHOUGH American textbooks on obstetrics do not mention them there are scattered references in medical writings to vascular spiders and palmar erythema as banal complications of pregnancy which tend to clear up following delivery (4 6 7 8 11 12 13 14 15 16 17 18 23 24 29 30 32). The general subject of vascular spiders and palmar erythema has been the theme of extensive reviews and there has been a revived interest in these phenomena recently with many contributions from internists and dermatologists. No systematic study of these vascular lesions and their natural history in pregnancy has been made although there are reports of changes in capillaries (20). We therefore undertook a comprehensive investigation of the problem in the clinics and on the wards of the obstetrical service of the Cincinnati General Hospital. In addition we have collected from the literature all related reports we have been able to find. The significance of these vascular changes in the skin is not known but clinical relationships suggest that there is some connection with endocrine changes. These are under investigation. It is hoped that more attention will be given these phenomena by specialists in the fields of obstetrics endocrinology and gynecology. The purpose of this paper is to report the results of the clinical study and a review of the literature. The completed analysis of all possible correlations among the observations made will be reported later.

DESCRIPTION OF THE VASCULAR SPIDER AND PALMAR ERYTHEMA

The vascular spider has been called by many names it has been designated nevus

From the Department of Internal Medicine and the Department of Obstetrics of the College of Medicine, University of Cincinnati and the Cincinnati General Hospital.
This investigation was supported by research grant from the Division of Research Grants and Fellowships of the National Institute of Health, U. S. Public Health Service.

angioma, and telangiectasis. The type occurring in persons with chronic liver disease has been described in detail elsewhere (6). Three features characterize the usual variety a body legs and surrounding erythema. A central point or eminence constitutes the body of the spider and in small or beginning lesions this may be the only abnormality. In large ones it may project one or more millimeters above the level of the surrounding skin surface and when of sufficient size its pulsations may be felt. Branching legs or radicles come away from the body and decrease in size as the periphery is reached. There may be some irregularity of the legs as they dip out of sight and reappear further away from the center. The entire area encompassed by the legs is redder than the adjacent skin and in some instances the erythema may occur with few or no visible radicles. The skin may reveal other changes consisting chiefly of scattered vascular strands which have a resemblance to the silk threads in American paper money. In studying the earliest visible changes in the skin during pregnancy we have seen several instances of a very pale area in the skin later becoming the site of a vascular spider. After one or more weeks a red spot of pin head size appears in the center of the pale area and this gives rise to the anemic halo (Fig. 1) which has been described (23) and pictured before (12). Not all of these pale spots subsequently develop vascular changes some gradually disappear. The temperature over a vascular spider is higher than that of the surrounding skin because of the local increase in arterial blood. A fiery red color is characteristic and the lesion does not appear in infra red photographs (5). Blood flows from the body toward the periphery as may be seen in the refilling of a spider following its obliteration by pressure or by gently pressing a glass slide over the area. There is a curious predilection for distribution

Fig. 1

Fig. 1. The anemic halo. This is the earliest stage of the vascular spider. Here pinpoint red spot is found occupying the center of small area paler than adjoining skin.

Fig. 2. Typical large vascular spiders, one of which has been covered with oil to reveal the vessels radiating from the center. In those not covered with oil the erythema surrounding the central punctum is prominent.

Fig. 2.

over the upper parts of the body with the face, neck, upper chest and arms frequently affected. It should be emphasized that as the study progressed with repeated scrutiny and concentration we have detected smaller and smaller lesions. Indeed in certain persons with lightly pigmented skin which had a conspicuous pattern of vascular marking we noted spiders appear at the level of barely perceptible visibility in the pale regions. Thus a single small red spot appeared to be surrounded by an anemic halo. Later the body grew larger, legs sprouted outward and grew in a centrifugal direction branching when they reached sufficient size. We have recorded as

spiders in our data only such lesions as we were able to record by ordinary black and white photography. Various types of lesions are illustrated in Figures 1 to 6.

We have no observations on the microscopic characters of the vascular spider or palmar erythema of pregnancy. Histological details of the spider of chronic hepatic disease have been published elsewhere (6).

Palmar erythema may occur in two distinct forms in women during pregnancy. The first variety is similar to the "liver palms" of chronic hepatic disease. It begins as a diffuse redness most prominent in the proximal part of the hypothenar eminence. Cyanotic spots may appear in the red areas. In more advanced stages the thenar eminence is involved also and a more extensive area of the hypothenar eminence becomes bright red. Next the parts of the palm between the metacarpophalangeal joints develop red spots and the palmar pads of the finger tips become red. Later the base of the nails may be affected. The red areas are sharply separated from adjoining skin of normal color. The other variety consists of a diffuse mottled erythema involving the entire palmar surface with a speckling of pale areas a millimeter or more in diameter. This is an exaggeration of the nor-

mal mottling of the palm. At times there is a patchy cyanosis of parts of the palm so that there is an irregular display of red, white and blue. There is a tendency for the vascular markings of the palm to show some variation, part of which is spontaneous and part of which may be induced by elevating or depressing the hand. In some instances the type of erythema has changed during the course of observation and the localized type has become the diffuse type or vice versa. There is a trend for redness to increase in intensity as pregnancy runs its course. This may be pronounced early after the first appearance of redness or may be gradual throughout gestation. These vascular changes of the hand have no regular relation to edema of the hands. A number of women studied before palmar erythema became apparent had cold sweating hands and an increase in the vascular markings of the arms with reticulated areas of cyanosis surrounding pale islands of skin similar to the pattern which may become fixed in erythema *ab igne*. The types of palmar erythema are demonstrated in Figures 7 to 9.

REVIEW OF THE LITERATURE VASCULAR SPIDERS

In an earlier paper (6) one of us reviewed some of the casual and detailed reports of

vascular spiders in pregnant women and pointed out the curious complete absence of comment on these common vascular changes in American textbooks of obstetrics.

So far as we have been able to determine the first observation of spiders appearing during the course of pregnancy was recorded by Corbett in the *British Journal of Dermatology* in 1914 (11). He merely stated that he had seen spider angiomas appear in the skin during pregnancy and disappear entirely after delivery. The next note on cutaneous spiders in pregnancy was recorded by Zeisler (32). He suggested the possibility of syphilis as a causative agent. Konrad (17) gave a more detailed description in 1925 calling attention to the

Fig 6. Vascular spider on the knee, a very rare location and subsequent picture revealing its disappearance following delivery.

Fig. 7. Palmar erythema. On the left is the variety which is most marked on the hypothenar eminence. In the center of the thenar eminence, the palm between the palms near the metacarpophalangeal junction and the finger tips. On the right the palm is diffusely involved with mottled erythema. C. nodes, and pallor which is an exaggeration of the mottled pattern seen in the normal hand.

appearance of telangiectases on the face, neck and arms during the second month of pregnancy. This was the first emphasis on the distribution over the upper parts of the body characteristic of the acquired cutaneous spider of pregnancy as well as that of hepatic disease. The abrupt fading or disappearance of these marks in the postpartum period was observed. A similar finding was reported in a woman who had a pituitary tumor (1) and the possibility was considered that an endocrine disorder might be responsible for the skin lesion. Two examples of spiders in pregnancy were encountered by Urbach (26) who described them in detail. They vanished shortly after delivery. Gougerot and Meyer (16) suggested a possible familial tendency. They observed the appearance of typical spider-like angiomas during the fifth month of pregnancy in four consecutive gestations, in a woman whose two sisters had also acquired spiders during pregnancy. Because of syphilis in the family they believed the lesions to be stigmas of hereditary syphilis. Distribution on the neck, arms, and hands was noted. There were no mucosal lesions and no tendency to bleed.

Another report (23) described a case in which spiders were not present during the first and second pregnancies but in the third month of the next pregnancy appeared on the

neck, chest and arms. The paper included a description of spiders of several varieties and sizes with the larger ones typical in shape, having an elevated central boss and a peripheral anemic halo. The authors believed the distribution was related to the cutaneous nerves derived from the brachial plexus. In a report by Madden on generalized angiomas (19) 2 cases of vascular spiders acquired during pregnancy were included. In one, a 30 year old white woman they appeared during the third month, increased in number up to the seventh month and all disappeared about 2 months after the second pregnancy was terminated. Similar smaller lesions had appeared during the first pregnancy. Another patient acquired similar vascular spiders in the fifth month of pregnancy. Mitchell (21) referred to 3 similar cases.

Forman (15) described a case in which the woman acquired spiders early in the second month of 11 consecutive pregnancies, each of which ended with delivery of a stillborn fetus before term. The spiders faded rapidly within a week after labor. He believed that an endocrine disturbance was responsible. In addition the coming and going of cutaneous spiders concurrently with the waxing and waning of symptoms in a patient with peptic ulcer was noted. Vignes, Hanoun and Vial (29) have reviewed some of the European literature on spiders in women during pregnancy and have recorded their familiarity with this lesion. Davis (12) has contributed a learned discussion of subcutaneous hemangioendotheliomas associated with pregnancy in which he discusses the rare malignant variety and includes a number of excellent photographs of typical vascular spiders. He collected a series of 11 such cases during a 2 year period from various antenatal clinics. The description given of a type characterized by a 'pigmented warty growth projecting under the superficial layers of the skin' classifies it as one of the pigmented warts discussed by Brickner (9, 10). The suspected relationship of this type of lesion to the much commoner vascular spider of pregnancy has been discussed (6).

Smith (24) has recorded observations on spider nevi appearing during the last month of the second pregnancy in a 26 year old woman

Fig. 8. Photograph of the hand during and after the occurrence of the sharply localized variety of the palmar erythema of pregnancy.

During a third pregnancy they appeared again on the back and upper chest during the fifth month. Some idea of the difficulty of tracking down medical reports of this phenomenon can be seen in the title of Smith's note—The Treatment of Hereditary Telangiectasia.

Walsh and Becker (30) in their monograph on erythema palmare and naevus araneus like telangiectases gave full description of 6 cases in which vascular spiders developed during pregnancy (in 4 palmar erythema was also present). In some of the patients spiders had been present before pregnancy. Their advent occurred anywhere from the third to seventh month of pregnancy. Spiders tended to parallel the palmar erythema in the time of appearance and disappearance but there were some exceptions. These authors discussed the number, size, configuration and distribution of the vascular spiders. For the first time arterial pulsation was described in the spider of pregnancy. Their investigation included inspection with the capillary microscope and histologic study. A low power view of one of their biopsy specimens gives a clear idea of the two types of vessels encountered: (1) the thick coiled stem artery in the subcutis branching directly into (2) veins of comparable size. This they termed an arteriovenous anastomosis but did not note that it is not a true arteriovenous anastomosis but has a multitude of veins branching from a central artery and these veins distribute blood into

Fig. 9. The hand during and after the occurrence of the diffuse mottled palmar erythema of pregnancy.

a capillary bed before it is conveyed away in true veins. They did not find any evidence of hereditary tendency except in the cases presenting palmar erythema nor did they see any indication that the spiders had followed minor trauma such as mosquito bites, pinpricks and the like. There was no incrimination of syphilis or hepatic disease. They thought the most probable cause to be some endocrine disturbance. Newman (22) believed the cause was an increase in blood volume plus the effects of the hormone progesterone.

Bean (6) reported observations in 41 women who acquired vascular spiders during pregnancy. In many instances they were observed to appear from the second to the fifth month of

pregnancy. Usually they disappeared at or shortly after the time of delivery. There was no indication that hepatic disease was responsible for the vascular spiders in the women (Table I). Data from pregnant women (27) might support the suggestion that quantitative changes in circulating estrogens are responsible for the appearance of acquired vascular spiders in pregnancy (6) and hepatic diseases.

REVIEW OF THE LITERATURE PALMAR ERYTHEMA

It is likely that earlier references to palmar erythema acquired during pregnancy exist but the first notice of it that we have found was that by Feldman in 1939 (13, 14). In a very brief comment he discussed a woman in whom redness of the palms appeared during her second and third and fourth pregnancies and disappeared when pregnancy was terminated. He speculated about a possible relationship to increased blood volume and the hormone problem. Walsh and Becker (30) have contributed the classic paper in this field and were the first to record the concurrent appearance of vascular spiders and palmar erythema in pregnancy with their subsequent clearing after delivery. Much of the early literature on palmar erythema was reviewed by these authors.

In a brief note (3) one of us suggested that vascular spiders and palmar erythema observed in pregnancy, chronic hepatic disease, and nutritional deficiency disorders might be caused by estrogenic hormones and presented preliminary studies which indicated that such changes in blood vessels of the skin might be induced by administering estrogens to susceptible persons. In the first paper exclusively devoted to the subject of erythema of the palms in pregnancy, Lofgren (18) described in detail 4 cases he had investigated. He presented striking photographs of the return to normal which had occurred by the fourth postpartum month in a woman with the palmar erythema of pregnancy. He made the suggestion independently that estrogenic substances might be responsible for their appearance. To test his hypothesis he administered estradiol benzoate to one of the women 4½ months after delivery. There was definite increase in the palmar red-

ness, but it did not reach the intensity of the erythema present during pregnancy.

A review of the subject of palmar erythema and cutaneous vascular spiders (4) included the suggestion but no further evidence that these changes in the skin were related to high levels of circulating estrogens. No discussion of the problem in pregnancy was included. In an extensive survey of the cutaneous arterial spider (6) it was mentioned that the anatomical substrate of palmar erythema might be related to the arteriovenous glomus bodies so profusely distributed in the palmar skin. In addition to hepatic disease and normal pregnancy, palmar erythema is common in pulmonary tuberculosis (2, 25) and it was suggested that clubbing of the fingers may be related to the associated increase in blood flow (4).

These few references are all we have been able to find in searching recent medical writings on the subject. Doubtless there are other reports. One of the main reasons for undertaking this study was the lack of any systematic information on the incidence, course, and probable significance of vascular spiders and palmar erythema which occur during pregnancy.

PROCEDURES

The present study was set up to learn what we could of the natural history of the vascular spider and palmar erythema acquired during pregnancy. Thanks to the co-operation of members of the obstetrical service we were permitted to examine each patient seen on every visit to the prenatal clinic, during hospitalization for delivery and again at the postpartum visit 6 weeks after discharge following the 4 to 10 days of hospitalization for delivery. All initial examinations were made by the senior author and subsequent ones were made by various members of the group in addition. Observations were begun in July 1946 but it was not until October 1946 that every woman was examined on each clinic visit. At that time a system of examination and record keeping was put into effect. Because there was neither adequate time nor personnel our inspection was limited to the hands, lower and upper arms, face, neck and upper chest. Con-

ditions of lighting were kept constant. An artificial blue light was used and all patients were examined while standing before the light. A record was kept of the presence or absence of vascular spiders and their location and number if present. Palmar erythema was recorded if present, and whether of the diffuse or sharply localized form. A notation was made of the depth of skin color in both white and negro patients. A very large number of photographs was taken and in some cases a series of them was made throughout pregnancy in the hospital shortly after delivery and again at the final postpartum visit. In patients who had either type of vascular change in the skin an effort was made to ascertain its time of appearance but this information was not very reliable except that some patients were aware of vascular spiders or palmar erythema antedating pregnancy. Others had never noticed either. In some instances we collected 24 hour specimens of urine for hormone assay but the results are not adequate for detailed analysis. In a few patients liver function studies were done.

Our subjects included all women examined in the prenatal clinic who were in attendance in October 1946 and all new clinic patients who came in through October 23, 1947.

Our discussion where possible deals with the largest number of cases fully studied. In most instances data are derived from all pertinent records but in some of the figures only those with complete records were included. Records were designed so that the information could be transferred to International Business Machine punch cards to facilitate processing. Charts of distribution of vascular spiders were kept to follow individual lesions. Degree and type of palmar erythema were noted.

In order to make extensive correlations with other data concerning the patient and her offspring we obtained information on age, color, parity, on sex, weight, viability, and normality of offspring on complications related to toxemia and eclampsia, on lactation and season of the year. The date of the last menstrual period was recorded in order to learn the time in pregnancy when the skin lesions appeared or the duration of pregnancy at the time of the first visit if lesions were

already manifest. The date of delivery was recorded and in the final analysis the time of appearance of vascular changes was based on recalculation from date of delivery in all pregnancies which went to term. Some of the possible correlations have been made but many await future study.

The total number seen in the clinic was 1,243. There were 484 white and 759 negro women. Records have been fully analyzed on 392 women who were seen during hospitalization and at the routine postpartum visit. An additional 537 were seen during the week after delivery but had not returned for follow up in spite of our special efforts to make a final examination. The remainder were under observation when we began compiling this paper.

OBSERVATIONS VASCULAR SPIDERS

Vascular spiders were found in 321 or 66.6 per cent of the 484 white women observed and in 87 or 11.4 per cent of the 759 negro women at some time during pregnancy. Since women presented themselves at varying stages of pregnancy for their first clinic visit our figures on incidence of spiders throughout pregnancy are not derived from large numbers there being relatively few women seen during the second and third months of pregnancy while the totals were very high by the last month. In Figures 10 and 11 we have calculated the percentage of all women seen in any month of pregnancy who had vascular spiders at that time. There were relatively few subjects seen in the early months of pregnancy. In Figure 10 it is seen that 14 per cent of white women had vascular spiders by the second month of pregnancy. For the next 3 months there was a general tendency for the proportion having spiders to increase rapidly. Following this there was a slow but steady increase of positive cases up to the time of delivery. By the ninth month of pregnancy 66 per cent of all white women under observation had vascular spiders. We do not have all the control observations desirable on incidence of vascular spi-

The discrepancies between the numbers in the text and those in Figures 10, 11, 14 and 15 have resulted from our using data from completely observed cases in the charts—women seen prenatally at and after delivery and 1 the routine postnatal follow-up. Numbers in the text are derived from all records with relevant information, even if follow up is lacking. No difference has been more than 5 per cent.

Fig. 11. Percentage of white women with vascular spiders during and after pregnancy.

Fig. 12. Percentage of negro women with vascular spiders during and after pregnancy.

ders in unmarried childless or parous women of various ages. In order to get some idea of their incidence in a representative group of women we observed 58 nonpregnant white women who had one or more children and found typical vascular spiders in 12 per cent. While the number of women without a history of pregnancy might well supply a lower figure the percentage of white women with spiders during pregnancy is significantly and markedly higher than the control group of nonpregnant women who had borne children. Other control observations are given in Table I.

Nine white women had vascular spiders which they were certain had existed before the first pregnancy.

Findings in negro women are different, chiefly in the much lower incidence of vascular spiders in members of this race. In Figure 11 we find that no spiders were observed prior to the fourth month by which time they had appeared in 8 per cent of all subjects seen during this month. The incidence rose slowly thereafter until a peak was reached in the ninth month when 14.2 per cent were found to have spiders.

This notable discrepancy between incidence in white and negro women highlights an aspect of the study in which we have correlated the depth of skin pigmentation with the finding of vascular spiders among both white and negro women. An estimate of degree of pigmentation of the skin was made on each person and

recorded as light, medium, and dark. White women with red hair were recorded in a separate category. This was checked at each clinic visit without access to previous estimate of pigment by the observer. While this is at best only a semiquantitative evaluation there was surprising consistency in the routine observations by each member of the study group and good consistency between different observers. In Figure 12 we have charted the percentage of women with different depths of skin pigment in whom we observed vascular spiders. There was a consistent tendency for them to be found more often in those with skin of lighter color. This may indicate merely the obvious fact that vessels in the skin can be seen more readily in persons with light skin but the additional possibility exists that there is a greater tendency for such vascular lesions to develop in women with light skin. There was a similar trend among negro women whose depth of skin pigment was recorded as light, medium, or dark.

In Figures 10 and 11 the highest incidence of vascular spiders in white and negro women during the last month of pregnancy is compared with their incidence at the regular postpartum follow up. In white women the percentage fell from 69 to 20. In negroes the corresponding change was from 14 to 5 per cent. Thus about three-fourths of the women who had vascular spiders in the ninth month of pregnancy had lost them by the seventh week after delivery. In Figure 13 we have given in detail the rate at which vascular spiders and palmar erythema were lost during the last month of pregnancy and during the puer-

TABLE I.—INCIDENCE OF VASCULAR SPIDERS AND PALMAR ERYTHEMA IN CONTROL GROUPS

	Number	Negative %	Spiders %	Palmar erythema %

†Data not complete.

perum Data are derived from all subjects with observations, regardless of follow up. A few women suddenly lost vascular spiders, or they decreased in size during the month before delivery, but this was uncommon. The period of most rapid loss of spiders was during the week immediately following delivery. The loss thereafter was more gradual up to the time of our final observation. In the few women whom we have seen up to a year after delivery there has been a further decrease in size and number of lesions unless another pregnancy intervened. In Figures 10 and 11 the data for disappearance refer to women who had lost all vascular spiders. In those still positive at the postpartum check up many had lost some but not all of the lesions and in others they had decreased in size so the quantitative aspects of the changes were even more dramatic than is suggested from the figures. There was a tendency for lesions which appeared late in pregnancy to fade early and those which appeared early to disappear some-

TABLE II.—DISTRIBUTION OF SPIDERS IN WHITE AND NEGRO WOMEN

what later. This is partly related to size of individual spiders, the larger ones usually taking longer to vanish completely. Without charts marking the area of each lesion and photographic records usually it was impossible to identify precisely the area where a spider had been. At times a small freckle marked the spot and at times the skin was slightly atrophic, but these were exceptional findings. In 3 instances we noted spiders after delivery which were not recorded before. We believe this represents an earlier oversight rather than the actual development of new lesions during the puerperium.

In Table II we have compared the location of vascular spiders in white and negro women. There are notable differences. In negroes the hand was the site of about half the spiders whereas in white women it was the site of only a quarter of the lesions. The difference was even more striking where the palm was considered lesions being almost three times as common on the palm in negro women as in white women. The other findings are given in the table. Aside from differences in pigmentation we have no ready explanation for these contrasts.

OBSERVATIONS PALMAR ERYTHEMA

Palmar erythema was observed in a total of 300 or 62.5 per cent of the white women and 263 or 35 per cent of the negro women in this study. Figures 14 and 15 give the incidence throughout pregnancy and by the time of the postpartum follow up. The trend of appearance of palmar erythema in Figure 14 was

Fig. 10. Percentage of white women with vascular spiders during and after pregnancy.

ders in unmarried, childless, or parous women of various ages. In order to get some idea of their incidence in a representative group of women we observed 58 nonpregnant white women who had one or more children and found typical vascular spiders in 12 per cent. While the number of women without a history of pregnancy might well supply a lower figure the percentage of white women with spiders during pregnancy is significantly and markedly higher than the control group of nonpregnant women who had borne children. Other control observations are given in Table I.

Nine white women had vascular spiders which they were certain had existed before the first pregnancy.

Findings in negro women are different, chiefly in the much lower incidence of vascular spiders in members of this race. In Figure 11 we find that no spiders were observed prior to the fourth month, by which time they had appeared in 8 per cent of all subjects seen during this month. The incidence rose slowly thereafter until a peak was reached in the ninth month when 14.2 per cent were found to have spiders.

This notable discrepancy between incidence in white and negro women highlights an aspect of the study in which we have correlated the depth of skin pigmentation with the finding of vascular spiders among both white and negro women. An estimate of degree of pigmentation of the skin was made on each person and

Fig. 11. Percentage of negro women with vascular spiders during and after pregnancy.

recorded as light, medium and dark. White women with red hair were recorded in a separate category. This was checked at each clinic visit without access to previous estimate of pigment by the observer. While this is at best only a semiquantitative evaluation there was surprising consistency in the routine observations by each member of the study group and good consistency between different observers. In Figure 12 we have charted the percentage of women with different depths of skin pigment in whom we observed vascular spiders. There was a consistent tendency for them to be found more often in those with skin of lighter color. This may indicate merely the obvious fact that vessels in the skin can be seen more readily in persons with light skin but the additional possibility exists that there is a greater tendency for such vascular lesions to develop in women with light skin. There was a similar trend among negro women whose depth of skin pigment was recorded as light, medium or dark.

In Figures 10 and 11 the highest incidence of vascular spiders in white and negro women during the last month of pregnancy is compared with their incidence at the regular post partum follow up. In white women the percentage fell from 60 to 20. In negroes the corresponding change was from 14 to 5 per cent. Thus about three-fourths of the women who had vascular spiders in the ninth month of pregnancy had lost them by the seventh week after delivery. In Figure 13 we have given in detail the rate at which vascular spiders and palmar erythema were lost during the last month of pregnancy and during the post

Fig. 16 Comparison of the month of appearance and the time of disappearance of palmar erythema.

spiders. Palmar erythema tended to fade more rapidly in negro than in white women (Fig. 13). We believe that the change in the vessels in the palm is more labile and has a considerable functional element. The distribution and intensity of the redness change from time to time. There is some spontaneous variation in the combinations of mottled erythema, cyanosis and pallor in many instances. There is a more abrupt onset and fading is complete in more women at the time of follow up.

We have found no explanation for the fact that either palmar erythema or vascular spiders may occur alone or in association with the other. Palmar erythema was observed in 67 per cent of the white women who had vascular spiders. Vascular spiders were observed in 71 per cent of the white women who exhibited palmar erythema. Thus if either type of vascular change was found the other was about twice as likely to be present as to be absent. This suggests but does not prove that there may be a common cause. In Figure 17 we have plotted the known month of appearance of vascular spiders and of palmar erythema. There is a tendency for them to occur near the same time but there are notable exceptions. Further data are needed to determine whether the tendency for palmar erythema to appear before spiders in negro women and the reverse in white women is substantiated. Their parallel course of increase in intensity throughout gestation and similar rapid decrease or disappearance is further support for this idea. One may suggest that the sites affected i.e. palms or other parts of the body are determined by inherent properties of the

Fig. 17 Comparison of known month of appearance of palmar erythema and vascular spiders. Each point or x represents 1 case.

vessels to react to the stimulus which provokes the change. This may be a genetic peculiarity though we have no proof that this is the case. In a few women observed in two or more pregnancies we have found a tendency for one or the other type of lesion to recur. There have been exceptions. Thus the supposition that there is only one mechanism at work in pregnancy which evokes vascular spiders or palmar erythema or both is far from established though the natural history of the phenomena points in this direction.

OTHER OBSERVATIONS

Although we did not see any clinical indication of hepatic disease complicating pregnancy we carried out some liver function studies on 26 white women in the present investigation to see whether there was any laboratory evidence of impaired function or any difference in those with vascular spiders or palmar erythema and those without such vascular changes. The icterus index, bromsulphalein retention (at 45 minutes after 5 mgm per kgm), cephalin cholesterol flocculation and thymol turbidity tests were performed in the third trimester of pregnancy. Those tests did not reveal any significant sign of hepatic damage and the very minor deviations from normal were found regardless of presence or absence of vascular spiders or palmar erythema or both. There

Fig. 3. Rate of disappearance of vascular spiders and palmar erythema expressed as per cent. Subjects were called positive when either type of palmar erythema was noted, or one or more spiders. They were classed as negative when all vascular spiders or the palmar erythema had disappeared.

considerably different from that for vascular spiders in Figure 10. While only 14 per cent of the white women seen in the second month of pregnancy had vascular spiders, palmar erythema was present in 33 per cent at that time. From the second through the ninth month there was a gradual rise. The dip in the curve from the third to the fourth month does not mean that some women lost their palmar

Fig. 5. Percentage of negro women exhibiting palmar erythema during the course of pregnancy and after delivery.

erythema during this time but that it was less common in the women making their first clinic visit during the fourth month. By the time of the regular postpartum visit palmar erythema had faded in all but 9 per cent of the women. This compares with 30 per cent who retained vascular spiders at this time. Three white women had palmar erythema before the onset of the first pregnancy and in two it existed in other members of their family.

In Figure 15 the curve for incidence of palmar erythema in negro women is given. This may be compared with a similar curve for vascular spiders in Figure 11. While no instance was found in the second month, palmar erythema had appeared in 17 per cent by the third month, and there was a slow but steady rise to a peak of 39 per cent by the ninth month. This had fallen to 4 per cent by the postpartum follow-up. Palmar erythema was almost three times as common as vascular spiders in negro women while there was only a slight difference in the incidence of vascular spiders and palmar erythema in white women. The most probable cause is the variation in skin pigment which is much less deep in the palms than in other areas of skin of negro women.

In Figure 16 the time of appearance has been compared with the time of fading of palmar erythema. There is an indication that the lesion appearing late fades early and vice versa. In 10 per cent the lesions disappeared before or during the last week of pregnancy a larger proportion than in the case of vascular

erythema during this time but that it was less common in the women making their first clinic visit during the fourth month. By the time of the regular postpartum visit palmar erythema had faded in all but 9 per cent of the women. This compares with 20 per cent who retained vascular spiders at this time. Three white women had palmar erythema before the onset of the first pregnancy and in two it existed in other members of their family.

In Figure 15 the curve for incidence of palmar erythema in negro women is given. This may be compared with a similar curve for vascular spiders in Figure 11. While no instance was found in the second month, palmar erythema had appeared in 17 per cent by the third month and there was a slow but steady rise to a peak of 39 per cent by the ninth month. This had fallen to 4 per cent by the postpartum follow-up. Palmar erythema was almost three times as common as vascular spiders in negro women while there was only a slight difference in the incidence of vascular spiders and palmar erythema in white women. The most probable cause is the variation in skin pigment which is much less deep in the palms than in other areas of skin of negro women.

In Figure 16 the time of appearance has been compared with the time of fading of palmar erythema. There is an indication that the lesion appearing late fades early and vice versa. In 10 per cent the lesions disappeared before or during the last week of pregnancy. A larger proportion than in the case of vascular

spiders. Palmar erythema tended to fade more rapidly in negro than in white women (Fig. 13). We believe that the change in the vessels in the palm is more labile and has a considerable functional element. The distribution and intensity of the redness change from time to time. There is some spontaneous variation in the combinations of mottled erythema, cyanosis, and pallor in many instances. There is a more abrupt onset and fading is complete in more women at the time of follow-up.

We have found no explanation for the fact that either palmar erythema or vascular spiders may occur alone or in association with the other. Palmar erythema was observed in 67 per cent of the white women who had vascular spiders. Vascular spiders were observed in 71 per cent of the white women who exhibited palmar erythema. Thus if either type of vascular change was found the other was about twice as likely to be present as to be absent. This suggests but does not prove that there may be a common cause. In Figure 17 we have plotted the known month of appearance of vascular spiders and of palmar erythema. There is a tendency for them to occur near the same time but there are notable exceptions. Further data are needed to determine whether the tendency for palmar erythema to appear before spiders in negro women and the reverse in white women is substantiated. Their parallel course of increase in intensity throughout gestation and similar rapid decrease or disappearance is further support for this idea. One may suggest that the sites affected, i.e. palms or other parts of the body, are determined by inherent properties of the

Fig. 17 Comparison of known month of appearance of palmar erythema and vascular spiders. Each point or x represents 1 case.

vessels to react to the stimulus which provokes the change. This may be a genetic peculiarity though we have no proof that this is the case. In a few women observed in two or more pregnancies we have found a tendency for one or the other type of lesion to recur. There have been exceptions. Thus the supposition that there is only one mechanism at work in pregnancy which evokes vascular spiders or palmar erythema or both is far from established though the natural history of the phenomena points in this direction.

OTHER OBSERVATIONS

Although we did not see any clinical indication of hepatic disease complicating pregnancy we carried out some liver function studies on 26 white women in the present investigation to see whether there was any laboratory evidence of impaired function or any difference in those with vascular spiders or palmar erythema and those without such vascular changes. The icterus index, bromsulphalein retention (at 45 minutes after 5 mgm per kgm) cephalin cholesterol flocculation and thymol turbidity tests were performed in the third trimester of pregnancy. Those tests did not reveal any significant sign of hepatic damage, and the very minor deviations from normal were found regardless of presence or absence of vascular spiders or palmar erythema or both. There

Fig. 8. A comparison of the incidence of vascular spiders, palmar erythema or both in women with toxemia compared with the whole group.

was no indication that damage to the liver comparable to that usually found in chronic cirrhosis, existed in the pregnant women in this study. Nothing suggested that vascular lesions in pregnancy have been caused by hepatic malfunction.

Although all the data have not been analyzed regarding age of the mother, number of pregnancies, sex and viability of offspring and lactation with reference to the incidence and number of vascular spiders, and the incidence, type and degree of palmar erythema, our studies so far indicate no striking relationships. Thus the vascular changes in the skin had no notable association with first or later pregnancies, with male or female offspring with age or youth of the mother with lactation or its failure to occur or to continue properly. We have studied hypertension and toxemias more extensively since there is some evidence and more belief that humoral factors play a part in their genesis. Patients having systolic blood pressure of more than 140 millimeters of mercury and diastolic blood pressure of more than 90 millimeters of mercury were classed as hypertensives. Hypertensive patients with albuminuria, edema, symptoms of headaches, etc. or convulsions in the third trimester of pregnancy were classed as toxemias. In 1145 of the patients studied so far there were 24, or 2.1 per cent with hypertension during pregnancy. In another 99 or 8.7 per cent, there was toxemia. These diagnoses were made by members of the obstetrical staff independently of our own studies, and the data were combined only after the records were complete. The number with hypertension was too small to have much significance,

but even in this group the incidence of vascular spiders or palmar erythema, or the two in combination was very nearly the same as in the whole group. Since the number with toxemia were larger we have compared the incidence of vascular spiders and palmar erythema in this group with the incidence in the entire series in Figure 18. While there are slight differences the figures agree so nearly that we conclude that the changes in the skin we have observed have no essential relation to toxemia or its absence.

GENERAL CONSIDERATIONS

The studies we have carried out indicate that vascular spiders and palmar erythema, alone or in combination are found frequently as accompaniments of normal pregnancy. Since the investigation was intensive and persistent we discovered many lesions of which the subjects were wholly unaware. Many however were obvious and had been noticed, and in some persons they were the source of embarrassment or worry.

Since vascular spiders or palmar erythema may be found in normal nonpregnant women we have been particularly interested in their fate after pregnancy since our control observations do not include women in a wide range of ages who had never been pregnant. Such observations as we have made (Table I) indicate that a vascular spider may be found in about 10 per cent of white women who have borne children. In a study made by one of us during a nutrition survey of American troops in various islands in the Pacific during World War II it was found that vascular spiders were seen in 14.9 per cent of the white and in none of the negro soldiers. Even with these as a base line there is a marked and consistent increase in the number of women with vascular spiders and in the number of spiders per woman from the second or third month of pregnancy until term. At this time there is a sudden decrease in size of individual lesions, a complete disappearance of many so that by the seventh week after childbirth the number approaches that found in control groups. Subsequently there is a further decrease which apparently continues slowly so long as another pregnancy does not occur.

This study serves as a companion for similar investigations on vascular spiders and palmar erythema in persons suffering with chronic hepatic disease (4-6). Although the number of patients with hepatic disease was relatively small it was ample to establish the fact that both spider nevi and palmar erythema may appear as complications of chronic or subacute disease of the liver. If and when the state of the liver improves these vascular changes may recede just as they do following the completion of gestation, though rarely with such dramatic suddenness. Vascular spiders in well established cirrhosis are usually larger and occur in greater numbers than in pregnant women. Their similar distribution over the upper part of the body, their similar shape, the palpable pulsation and intravascular pressure of 50 to 80 millimeters of mercury are strong indications of their kinship. We have not had an opportunity to observe a woman who had known of vascular spiders during a pregnancy who later had them with chronic liver disease nor have we encountered a woman with cirrhosis who became pregnant though some with ascites suspected pregnancy. Nor have we compared the histologic picture of the lesions in cirrhosis with those of pregnancy. We are however convinced that there is no fundamental difference between those which appear in pregnancy and those which appear in cirrhosis. It has been suggested that a possible common factor in normal pregnancy and chronic liver disease might be a high level of circulating estrogenic hormones (3) or related endocrine substances perhaps of adrenal origin (6). The fact that we have been able to find no significant abnormality of hepatic function in pregnant women with palmar erythema and vascular spiders as compared with those who do not have them suggests that disturbed liver function in pregnancy is not responsible for their occurrence.

As collateral testimony that estrogenic hormones may produce an effect on the vessels of the skin qualitatively similar to the well documented effect on vessels of the uterus we have superimposed Venning's (27-28) curve of estrogen excretion throughout pregnancy upon our figures for the incidence of vascular spiders and palmar erythema in white and negro

Fig. 19. A comparison of the incidence of vascular spiders and palmar erythema with the urinary excretion of estrogens (Venning) during pregnancy.

women during pregnancy (Fig. 19). Although the forms of the curves do not agree with precision there is a similarity. Evidence for the critical early months is inadequate for analysis. Crucial data in individual patients must be obtained in the future. There is however no established finding which invalidates the hypothesis that humoral agents with estrogenic function give rise to vascular changes in the skin during the course of normal pregnancy and during the active stage of chronic liver disease.

Our studies have established the rather surprising frequency of the vascular spider and palmar erythema as banal accompaniments of normal pregnancy. We have advanced the hypothesis that these phenomena may be caused by hormones and have implicated the estrogenic substances in particular. The facts we have recorded should be known to obstetricians if only for the occasional comfort they bring to women whose worry about such blemishes may add its needless burden to the trials of pregnancy. The speculations must stand or fall according to the results of hormone assays we now have under way.

SUMMARY

1. We have presented an interim analysis of data concerning the incidence, natural history and fate of vascular spiders and palmar erythema as observed in 1243 women in the obstetrical clinic of the Cincinnati General Hospital.

1 The literature on these cutaneous vascular changes has been reviewed. Vascular spiders apparently were first noticed as a benign complication of normal pregnancy by Corbett in 1914 and have been recorded by dermatologists and internists at intervals since then. The first note on palmar erythema of pregnancy which we have found was published by Feldman in 1939. No word about such lesions has been found in the American textbooks on obstetrics which we have consulted.

3 Vascular spiders have been found in about two-thirds of the white women and 11 per cent of the negro women during pregnancy. They tend to appear in the early months of pregnancy especially during the second through the fifth months. They increase slowly in number and in size until term or shortly before. About three-fourths of them have faded by the seventh week after delivery.

4 Details of the vascular spider of pregnancy have been presented in photographs of the involved skin before and after delivery and demonstrate the rapid return to normal.

5 Two types of palmar erythema have been described and photographs presented.

6 Almost two-thirds of the white women and slightly more than one-third of the negro women were observed to have palmar erythema during pregnancy. The appearance and the fading were more abrupt than with vascular spiders but the trends of appearance and disappearance were similar.

7 While the difference in incidence of the cutaneous vascular changes in white and negro women was large we have suggested that other factors than skin pigment alone may be involved. The depth of skin color is a major consideration. Vascular spiders and palmar erythema have not been reported in negroes during pregnancy heretofore.

8 Tests of liver function did not reveal significant abnormality or differences between those with and without spiders or palmar erythema.

9. There was no marked difference in incidence or number of vascular spiders or of

palmar erythema between subjects who later developed toxemia and those who escaped it.

10 We have compared the vascular spider of pregnancy with that found in chronic liver disease and find no basic differences. They are apt to be larger and more numerous in persons with cirrhosis than in pregnant women.

11 We have advanced the hypothesis that vascular spiders and palmar erythema develop as a response to the stimulus of high levels of estrogenic substances circulating in the blood for long periods. Studies are in progress to test its validity.

THORACIC COMPLICATIONS OF AMEBIASIS

ROBERT R SHAW M D., Dallas, Texas

AMEBIASIS is a disease which is of interest to the internist the general surgeon and the surgeon who is limiting his practice to thoracic diseases. Although the disease in its incipency is an intestinal infestation there are complications which may require surgical relief. The treatment of the intestinal infestation is entirely a medical problem. The complication of an hepatic abscess however although best treated by medical measures should be conducted under the observation of a surgeon since surgical management of the abscess may become necessary if further complications set in. The hepatic abscess in turn may cause complications within the thorax which may require the services of a surgeon trained in the treatment of thoracic diseases. Surgery may be necessary to eliminate fistulous channels between the liver and bronchi left by the infection to re-expand an imprisoned lung or to remove damaged pulmonary tissue. Due to the increasing tendency to resect pulmonary tissue for pulmonary suppuration occasionally the diagnosis of amebic pulmonary suppuration may not be suspected until the time of operation. Now that more meticulous technique is possible in pulmonary resection and decortication the high mortality (33 per cent) previously reported by Ochsner and DeBaakey (2) for surgery in this type of infection need not be feared. Four patients having thoracic complications of amebiasis treated during the past 2 years by various surgical procedures will be reported in this paper. Another patient having a complicating pericarditis from an amebic hepatic abscess who was treated by my associate will be briefly discussed. All of these patients have completely recovered from the hepatic abscess and its complications.

INCIDENCE

The general incidence of infestation with the *Endamoeba histolytica* is much higher in the

general population than is usually realized. Statistics obtained from surveys a few years ago would probably not now be even high enough since during the war so many men in the military forces saw service in areas where amebic dysentery was a very common disease. Craig estimated the prevalence of infestation in the population at large at from 5 to 10 per cent. There have been surveys that have cited the incidence as high as 33 per cent. Ochsner and DeBaakey (3) in their writings upon this subject believe that an incidence of 20 per cent is a reasonable figure. It has been found that hepatic abscesses will complicate infestations with the *Endamoeba histolytica* in approximately 5 per cent of all cases. Furthermore there will be complications within the thoracic cage in approximately 15 per cent of patients having hepatic abscesses. The sex incidence has never been adequately explained in the case of hepatic abscesses. Males predominate over females in the occurrence of this complication in a ratio of 15 to 1. The age incidence is also of some interest since it has been found that the majority of patients having hepatic abscesses fall between the ages of 20 to 50 years.

PATHOLOGY

Amebic abscesses of the liver undoubtedly occur due to the migration of the parasites through the portal system into the liver. Here the parasites clog the small capillaries and venules and set up a lytic process which destroys tissue. A small abscess develops and the necrotic zone of the liver tissue surrounding the abscess pours fluid and debris into the abscess cavity. The amebas are usually best found deep within the wall of the abscess very close to the healthy liver tissue. The abscesses are single in approximately 65 to 88 per cent of the cases (3). In cases in which the abscesses are multiple there may be coalescence of the abscesses but if this fails to occur the prognosis is much more grave. Approximately 85 to 96 per cent (3) of all hepatic abscesses of

phragm into the pleural cavity or directly into the lung through adhesions that have been formed because of the inflammatory process. If the abscess is in the left lobe of the liver the extension of the abscess may be into the pericardial sac causing a pericarditis. Pleuropulmonary complications on the left seldom occur. There have been described in the literature solitary abscesses within the lung substance which are not adjacent to the diaphragm. It must be postulated that these abscesses are embolic in origin and that the abscesses reached the pulmonary circulation by going through the hemorrhoidal veins into the vena caval system or by anastomotic channels between the venules of the portal and the vena caval systems within the liver. Abscesses of this type are the exception.

SYMPTOMATOLOGY

In approximately 50 per cent of all cases of pleuropulmonary complications from hepatic

the liver are found within the right lobe of the liver probably because of the size of this lobe as compared with the left lobe. The thoracic complication comes about because of a direct extension of the abscess through the dia-

Fig. 2a.

Hepatic abscess which has ruptured into right lower lobe. a Posteroanterior view shows abscess in base of right lung. b Lateral view shows the shadow cast by the pulmonary abscess to be continuous with the right diaphragmatic outline. c, Ten days following resection of lower lobe and repair of diaphragm.

Fig. 2b.

abscesses there will be no history of a previous dysentery. The most usual complaint of a patient having a pleuropulmonary complication is pain in the lower right chest and in the shoulder. There is a cough which early is not productive. Later there is usually an episode of hemoptysis which then gives way to the coughing up of sputum which is described as being like chocolate or anchovy paste. A septic type of fever with or without chills will always be present. The patient also suffers from the usual signs of infection i.e. anorexia, malaise and weakness. There may be extreme weight loss.

ROENTGENOGRAPHIC APPEARANCE

The roentgenographic appearance of the chest is characteristic enough to be almost diagnostic in cases of thoracic complications from amebic hepatic abscesses. There is a hump like localized elevation of the diaphragm

Fig. 2c.

which is usually best seen in the lateral view (Figs. 2b and 4b). If there has been perfora

tion of the abscess directly into the pulmonary tissue there will be present a shadow in the base of the involved lobe with the apex of the shadow tapering off toward the pulmonary hilum (Figs. 1b and 1b). There may or may not be an annular shadow with a fluid level indicating a pulmonary abscess depending upon the amount of pulmonary tissue destruction and whether the communicating bronchus will admit air to the pulmonary abscess. In case of a complicating empyema there will be the appearance of pleural fluid. A pyopneumothorax may be present at the time of the first examination if a bronchus is open into the pleural space. Since the lung is adherent to the diaphragm the collection of pleural exudate may be more lateral than basal (Fig. 3b). Loculation of the pleural exudate is a common occurrence with amebic empyema (Fig. 4a). An hepatic abscess in the left lobe of the liver can be suspected if a roentgenogram of the abdomen following barium by mouth reveals the stomach to be displaced posteriorly and laterally. A widened pericardial shadow would indicate possible rupture into the pericardial sac.

PROGNOSIS

The prognosis of pleuropulmonary complications of an hepatic abscess due to the *Endamoeba histolytica* vary with the type of complication. The prognosis is much more severe if an empyema results. Ochsner and DeBailey (2) reported that in a collected series of empyema complicating hepatic abscesses the mortality was 77.7 per cent. In their own series the mortality was 66.6 per cent. The mortality was lower when a pulmonary abscess developed without the occurrence of an empyema. In this case it was 42.2 per cent in the collected series and 22.2 per cent in their series. The lowest mortality occurred when a bronchohepatic fistula developed without the occurrence of either empyema or pulmonary abscess. There was a mortality of 10 per cent in the collected series in this type of complication and no mortality in the series reported by Ochsner and DeBailey. This mortality was greatly reduced when emetine therapy was given. In the 153 patients in the collected series with pleuro-

pulmonary complications the mortality of 56.6 per cent when emetine was not used dropped to 9.1 per cent with emetine therapy. In the series reported by Ochsner and DeBailey (2) there was 60 per cent mortality without the use of emetine and no mortality when emetine was used. Ochsner and DeBailey (2) also further warned against unnecessary surgical drainage procedures in the case of hepatic abscesses and their pleuropulmonary complications. They showed that there was a 33 per cent mortality in the patients upon whom operations had been performed. They deserve much credit for pointing out the efficacy of emetine therapy in hepatic abscesses and their pleuropulmonary complications. With present techniques and with chemotherapy however surgery if necessary is safer than these authors indicate.

TREATMENT

Emetine is a specific drug for the hepatic abscess caused by the *Endamoeba histolytica*. Even after a pleuropulmonary complication has occurred, emetine should be used in an attempt to avoid surgery and in conjunction with surgery should surgical interference become necessary. Emetine is a drug which must be used with extreme care because of its toxicity for cardiac muscle. Under ideal conditions an electrocardiogram should be made before treatment is instituted. A course of therapy should then be instituted once the diagnosis of an hepatic abscess has been established giving 1 grain doses intramuscularly daily for 6 to 10 days. Following this course of treatment the electrocardiographic tracings should be repeated to determine whether or not there has been myocardial damage. If the patient also has signs of amebic dysentery, such drugs as carbarsone and diiodoquin should be administered. It should be remembered however that this type of drug is toxic to the liver and should be used very cautiously if there are signs of extreme liver damage due to the abscess. In conjunction with the emetine therapy the abscess cavity within the liver should be aspirated if this is possible. If there is tenderness and bulging of the lower costal margin due to the presence of the abscess, aspiration with a long needle with an

adequate lumen should be attempted in the most tender area. If pus is obtained as much of the pus as possible should be aspirated. The aspiration of the abscess not only serves the purpose of evacuating the cavity but also draws fluid from the liver into the abscess cavity and by doing this also causes the amebas to migrate toward the abscess cavity where they in turn will be removed at a subsequent aspiration. This drawing of fluid into the abscess cavity also allows the emetine to come in better contact with the amebas within the wall of the abscess. Aspirations of the abscess cavity should be repeated until a significant amount of pus cannot be obtained. As a rule even though the hepatic abscess has ruptured through the diaphragm into the pulmonary tissue and has found an outlet through the bronchial tree the cough and expectoration will promptly cease after the evacuation of the abscess by aspiration and the treatment with emetine.

INDICATIONS FOR SURGERY

Surgical interference becomes necessary in amebic hepatic abscesses which have caused pleuropulmonary complications if (1) secondary infection has occurred (2) an empyema has resulted which cannot be cured by repeated aspirations (3) a persistent abnormal channel between the bile duct system and bronchi persists (4) fibrosis of pulmonary tissue as result of the abscess continues to be symptom-producing.

The most common indication for drainage of the hepatic abscess will be secondary infection. Once an abscess in the liver due to the *Endamoeba histolytica* has become secondarily infected by pyogenic organisms it must be drained. This drainage can usually be accomplished through an extraperitoneal route. Complications within the peritoneum and pleura will be thus avoided. One of the most serious and annoying complications of drainage of an hepatic abscess is the gangrenous infection of the skin and subcutaneous tissue which may result. This complication occurred in Case 1 of the present report. If this complication results it is necessary to excise the gangrenous tissue entirely down to healthy tissue. This may require the excision of a

considerable amount of skin and the raw surface may have to be covered by skin grafting at a later date.

Pleuropulmonary complications are usually best handled by thoracotomies employing reparative surgery without external drainage. In the case of an empyema which will not clear with repeated aspirations a thoracotomy can be done and a decortication of the lung and diaphragm performed. In the course of this decortication it will be necessary to close the opening in the diaphragm. As a rule the hepatic abscess has erupted into the pleural cavity or pulmonary tissue in such a way that the abscess has practically healed itself. It is not necessary in these cases to employ subsequent counterdrainage for the hepatic abscess. Resection of damaged pulmonary tissue will be necessary. In most cases this will require no more than a wedge resection of the fistulous area. In other cases however it may be preferable to remove an entire lobe. After the products of the infection have been as cleanly removed from the chest as possible the pleural cavity should be drained with an intercostal drain connected to a negative pressure system. The chest is then closed.

Rupture of an hepatic amebic abscess through the pericardium into the pericardial sac is a serious complication and as judged by review of the literature has usually proved fatal. With prompt treatment recovery is possible. Aspiration of the pericardial exudate and emetine therapy should be carried out immediately. This may be all that will be required to bring about recovery. Other complications may ensue which will require surgery. My associate (4) while in the medical corps during the late World War had under his care a soldier who developed an hepatic abscess of the left lobe of the liver. The abscess ruptured into the pericardial sac and peritoneal space beneath the left leaf of the diaphragm. The subdiaphragmatic space was drained anteriorly. It was soon evident that the abscess had perforated the wall of the stomach and a gastric fistula resulted. Posterior drainage was later instituted through resection of the 9th and 10th ribs in the mid axillary line. Eventually the gastric fistula closed and all draining sinuses healed. Eme

tion of the abscess directly into the pulmonary tissue there will be present a shadow in the base of the involved lobe with the apex of the shadow tapering off toward the pulmonary hilum (Figs. 1b and 2b). There may or may not be an annular shadow with a fluid level indicating a pulmonary abscess depending upon the amount of pulmonary tissue destruction and whether the communicating bronchus will admit air to the pulmonary abscess. In case of a complicating empyema there will be the appearance of pleural fluid. A pyopneumothorax may be present at the time of the first examination if a bronchus is open into the pleural space. Since the lung is adherent to the diaphragm the collection of pleural exudate may be more lateral than basal (Fig. 3b). Loculation of the pleural exudate is a common occurrence with amebic empyema (Fig. 4a). An hepatic abscess in the left lobe of the liver can be suspected if a roentgenogram of the abdomen following barium by mouth reveals the stomach to be displaced posteriorly and laterally. A widened pericardial shadow would indicate possible rupture into the pericardial sac.

PROGNOSIS

The prognosis of pleuropulmonary complications of an hepatic abscess due to the *Endamoeba histolytica* vary with the type of complication. The prognosis is much more severe if an empyema results. Ochsner and DeBakey (2) reported that in a collected series of empyema complicating hepatic abscesses the mortality was 77.7 per cent. In their own series the mortality was 66.6 per cent. The mortality was lower when a pulmonary abscess developed without the occurrence of an empyema. In this case it was 42.2 per cent in the collected series and 22.2 per cent in their series. The lowest mortality occurred when a bronchohepatic fistula developed without the occurrence of either empyema or pulmonary abscess. There was a mortality of 10 per cent in the collected series in this type of complication and no mortality in the series reported by Ochsner and DeBakey. This mortality was greatly reduced when emetine therapy was given. In the 153 patients in the collected series with pleuro-

pulmonary complications the mortality of 56.6 per cent when emetine was not used dropped to 9.1 per cent with emetine therapy. In the series reported by Ochsner and DeBakey (2) there was 60 per cent mortality without the use of emetine and no mortality when emetine was used. Ochsner and DeBakey (2) also further warned against unnecessary surgical drainage procedures in the case of hepatic abscesses and their pleuropulmonary complications. They showed that there was a 33 per cent mortality in the patients upon whom operations had been performed. They deserve much credit for pointing out the efficacy of emetine therapy in hepatic abscesses and their pleuropulmonary complications. With present techniques and with chemotherapy however surgery if necessary is safer than these authors indicate.

TREATMENT

Emetine is a specific drug for the hepatic abscess caused by the *Endamoeba histolytica*. Even after a pleuropulmonary complication has occurred, emetine should be used in an attempt to avoid surgery and in conjunction with surgery should surgical interference become necessary. Emetine is a drug which must be used with extreme care because of its toxicity for cardiac muscle. Under ideal conditions an electrocardiogram should be made before treatment is instituted. A course of therapy should then be instituted once the diagnosis of an hepatic abscess has been established giving 1 grain doses intramuscularly daily for 6 to 10 days. Following this course of treatment the electrocardiographic tracings should be repeated to determine whether or not there has been myocardial damage. If the patient also has signs of amebic dysentery, such drugs as carbaritone and diodoquin should be administered. It should be remembered however that this type of drug is toxic to the liver and should be used very cautiously if there are signs of extreme liver damage due to the abscess. In conjunction with the emetine therapy the abscess cavity within the liver should be aspirated if this is possible. If there is tenderness and bulging of the lower costal margin due to the presence of the abscess, aspiration with a long needle with an

clans. At one hospital a diagnosis of carcinoma of the sigmoid colon had been made and resection of the colon was advised. The patient refused the operation and left the hospital against advice. The dysentery continued and he finally developed a severe pain in the anterior aspect of the lower right chest. He was admitted to a hospital and the abscess in the liver drained by the extraserous route. The patient was an adult male appearing chronically ill. There had been obvious weight loss. The physical examination was negative except for the region of the upper abdomen and lower right anterior chest. There was a transverse incision at the level of the 6th rib adjacent and lateral to its costal cartilage. Purulent material drained from this incision. Posterior-anterior and a right lateral roentgen view of the chest showed a localized humping of the diaphragm anteriorly under the middle lobe (Fig. 1). The middle lobe was shrunken in size and only partially air containing. The patient continued to run a low grade temperature elevation and there appeared a gradual extension of induration and inflammatory reaction about the incision on the chest.

On the 23th of July the patient was returned to the operating room and the sinus tract was explored. At the bottom of the incision there was a small

Fig. 4c.

tract which led into the pleura. For about 4 to 5 centimeters on either side of the incision there was obvious involvement of the chest wall with a meaty infection. With the cutting current of the endotherm a wide oval section of skin and subcutaneous tissue

Fig. 3c

tine therapy along with sulfadiazine was used early in the treatment of the infestation but surgery became finally necessary to bring about complete recovery.

POSTOPERATIVE MANAGEMENT

If emetine therapy had not been used previously either because a true diagnosis was not suspected or the urgency of the situation made it unwise to wait, it should be instituted

postoperatively with the safeguard of careful studies of the myocardium as outlined. Following the course of emetine therapy it is usually advisable to give a course of carbarsone or diodoquin for the dysentery. The use of this subsequent therapy will depend upon whether or not amebas can be demonstrated in the stools.

CASE REPORTS

CASE 1: C. T. H., aged 43 years, white male. This patient was admitted to Baylor University Hospital June 3, 1945 as a transfer from another hospital. At the former hospital an amebic abscess of the liver had been drained 2 weeks previously. At the time of the drainage of the abscess it had been found that the abscess had perforated the diaphragm into the right middle lobe. For 1 year previous to the original admission to this hospital the patient had complained of dysentery and had been seen by various phy-

*Case 1 was included in this report by the permission of Dr. Walton H. Cochran, his physician. This patient, although observed by the author, was not under his care.

cians. At one hospital a diagnosis of carcinoma of the sigmoid colon had been made and resection of the colon was advised. The patient refused the operation and left the hospital against advice. The dysentery continued and he finally developed a severe pain in the anterior aspect of the lower right chest. He was admitted to a hospital and the abscess in the liver drained by the extracutaneous route. The patient was an adult male appearing chronically ill. There had been obvious weight loss. The physical examination was negative except for the region of the upper abdomen and lower right anterior chest. There was a transverse incision at the level of the 6th rib adjacent and lateral to its costal cartilage. Purulent material drained from this incision. Posterioranterior and a right lateral roentgen view of the chest showed a localized humping of the diaphragm anteriorly under the middle lobe (Fig 1). The middle lobe was shrunken in size and only partially air containing. The patient continued to run a low grade temperature elevation and there appeared a gradual extension of induration and inflammatory reaction about the incision on the chest.

On the 28th of July the patient was returned to the operating room and the sinus tract was explored. At the bottom of the incision there was a small

Fig 4c.

tract which led into the pleura. For about 4 to 5 centimeters on either side of the incision there was obvious involvement of the chest wall with a meaty infection. With the cutting current of the endotherm a wide oval section of skin and subcutaneous tissue

including the right nipple was excised. The underlying muscles were relatively healthy. The old sinus was opened and the degenerated portion of the 6th rib along with a portion of the 5th rib were excised. This had bare a small cavity in the anterolateral and anterior portion of the right pleural cavity and a small abscess in the right middle lobe. The wound was packed with dry gauze. Pathological report showed amebiasis of the skin and subcutaneous tissue. Following the excision of the amebic abscess of the chest wall there was progressive healing and improvement and the whole wound finally healed without necessitating skin grafting. The patient has remained well.

CASE 2: H. P., aged 35 years, colored male. This patient was admitted to Parkland Hospital on November 9, 1947. He gave a history of epigastric distress after meals for 10 months. Two months before admission he developed a dry nonproductive cough worse in the evening and at night. Five weeks before admission he quit work because of weakness. Three weeks later he had an episode of coughing up of blood and rust-like sputum. He had lost 25 pounds in weight during the previous 5 weeks. There had been no pain in the chest. Two years before there had been a period of 2 months when the patient had frequent episodes of pain around the umbilicus and left abdomen. This pain was relieved by eating or by drinking milk. The patient stated that he had the bloody flux for several months.

Physical examination revealed a chronically ill colored male coughing frequently. The right chest was slightly sunken and lagged during respiration. There was dullness on percussion at the right base posteriorly and in the axilla. Breath sounds were depressed in the right posterior chest and a few coarse rales could be heard. The patient was noted to have marked pulmonary osteoarthropathy. Roentgenograms of the chest revealed a dense shadow in the base of the right lower lobe adjacent to the mediastinum (Fig. 2). There was a fluid level indicating pulmonary abscess. The remainder of the lung fields were clear. A bronchoscopy was performed on the 26th of November. The tracheal mucosa appeared normal. There was a considerable amount of mucopurulent secretion coming from the right lower lobe bronchi. This secretion was not foul. The diagnosis was nonpurulent abscess of the right lower lobe of lung.

On November 24 the right chest was opened following removal of the 7th rib. The pleural cavity was found to be free except where the lower lobe was densely adherent to the diaphragm. The structures at the hilum of the lower lobe were handled by dissection technique. The artery and vein were secured and severed. The bronchial stump was closed with individual sutures of No. 30 cotton. The dense adhesions to the diaphragm were then separated. Separating these adhesions the abscess in the base of the lung was broken into and it was found to have been caused by the eruption of an abscess in the liver through the diaphragm into the lower lobe. There was a large crater approximately 5 centimeters in

diameter and 2 centimeters in depth in the liver. The diaphragm was drawn together with mattress sutures of No. 30 cotton. A drain was placed in the 8th interspace in the posterior axillary line and connected to a water-seal bottle. The chest was closed. Pathological report was: Specimen consisted of right lower lobe of lung. In the base of the lobe surrounded by a large margin of normal appearing pleura there is a crater which is 7 by 6 centimeters in size and which extends up into the parenchyma of the lung for about 4½ centimeters. This cavity is lined by very friable necrotic shaggy shreds of grey to reddish brown tissue and a small amount of thick purulent greyish green exudate is adherent to the wall. Communicating by an opening of 7 centimeter with the larger cavity is a smaller cavity 3.5 centimeters in diameter near the hilum. There is a smaller cavity of the same type of 2 centimeters in diameter near the base. The lung parenchyma is atelectatic and contains a small excess amount of blood. Microscopic examination of the sections of the lung reveals: The abscess wall shows the latter to contain on its surface a small amount of eosinophilic debris containing a moderate amount of polymorphonuclear neutrophilic leucocytes. Lying in this eosinophilic debris loosely attached to the lining of the abscess cavity are present numerous large round and slightly oval bodies which are sharply demarcated measuring 25 to 35 microns in size. These possess slightly eccentric nuclei which are quite small and hyperchromatic and contain a central nucleolus. The cytoplasm is distinctly eosinophilic, rather opaque in appearance and usually contains either intact or hemolyzed red blood cells and other debris. These bodies are entirely characteristic of the trophozoites of *Endamoeba histolytica*. Pathologic diagnosis was chronic amebic abscess of the lower lobe of the right lung. The diagnosis of amebiasis with amebic abscess of the liver rupturing into the right lower lobe was made at the time of surgery. The patient was immediately started on a course of emetine hydrochloride grains ½ three times a day. In addition the patient received postoperatively 50,000 units of penicillin every 3 hours until the 15th postoperative day. The patient was discharged on the 20th postoperative day. The patient's temperature which had been running consistently between 101 and 103 degrees preoperatively dropped rapidly to normal on the second postoperative day and remained normal until the time of discharge. The patient was discharged on the 20th postoperative day. He has remained well.

CASE 3: E. R., aged 3 years, colored male. This 33 year old colored male was admitted to Parkland Hospital on October 20, 1946. He gave a history of pain in the right chest for 6 months and swelling of the right breast for 2 weeks. One month before he had had a hemoptysis. This spitting up of blood had persisted for 3 weeks following which the cough was productive of thick sputum which was clear. The pain in the chest was a constant sharp nonradiating pain aggravated by cough and deep inspiration.

There had been swelling of the ankles with the present illness. He had lost 10 to 12 pounds in weight in the last 6 months. The patient thought that he had had a daily fever. The past history revealed that the patient had had diarrhea beginning about 11 years ago. This had continued with about 4 or 5 daily stools until 9 months ago. The stools had contained blood.

Physical examination revealed lagging of inspiration on the right side of the chest with decreased fremitus and dullness to percussion on the right both anteriorly and posteriorly. There were coarse moist rales at the right apex posteriorly. The breath sounds were diminished over the entire right chest below the second rib anteriorly and posteriorly. Examination of the sputum revealed *Endamoeba histolytica* cysts and trophozoites. Examination of the stools revealed cysts and *Endamoeba histolytica*.

The admission roentgenogram of the chest showed total obscuration of the right hemithorax. Subsequent to aspiration of the pleural fluid it could be seen that the loculated pleural fluid was chiefly in the lateral portion of the chest and that the base of the lung was adherent to the diaphragm over most of its surface (Fig. 3). On admission to the hospital the patient was given diodoquin 0.4 grains three times a day and emetine 1 grain intramuscularly daily. Several thoracenteses were done with aspiration of fluid from the right chest. The fluid was slightly turbid thin and yellow in character. Examination of the fluid was negative for ameba.

On December 2, 1947 the right chest was opened through the 7th rib bed. A thick layer of fibrin was removed from the right lower and middle lobes. The anterior inferior segment of the right lower lobe which had been perforated by an abscess which came up through the diaphragm from the liver was excised. The diaphragm was closed without drainage. Pathological diagnosis was chronic, fibrinous and fibrous pleuritis chronic fibroid pneumonia of lung. Following this operation the right lung expanded poorly so that on December 20 the chest was re-opened and a redecoration was done. Following this procedure the lung slowly re-expanded. The patient was discharged from the hospital on January 20, 1947.

The patient was followed in the surgical outpatient clinic. On July 21 the patient was seen at which time he stated he was very well. He had no cough and his general condition was good. X-ray examination showed complete reabsorption of the fluid. Examination of the stools at this time was negative for ameba. The patient was advised to do full work.

CASE 4. F. R., aged 50 years, white, male. This patient developed a severe dysentery while working as a civilian employee with the army on the island of Guam. He was returned to the United States for further treatment. Upon admission to the Lisbon Veterans Administration Hospital he complained of severe pain in the right lower chest and cough and expectoration of bloody material. The patient was febrile. There had been a noticeable loss of weight.

Physical examination showed the patient to be an emaciated white male of about the stated age. There was dullness to percussion over the lower two-thirds of the right chest both anteriorly and posteriorly. There was tenderness around the lower right costal margin. There was some appearance of bulging of the right anterior chest in the inferior portion and a fullness in the right upper quadrant of the abdomen. Around this area the patient was tender to palpation. Examination of stools and sputum revealed the *Endamoeba histolytica*. X-ray examination of the chest (Fig. 4) revealed a loculated hydropneumothorax on the right. There was a localized elevation of the diaphragm best seen in the lateral film. This elevation of the diaphragm was in the anterior chest. The pulmonary tissue above this elevation appeared dense and atelectatic. In subsequent x-ray examinations a fluid level could be seen in this region. Turbid yellow fluid was aspirated from the right chest. This fluid was later found to be purulent so rib resection drainage was instituted. At a later date a subcostal anterior drainage of the large liver abscess was carried out by the extracostal route. The patient gradually improved. The lung slowly re-expanded. All drains were removed and the sinuses healed. The patient suddenly began to have hemoptyses which although not severe were annoying. It was evident due to bile in the sputum that there was a broncho-biliary fistula. A thoracotomy was advised for the purpose of breaking up this abnormal channel.

At operation on March 23, 1948 the right chest was opened through the 7th rib bed. The right pleural cavity was completely obliterated by adhesions which could be easily separated except around the previous drainage site and over the diaphragm. When the right lower lobe was separated from the diaphragm it was found that there was an opening through the diaphragm approximately a centimeter in diameter which led into a defect in the liver. The examining finger could be inserted through this opening into the hepatic cavity and counterdrainage was then secured through the previous drainage site through the anterior upper abdominal wall. A catheter was put in place and secured. The hole in the diaphragm was then closed. Examination of the indurated area in the base of the right lower lobe revealed a small abscess approximately a centimeter in diameter with a surrounding wall of infiltration. It was not thought necessary to remove this indurated area. Two mattress sutures were used to obliterate the small cavity. A drain was placed in the 10th interspace in the posterior axillary line and connected to a water-seal bottle. The chest was closed. The drainage tube was removed on the 2nd postoperative day since the lung was fully expanded. However on the 6th day it was evident that pleural fluid was reaccumulating. Aspiration yielded old blood indicating that there had been bleeding into the pleural space following removal of the intercostal drain. Drainage was reinstituted at the site of the original rib resection through the 6th rib. The patient gradually improved. The drains in the pleura

and hepatic abscesses were gradually shortened and eventually removed. The condition of the patient is now satisfactory. There have been no recurrences of the hemoptyses.

CONCLUSIONS

1. Hepatic abscesses are common complications of amebic dysentery. These abscesses are best treated by emetine therapy and should not be treated surgically unless certain indications are present.

2. Pleuropulmonary complications of hepatic abscesses can in the majority of patients be successfully treated with emetine therapy.

3. Surgery will be required if (1) the lung cannot be re-expanded (2) a bronchobiliary

fistula persists, (3) secondary infection occurs and (4) when damaged pulmonary tissue produces a continued morbid state.

4. Formal thoracotomies with removal of as much of the products of the infection as possible are preferable to drainage procedures.

5. Proper surgical intervention should further lower the mortality and morbidity in this disease.

CARCINOMA OF THE NASOPHARYNX

Report of 150 Cases

MARVIN W. SIMMONS, M.D., McMinnville, Oregon and IRVING M. ARIEL, M.D., Minneapolis, Minnesota

CANCER of the nasopharynx is a highly malignant disease which has recently attracted the attention of pathologist and clinician. Usually the signs and symptoms of metastases from this growth have obscured the existence of the primary neoplasm accordingly adequate descriptions of the natural history of nasopharyngeal cancer have been delayed.

Prior to the beginning of the twentieth century very few references were found pertaining to this disease. Jackson in 1901 discussed only 13 cases in the world literature of which the earliest case report was in 1837. Not until 1921 was an adequate description of this type of cancer presented when Regaud and Reverchon and Schminke published papers independently describing the pathologic features. Trotter in 1911 had described the classical Trotter's triad resulting from nasopharyngeal neoplasms which consists of impaired hearing, neuralgia of the second branch of the trigeminal nerve and asymmetry of the soft palate.

Since 1921 excellent papers have been published including those of New (1922, 1925, 1931) and 1943, Lurstenberg (1938) and Martin (1940). This report presents the pathological and clinical features of an unselected consecutive group of 150 patients with nasopharyngeal cancer who were treated at the Veterans Administration Hospital, Hines, Illinois from 1931 to 1946 inclusive. The diagnosis in each instance was confirmed histologically.

From the Department of Otolaryngology, University of Illinois, College of Medicine and Veterans Administration Hospital, Hines, Illinois.

Dr. Ariel is present at University of Minnesota Hospitals, Medical School, Department of Surgery, Dr. Simmons, President, University of Oregon Medical School, Department of Otolaryngology.

ANATOMY OF THE NASOPHARYNX

A brief review of the normal anatomy will serve better to explain the morbid processes. The nasal part of the pharynx is an irregular cavity with six walls: anterior, posterior, two lateral walls, a floor and a roof. Anteriorly it communicates with the nasal cavities through the choanae or posterior nares. The floor is formed by the upper surface of the soft palate. Seldom does cancer originate from the anterior wall or the floor.

Posteriorly the wall slopes superiorly and anteriorly blending into the roof or fornix which lies below the body of the sphenoid bone and is attached also to the basilar portion of the occipital bone. Its mucosa is thrown into multiple folds and contains much lymphoid tissue (adenoids).

The lateral walls contain the openings of the eustachian tubes. Behind the openings, the cartilage of the tube forms a prominent ridge, the torus. Superior and posterior to the torus is the pharyngeal recess or fossa of Rosenmueller and directly above the upper end of the fossa of Rosenmueller is the foramen lacerum affording entry into the intracranial cavity.

Histologically, pseudostratified ciliated columnar epithelium (respiratory epithelium) is seen to line the nasopharynx which changes into stratified squamous epithelium as one enters the oral part of the pharynx. There is an abundance of lymphoid tissue. Goblet cells and mixed glands of serous and mucous cells are present also.

Lymphatics. Because tumors of the nasopharynx produce early and extensive cervical metastases, a knowledge of the lymphatics of this region is of paramount importance. Lymphatic drainage of the nasopharynx is mainly into nodes in the retropharyngeal area and into nodes along the superior portion of the

and hepatic abscess were gradually shortened and eventually removed. The condition of the patient is now satisfactory. There have been no recurrences of the hemoptyses.

CARCINOMA OF THE NASOPHARYNX

Report of 150 Cases

MARVIN W. SIMMONS M.D., McMinnville, Oregon, and IRVING M. ARIEL, M.D.,
Minneapolis, Minnesota

CANCER of the nasopharynx is a highly malignant disease which has recently attracted the attention of pathologist and clinician. Usually the signs and symptoms of metastases from this growth have obscured the existence of the primary neoplasm accordingly adequate descriptions of the natural history of nasopharyngeal cancer have been delayed.

Prior to the beginning of the twentieth century very few references were found pertaining to this disease. Jackson in 1901 discovered only 13 cases in the world literature of which the earliest case report was in 1837. Not until 1921 was an adequate description of this type of cancer presented when Regaud and Reverchon and Schminke published papers independently describing the pathologic features. Trotter in 1911 had described the classical Trotter's triad resulting from nasopharyngeal neoplasms which consists of impaired hearing, neuralgia of the second branch of the trigeminal nerve and asymmetry of the soft palate.

Since 1921 excellent papers have been published including those of New (1922, 1925, 1931) and 1943, Furstenberg (1938) and Martin (1940). This report presents the pathological and clinical features of an unselected consecutive group of 150 patients with nasopharyngeal cancer who were treated at the Veterans Administration Hospital, Hines, Illinois from 1931 to 1946 inclusive. The diagnosis in each instance was confirmed histologically.

ANATOMY OF THE NASOPHARYNX

A brief review of the normal anatomy will serve better to explain the morbid processes. The nasal part of the pharynx is an irregular cavity with six walls: anterior, posterior, two lateral walls, a floor and a roof. Anteriorly it communicates with the nasal cavities through the choanae or posterior nares. The floor is formed by the upper surface of the soft palate. Seldom does cancer originate from the anterior wall or the floor.

Posteriorly the wall slopes superiorly and anteriorly blending into the roof or fornix which lies below the body of the sphenoid bone and is attached also to the basilar portion of the occipital bone. Its mucosa is thrown into multiple folds and contains much lymphoid tissue (adenoids).

The lateral walls contain the openings of the eustachian tubes. Behind the openings the cartilage of the tube forms a prominent ridge, the torus. Superior and posterior to the torus is the pharyngeal recess or fossa of Rosenmueller, and directly above the upper end of the fossa of Rosenmueller is the foramen lacerum affording entry into the intracranial cavity.

Histologically, pseudostratified ciliated columnar epithelium (respiratory epithelium) is seen to line the nasopharynx which changes into stratified squamous epithelium as one enters the oral part of the pharynx. There is an abundance of lymphoid tissue. Goblet cells and mixed glands of serous and mucous cells are present also.

Lymphatics. Because tumors of the nasopharynx produce early and extensive cervical metastases, a knowledge of the lymphatics of this region is of paramount importance. Lymphatic drainage of the nasopharynx is mainly into nodes in the retropharyngeal area and into nodes along the superior portion of the

Fig. Schematic representation of the lymphatic drainage and nodal connections of the face and neck. (After Rouvière.)

internal jugular vein (13). The collecting lymphatic trunks are very numerous and originate from the pharyngeal tonsil, the roof of the posterior wall and lateral walls around the eustachian orifices. These combine and traverse the pharyngeal walls and usually terminate in the lateral retropharyngeal nodes; however, some terminate in nodes of the upper internal jugular chain. Some also may end in nodes further inferior or extend posteriorly and end in nodes along the spinal accessory nerve. Efferent channels from these nodes terminate in supraclavicular nodes. Hence, it can be seen why metastases from cancer of the nasopharynx may appear anywhere in the cervical region (Figs. 1 and 2).

INCIDENCE

During the 16 year period from 1931 to 1946 inclusive, there were 1976 patients with primary malignant tumors admitted to Vet

erans Administration Hospital, Hines, Illinois. Of this group 1,299 neoplasms were found involving the upper digestive and respiratory tract (exclusive of lip). Intra-oral carcinoma thus comprised 6.3 per cent of all malignant neoplasms. Carcinoma of the nasopharynx represented 11.5 per cent of all intraoral cancer and 0.7 per cent of all patients admitted to this hospital bearing malignant tumors. Martin (8) observed that cancer of the nasopharynx represented 2 per cent of all malignant growths at Memorial Hospital.

ETIOLOGY

Age. An accurate picture of the true age and sex incidence of nasopharyngeal carcinoma cannot be obtained from the records of a veterans hospital because of the select group of patients admitted. The average age of this series was 45 years; the youngest patient was 19 years and the oldest was 68 years. In 32

Fig. 2 Schematic representation of the lymphatics of the pharynx and their nodal connections. (After Rouvière.)

patients (21.3%) the age was below 40 years. Only 5 patients (3.3%) were over 60 years old. Because this disease occurs in patients who are relatively young the need for considering cancer of the nasopharynx in younger age groups is emphasized. Cancer of the nasopharynx occurs in children and in adults below 30 years more often than any other malignant growth of the upper respiratory and alimentary tracts (8).

Sex. The sex was exclusively male in this series. Other authors describe a marked predilection (80%) in the male sex for this disease entity (8, 9).

Race. In this group 88 per cent of the patients were white and 11.3 per cent were negro. The percentage of negro patients hospitalized at this institution for all causes is 15 per cent. Therefore the percentage of colored patients who had cancer of the nasopharynx does not differ significantly from the overall admission rate of negroes. One patient was Chinese, an incidence of 0.6 per cent of the entire group. Certain authors have described a high preponderance of nasopharyngeal carcinoma among the Chinese. Because of the select group of patients admitted at a Veterans Hospital for therapy, one would not expect a high admission rate of Chinese individuals.

Other factors. In the quest for certain factors which might have significance etiologi-

cally, analysis in this series was made of alcohol intake, smoking, and syphilis.

From our study one cannot say that either tobacco or alcohol contributes toward the production of cancer of the nasopharynx. A study of the incidence of syphilis revealed that 11 (7.3%) of the entire group had syphilis. No significance is attached to syphilis as an etiological factor since 5 per cent of all patients admitted to the hospital have positive Wassermann reactions.

A study to ascertain whether chronic infections, tonsillitis, or other infective or metabolic abnormalities contributed to the production of nasopharyngeal malignant neoplasms was found to yield negative results.

PATHOLOGY

Gross pathology. Nasopharyngeal carcinoma usually manifests itself early as a slight bulge or ulceration. It may originate in the irregular folds of persistent lymphoid tissue frequently present in the nasopharynx, usually in the fossa of Rosenmueller. This tiny lesion is frequently the source of massive cervical metastases. Not infrequently no demonstrable lesion is present and from 1 month to 2 years may elapse before the lesion becomes manifest.

As the tumor grows it may fill completely the nasopharynx with a bulky fungating friable mass or the lesion may be infiltrative and ulcerating.

Fig. Schematic representation of the lymphatic drainage and nodal connections of the face and neck. (After Rouvière.)

internal jugular vein (13). The collecting lymphatic trunks are very numerous and originate from the pharyngeal tonsil, the roof of the posterior wall and lateral walls around the eustachian orifices. These combine and traverse the pharyngeal walls and usually terminate in the lateral retropharyngeal nodes; however, some terminate in nodes of the upper internal jugular chain. Some also may end in nodes further inferior or extend posteriorly and end in nodes along the spinal accessory nerve. Efferent channels from these nodes terminate in supraclavicular nodes. Hence, it can be seen why metastases from cancer of the nasopharynx may appear anywhere in the cervical region (Figs. 1 and 2).

INCIDENCE

During the 16 year period from 1931 to 1946 inclusive there were 19,976 patients with primary malignant tumors admitted to Vet

erans Administration Hospital Hines, Illinois. Of this group 1,299 neoplasms were found involving the upper digestive and respiratory tract (exclusive of lip). Intra-oral carcinoma thus comprised 6.3 per cent of all malignant neoplasms. Carcinoma of the nasopharynx represented 11.5 per cent of all intraoral cancer and 0.7 per cent of all patients admitted to this hospital bearing malignant tumors. Martin (8) observed that cancer of the nasopharynx represented 2 per cent of all malignant growths at Memorial Hospital.

ETIOLOGY

Age. An accurate picture of the true age and sex incidence of nasopharyngeal carcinoma cannot be obtained from the records of a veterans hospital because of the select group of patients admitted. patients (21.3%) the age was below 40 years. Only 5 patients (3.3%) were over 60 years old. Because this disease occurs in patients who are relatively young the need for considering cancer of the nasopharynx in younger age groups is emphasized. Cancer of the nasopharynx occurs in children and in adults below 30 years more often than any other malignant growth of the upper respiratory and alimentary tracts (8).

Sex. The sex was exclusively male in this series. Other authors describe a marked predilection (80%) in the male sex for this disease entity (8, 9).

Race. In this group 88 per cent of the patients were white and 11.3 per cent were negro. The percentage of negro patients hospitalized at this institution for all causes is 15 per cent. Therefore the percentage of colored patients who had cancer of the nasopharynx does not differ significantly from the overall admission rate of negroes. One patient was Chinese, an incidence of 0.6 per cent of the entire group. Certain authors have described a high preponderance of nasopharyngeal carcinoma among the Chinese. Because of the select group of patients admitted at a Veterans Hospital for therapy, one would not expect a high admission rate of Chinese individuals.

Other factors. In the quest for certain factors which might have significance etiologi-

cally analysis in this series was made of alcohol intake, smoking and syphilis.

From our study one cannot say that either tobacco or alcohol contributes toward the production of cancer of the nasopharynx. A study of the incidence of syphilis revealed that 11 (7.3%) of the entire group had syphilis. No significance is attached to syphilis as an etiological factor since 5 per cent of all patients admitted to the hospital have positive Wassermann reactions.

A study to ascertain whether chronic infections, tonsillitis or other infective or metabolic abnormalities contributed to the production of nasopharyngeal malignant neoplasms was found to yield negative results.

PATHOLOGY

Gross pathology. Nasopharyngeal carcinoma usually manifests itself early as a slight bulge or ulceration. It may originate in the irregular folds of persistent lymphoid tissue frequently present in the nasopharynx, usually in the fossa of Rosenmueller. This tiny lesion is frequently the source of massive cervical metastases. Not infrequently no demonstrable lesion is present and from 1 month to 2 years may elapse before the lesion becomes manifest.

As the tumor grows it may fill completely the nasopharynx with a bulky fungating friable mass or the lesion may be infiltrative and ulcerating.

Fig. 3. Extension of nasopharyngeal carcinoma along base of brain with displacement of intracranial structures.

Location. Twenty-six patients (17.3%) of the 150 cases presented lesions in Rosenmueller's fossa. The next most frequent site was the posterior pharyngeal wall which was noted in 18 patients (12%) of which 6 (4%) were in the midline. The pharyngeal tonsil was the probable site of origin of the group that presented posterior pharyngeal wall lesions. The lateral wall (other than Rosenmueller's fossa) was the initial seat of the carcinoma in 10 patients (6.7%). A bulky cauliflower type of lesion filling the entire nasopharynx was described in 10 patients upon admission. Nine patients (6%) presented their initial lesion on the vault or roof. In 59 patients (40%) the exact location of origin could not be ascertained. This series, therefore, indicates that the most common site of origin of nasopharyngeal carcinoma is the lateral wall including the fossa of Rosenmueller.

The side involved was noted in all but 12 patients. In 42 cases (28%) the right side was involved in 39 cases the left side. In 57 patients (38%) both sides were involved.

Histology. Considerable controversy exists concerning the pathogenesis and nosology of

neoplasms arising from the nasopharynx (8, 12, 14, 15). We have adopted Stewart's classification (8).

In this series, epidermoid carcinoma comprised 34.7 per cent and transitional cell carcinoma 30.7 per cent. Anaplastic carcinoma was observed in 14 patients (9.3%) and in 8 instances (5.3%) the neoplasm was unclassified. Although certain anaplastic and unclassified neoplasms resembled lymphosarcoma it was felt that sufficient criteria were not present to warrant that histologic classification. During the same period 5 nasopharyngeal fibromas, 2 plasmocytomas and 2 adenocarcinomas of salivary gland origin were observed.

INTRACRANIAL EXTENSION

Extension of the tumor extradurally into the intracranial cavity frequently causes a host of neurologic symptoms duplicated by few other disease entities. In 2 cases in this series all cranial nerves were affected. The proximity of the foramen lacerum to the superior lateral wall of the nasopharynx affords an easy path for the cells to ascend and extend beneath the dura, stripping it from the base of the skull. In no case in our series was invasion of the dura observed.

Bone erosion may occur from pressure of the tumor or because of stripping of its nutrient periosteum from the bone by the spreading cancer. This was observed in 6 postmortem examinations in this series. The cranial nerves are affected usually by pressure and not by actual invasion (Fig. 3).

As the neoplasm extends forward the inferior orbital fissure may be invaded producing proptosis and pressure on the optic nerve may produce blindness. Only in terminal stages is papilledema or other evidence of increased intracranial pressure observed.

The brain was damaged apparently due to pressure in 6 cases. Of this group two had softening of the frontal lobe the cause, seemingly, of personality changes not infrequently noted in victims of this type of cancer.

Upon admission 44 patients (29.3%) had involvement of one or more cranial nerves. After admission 11 additional patients (7.3%) developed the symptoms of cranial nerve involvement. Freedom of any cranial nerve

Fig 4. Unilateral metastatic upper cervical nodes from a nasopharyngeal carcinoma.

Fig 5. Voluminous bilateral metastases to cervical nodes from nasopharyngeal carcinoma.

involvement was noted in 95 patients (63.3%)

The abducens nerve was the one most frequently involved (24%) because of its location over the foramen lacerum. The second most commonly involved nerve was the hypoglossal as observed in 28 patients (18.6%) due usually to compression of the nerve as it emerges from the skull through the hypoglossal canal.

The trigeminal nerve was the third most commonly affected cranial nerve as noted in 26 cases (17.3%). Next in order were the vagus and glossopharyngeal nerves with 24 cases (16%) and 23 cases (15.3%) respectively. These nerves were compressed usually as they emerged through the jugular foramen by cervical metastases rather than extension of the tumor within the skull. The oculomotor nerve was sixth in order with 18 patients (12%) demonstrating ophthalmoplegia. The seventh and eighth nerves are well protected within the internal auditory canal of the petrous temporal bone but when the facial nerve exits through the stylomastoid foramen it may be compressed by enlarged lymph nodes. Seventeen instances of facial paralysis were noted (11.3%). Only 4 patients had auditory nerve findings (2.6%). The optic nerve tract was affected in 7 patients (4.6%). Only 2 in

stances of involvement of the olfactory nerve were noted. The tumor was very extensive in each case and all of the 12 cranial nerves were involved. A Horner's syndrome was observed in 26 instances (17.3%).

CERVICAL METASTASES

Upon admission 125 patients (83.3%) presented cervical metastases. In an additional 5 patients (3.3%) metastases developed after admission. Thus 86.6% of all patients developed cervical metastases and in only 20 patients (13.3%) were no cervical metastases observed. In 67 of the cases (44.7%) bilateral neck metastases developed.

Any of the cervical chains may be involved and not infrequently all chains are invaded. The upper deep cervical lymph nodes were most frequently involved in this series (Figs. 1 and 2) and submental and submaxillary node involvements were only infrequently encountered.

Generalized metastases. Of the 37 autopsies obtained from 128 deaths there were 9 (24.3%) who had extension to the intracranial cavity. Of this number 4 patients did not have cervical metastases. Intracranial extension may

Upon admission 44 patients (29.3%) had involvement of one or more cranial nerves. After admission 11 additional patients (7.3%) developed the symptoms of cranial nerve involvement. Freedom of any cranial nerve

Chart 1 Time interval from date of symptoms to date of first seeking medical attention.

Involvement of several cranial nerves may produce a Gradenigo syndrome (1) or Trotter's triad. When metastases to cervical lymph nodes are marked or lateral extension occurs the jugular foramen syndrome is found as the ninth, tenth, eleventh and twelfth nerves and the cervical sympathetics are paralyzed. One observes weakness and asymmetry of the soft palate with loss of the gag reflex. Loss of taste on the posterior third of the tongue is present and the patient complains of dysphagia and accumulation of secretions in his pharynx. Passage of food into the lower respiratory tract occurs with consequent cough. Hoarseness may be noted due to paralysis of one vocal cord.

DIAGNOSIS

The disease is protean in its manifestations and may imitate many other neurological, otolaryngological and ophthalmological conditions. Description of nasopharyngeal cancers can be found in journals relating to the nervous system (4, 9, 18), the ear, nose and throat (8), the eye (2), as well as in journals of pathology (16), radiology (7) and general surgery (1). Early the symptoms are referable to areas other than the nasopharynx and accordingly the diagnosis is missed frequently. In this series the correct diagnosis was not suspected by the referring physician in 92 patients (61.3%). The following diagnoses were the ones erroneously made by referring

physicians: inflammatory lesions, 28 patients; cervical Hodgkin's disease, 20 patients; primary cervical carcinoma, 8 patients; cerebellopontine angle tumor, 1 patient.

Other diagnoses included organic brain disease, central nervous system lesions, neck abscess, otitis media and chronic sinusitis.

Previous to admission, 21 operative procedures had been performed on 19 (12.7%) patients in this series in the presence of the un-

Fig. 7. Horner's syndrome and deviation of tongue to side of lesion (twelfth nerve) in a patient with a nasopharyngeal carcinoma. Note smaller pupil and ptosis of upper lid, right eye.

occur without cervical metastases. Twenty patients (54%) had generalized metastases. The liver (15 cases) and lungs (9 cases) were the most frequent visceral organs involved.

Generalized metastases occur more frequently from nasopharyngeal carcinoma than from any other intraoral cancer. It was observed in only 13.9 per cent of 72 autopsies on patients with carcinoma of the tongue at this hospital (unpublished data).

SYMPTOMS AND CLINICAL COURSE

Initial symptom. Nasopharyngeal carcinoma develops insidiously and rarely presents initial symptoms due to the primary growth. Symptoms from cervical metastases and intracranial extension usually focus attention upon the existence of the neoplasm. In this series of 150 patients it was noted that the most frequent symptom was swelling of the neck observed in 73 instances (48.7%). Pain of the side of the face and head was the initial symp-

tom in 19 instances (12.6%). In only 6 patients (4%) was nasal obstruction a presenting symptom with an additional 3 patients (2%) who had associated deafness and epistaxis.

The ear was involved in 11 patients of this group (7.3%) who had a presenting complaint of earache, deafness, and tinnitus. In 7 patients (4.7%) the first symptom noted was referable to the eye and patients complained of poor vision, pain or diplopia. In an additional 4.7 per cent of the entire group various miscellaneous symptoms were present including loss of weight, paralysis of the lower legs due to spinal cord metastases and difficulty in talking.

Physical signs. In addition to bulky cervical metastases the physical signs usually result from pressure of the tumor upon contiguous structures. Conduction deafness was observed in 48.6 per cent of all patients. Signs referable to cranial nerve involvement were observed in 36.7 per cent of all cases.

suspected nasopharyngeal carcinoma. There were 7 tonsillectomies, 3 mastoidectomies, 3 multiple teeth extraction, 2 instances of incision and drainage of neck abscesses, 4 intra nasal polypectomies, 1 radical sinus resection and 1 paracentesis of the ear drum.

DELAY IN DIAGNOSIS

In 39 cases (26%) the patient sought medical attention within 1 month after onset of symptoms. In Chart 1 this group of patients is considered as showing no delay in seeking medical attention. The average lapse of time

Fig. 8. Irradiated skin reaction demonstrating location of lateral facial portals.

Fig. 9. Irradiated skin reaction demonstrating location of infraorbital portals.

before the patient applied for medical care was 3.2 months. Twenty patients (13.6%) delayed over 6 months.

After the first visit to the physician an average lapse of 6.9 months occurred before the correct diagnosis was made by the doctor (Chart 2). In 13 patients (8.7%) the diagnosis was made within the first month this was considered as no delay. In 22 patients (14.6%) more than 1 year was required by the physician to make a correct diagnosis.

Chart 3 demonstrates that the average time interval from the onset of symptoms until the correct diagnosis was established was 9.4 months. In 42 patients (28%) the diagnosis was made after a lapse of 1 year following onset of the first symptom. In only 34 patients or 22.7 per cent was there a delay of less than 3 months.

DIFFERENTIAL DIAGNOSIS

Cancer is the most frequent lesion of the nasopharynx in the adult. A careful examination of the nasopharynx using a soft palate retractor and a curved mirror aided by finger palpation will permit the taking of a biopsy of any suspicious area. It is emphasized again that the lesion may be small and covered frequently by hypertrophied lymphoid tissue. Accordingly any irregularity or firmness warrants a deep bite with the biopsy forceps.

All children and young adults who have undergone resection of *adenoids* should be examined for possible neoplasia.

Nasopharyngeal fibroma found in adolescent males involute as maturity is reached. These tumors are characterized by a smooth surface and very profuse bleeding. Other tumors which have been described in this location are salivary gland tumors, chordomas from the primitive notochord, craniopharyngeomas from Rathke's pouch and plasmocytomas. To a less extent are found teratomas of the epipharynx, hemangiomas, lymphangiomas, choanal polyps and retropharyngeal lymph node tuberculosis.

Rarely does a tumor of the pituitary gland extend into the postnasal space. The differential diagnosis here is particularly important to avoid a possible craniotomy.

In all metastatic cervical neoplasms in which no primary lesion has been discovered careful scrutiny of the nasopharynx should be performed repeatedly. Nasopharyngeal carcinoma is one of the most frequent lesions which remains quiescent but produces early metastases.

Neurological symptoms occur early and frequently and should invite a careful examination of the nasopharynx.

Frequently the patient is not carefully studied and is referred for neurosurgical intervention. Concerning this feature Davis and Martin state:

We believe it is usually evidence of carelessness on the part of some examiner at

Fig. a and b, Nasopharyngeal carcinoma with intracranial extension and bilateral abducens nerve paresis before intensive irradiation. Portals for treatment are outlined.

some time during the course of the patient's history if the patient arrives in the hands of the neurologic surgeon with signs of intra-

cranial extension from a nasopharyngeal tumor which is only then recognized for the first time

PERCENT

Chart 4. Time interval from date of onset of symptoms to date of death in 128 deaths.

Roentgenograms have not been of significant aid in establishing the diagnoses and radiological evidence of bone destruction was noted in 6 cases of this series.

A biopsy should be taken always of any suspicious area to establish the diagnosis.

TREATMENT

Therapy of cancer of the nasopharynx is exclusively irradiation and all patients in this series were so treated. The early metastases, the anatomical inaccessibility and the undifferentiated features of the disease obviate success with surgery.

The patient's general condition during roentgen therapy must receive paramount consideration and maintenance on an adequate caloric intake supplemented with vitamins is essential. An oral hygienist should administer local hygienic measures before and during therapy.

Treatment of the primary lesion. Fractionated x radiation is recommended. The following factors are now utilized: 200 to 250 kilovolts, 50 to 60 centimeters target skin distance, a filter of 0.05 to 1 millimeter of copper and 4 to 6 milliamperes. The field size varies from 6 to 8 centimeters in diameter. The ports used are two lateral fields which may be combined with anterior infraorbital fields. A dosage of 700 r to each of two ports daily is given until about 3500 r; times two have been

administered. Supplemental therapy may include an additional 1000 milligram hours with the Martin Blady nasopharyngeal radium applicator (8) (Figs 8 and 9).

Treatment of the metastases from nasopharyngeal cancer. Patients that have metastases high in the neck may be treated through a portal which will include both the primary neoplasm and the cervical metastases. In most instances, too large a portal would be necessary so it is better to treat the primary as a separate entity and utilize a separate port for the cervical metastases. Externally applied deep x radiation therapy is preferred for the metastases. We believe with Martin (8) that it is advisable to limit the size of the port and treat only the visible metastatic lesions instead of using large ports which will cover the entire cervical area. A dose of 4000 to 5000 r measured in air may be administered. At the completion of this dose if any of the disease persists radon seeds (5 to 8 threshold skin erythemas) may be administered interstitially.

Following the first treatments of radiotherapy a rapid diminution of the severity of the symptoms occurs and cranial nerve paralyses may entirely disappear (Figs 10 and 11). Distant metastases should be treated with deep roentgen therapy and the dose determined by the symptomatic response. Small doses (750 to 1000 r) may frequently produce marked improvement.

Fig. 1 M. C. 35484. Adenoma of parotid gland. Eosin and methylene blue stain. $\times 162$

Fig. 2 F. L. 39987. Hemangioma of parotid gland. Phosphotungstic acid and hematoxylin stain. $\times 70$

the carotid artery. The mass was dissected free and removed together with the submaxillary gland.

The surgical specimen was an irregular firm mass 2 by 3 by 3.5 centimeters. It was made up of dark red tissue with a firm pinkish-tan mass representing the submaxillary gland at one end. Histologic sections showed a plexiform mass of capillary blood vessels in the salivary gland and surrounding tissues. The diagnosis was hemangioma (Fig. 3).

CASE 5. R. E. a 26 year old white male had noted a swelling at the angle of the left side of the jaw since childhood. It had varied in size, was occasionally tender and sensitive. Lately it had so increased in size as to interfere with shaving. Examination showed a soft mass 6.5 centimeters in diameter. At operation a multilocular dark gray cyst was found lying beneath the platysma muscle on the left side and closely attached to the submaxillary gland.

The surgical specimen measured 4 by 4 by 3.8 centimeters. A partially collapsed multiloculated cystic mass was attached to a fragment of normal salivary gland. Microscopic examination showed in addition to normal salivary gland several small cysts with thin fibrous endothelium-lined walls.

Diagnosis was cavernous lymphangioma (Fig. 4).

CASE 6. A. J. G. a 40 year old white male, noted a small painless swelling in the right side of the neck under the jaw, progressively enlarging for 6 months before hospital admission. On physical examination there was a discrete nontender resilient tumor the size of a walnut in the right submaxillary region. An x ray film showed no opacity. At operation the mass was found to be encapsulated, firmly adherent to the submaxillary gland at its inferior margin. It was easily shelled out when the capsule was incised.

The surgical specimen was ovoid lobulated encapsulated firm and yellowish brown. It measured 4 by 3.5 by 2.5 centimeters. On section the cut surfaces bulged and had a translucent cast with foci of hemorrhage in a yellowish-gray parenchyma. Microscopic study showed a compact mass of elongated smooth muscle fibers either lying in a parallel arrangement or forming an interwoven matrix. The nuclei were ovoid and plump without any evidence of increased cellular activity. There were fairly abundant fibrous strands and collagen. Special stains revealed most of the elements in the new growth to be of smooth muscle origin. The diagnosis was leiomyoma of submaxillary gland (Fig. 5).

Fig 5 A. J. G. S-40-530. Leiomyoma of parotid gland. Phosphotungstic acid and hematoxylin stain, $\times 165$.

Fig 6 T. W. 31399. Perineurial fibroma of parotid gland. Hematoxylin and eosin stain, $\times 150$.

ear for 3 years. This was a moderately soft, non tender, slightly movable mass, $1\frac{1}{4}$ inches in diameter. The cystic tumor located in the superficial portion of the left parotid gland was surgically excised. A small amount of yellow purulent appearing fluid escaped when the cyst was broken in one place during removal.

Pathological examination showed a soft fleshy encapsulated cyst containing friable pink tissue. Microscopically the tumor was similar to that in Case 8. The diagnosis was papillary adenocystoma lymphomatousum (Fig 7).

CASE 10. A. J. S. a 45 year old white woman was first seen November 9, 1933 because of a gradually enlarging mass on the right side of the face which was first noted following the extraction of a molar tooth 6 weeks previously. On examination the right parotid gland presented a rounded tumor just below the zygomatic arch and anterior to the auditory canal. The tumor was the size of a walnut. Intraorally there was a tense round firm bulging tumor on the medial aspect of the ascending ramus of the mandible. The clinical diagnosis was mixed tumor of the parotid gland. This was later changed to carcinoma simplex on the basis of an aspiration

biopsy. Despite temporary remission as a result of radiation therapy the patient died on July 19, 1938. At this time the local neoplasm had ulcerated and there was invasion of the right naris.

At autopsy the soft friable, reddish gray tumor was found to have penetrated the bones of the base of the skull and extended to the right temporal lobe of the brain. It had eroded the right orbit posteriorly, the right maxillary sinus and zygomatic arch, and it had destroyed the ethmoid bone and sella turcica. The origin was still thought to be the right parotid gland.

Cytologically the neoplasm consisted of closely packed elongated cells focally arranged and isolated by necrotic tissue. The cells blended with each other had plump oval nuclei, and were assembled in interlocking fascicles. Many bizarre nuclear forms and asymmetrical mitoses were seen. No cross striations were found but the malignant cells took the usual stains for muscle. The final diagnosis was leiomyosarcoma of the parotid gland (Fig 8).

CASE 11. W. B. a 60 year old, white male had noted a painless gradually enlarging mass in front of the right ear for 8 months. A smaller nodule was present in the neck. Examination showed a hard

Fig. 3. K. E. 10063. Hemangioma of submaxillary gland. Hematoxylin and eosin stain, X40.

CASE 7. T. W., a 14 year old white boy was seen because of a painless slowly growing tumor in front of the left ear of 6 years duration. The mass was firm, smooth slightly tender and fixed. It was about 3.5 centimeters in diameter. The preoperative diagnosis was mixed tumor of the parotid gland. It was operated upon with removal of a necrotic, dark brown tumor.

The mass weighed approximately 4 grams. In it there were many areas of soft to firm pale gray to dark red tissue. Histologically the tissue was made up of compactly arranged, elongated cells of uniform size and shape and talling reaction. These cells had clear fusiform nuclei. It was impossible to make out the ends of the fibers. This neoplastic tissue formed its own trophic. Many foci of calcification and localized hemorrhages were found. The diagnosis was perineurial fibroma (Fig. 6).

CASE 8. C. F. N., a 69 year old physician was first seen on July 30, 1930 with a painless swelling in the left parotid region of 1 month's duration. At operation surgical removal of a well encapsulated roughly ovoid tumor 3 by 2 by 3 centimeters was done. This tumor proved microscopically to be a papillary adenocystoma lymphomatous. One and

Fig. 4. R. L. 10066. Cavernous lymphangioma of submaxillary gland. Eosin and methylene blue stain, X45.

half years later he was readmitted to the hospital with similar swelling in the right parotid gland of 3 months duration. Excision of this tissue revealed a spherical cystic mass 3 centimeters in diameter which shelled out of the right parotid gland. During removal it ruptured and mucinous material escaped.

The surgical specimen contained salivary gland in addition to a soft reddish-gray mass measuring 3.3 centimeters in diameter. Section showed a firm, bulging, homogeneous pale red and gray surface with fleck of sticky mucin. Microscopic study showed portions of normal parotid gland. The rest of the specimen was made up of thick papillary projections composed of dense lymphoid tissue surmounted by ciliated mucin laden tall columnar epithelium. This tumor was similar to that removed from the left parotid region a year and a half previously. Diagnosis was giant papillary adenocystoma lymphomatous.

Before the operation on the left side the clinical diagnosis was mixed tumor of the parotid gland. However, before the one on the right, the tumor was suspected to be similar to the former one.

CASE 9. M. F., a 72 year old white male had noticed slowly enlarging lump in front of the left

Fig. 5 A. J. G. S-40-530. Leiomyoma of parotid gland. Phosphotungstic acid and hematoxylin stain, $\times 162$.

Fig. 6 T. W. 31399. Perineurial fibroma of parotid gland. Hematoxylin and eosin stain, $\times 120$.

ear for 3 years. This was a moderately soft, non tender, slightly movable mass $1\frac{1}{4}$ inches in diameter. The cystic tumor located in the superficial portion of the left parotid gland, was surgically excised. A small amount of yellow purulent appearing fluid escaped when the cyst was broken in one place during removal.

Pathological examination showed a soft, fleshy encapsulated cyst containing friable pink tissue. Microscopically the tumor was similar to that in Case 8. The diagnosis was papillary adenocystoma lymphomatosum (Fig. 7).

CASE 10 A. J. S. a 45 year old white woman was first seen November 9, 1933 because of a gradually enlarging mass on the right side of the face which was first noted following the extraction of a molar tooth 6 weeks previously. On examination the right parotid gland presented a rounded tumor just below the zygomatic arch and anterior to the auditory canal. The tumor was the size of a walnut. Intraorally there was a tense round firm bulging tumor on the medial aspect of the ascending ramus of the mandible. The clinical diagnosis was mixed tumor of the parotid gland. This was later changed to carcinoma simplex on the basis of an aspiration

biopsy. Despite temporary remission as a result of radiation therapy the patient died on July 19, 1938. At this time the local neoplasm had ulcerated and there was invasion of the right naris.

At autopsy the soft, friable reddish gray tumor was found to have penetrated the bones of the base of the skull and extended to the right temporal lobe of the brain. It had eroded the right orbit posteriorly, the right maxillary sinus and zygomatic arch, and it had destroyed the ethmoid bone and sella turcica. The origin was still thought to be the right parotid gland.

Cytologically the neoplasm consisted of closely packed elongated cells focally arranged and isolated by necrotic tissue. The cells blended with each other had plump oval nuclei, and were assembled in interlocking fascicles. Many bizarre nuclear forms and asymmetrical mitoses were seen. No cross striations were found but the malignant cells took the usual stains for muscle. The final diagnosis was leiomyosarcoma of the parotid gland (Fig. 8).

CASE 11 W. B. a 60 year old, white male had noted a painless gradually enlarging mass in front of the right ear for 8 months. A smaller nodule was present in the neck. Examination showed a hard

Fig. 7 M. F. 15006. Papillary adenocystoma lymphomatosum. Hematoxylin and eosin stain, $\times 7$.

ovoid slightly movable tumor 3 by 2 by 2 centimeters in the region of the right parotid gland and a smaller roughly spherical mass 1.5 centimeters in diameter lying beneath it. Although the primary choice was parotid tumor a clinical diagnosis of lymphoma was considered because of the enlarged node in the left side of the neck and a palpable node in the groin. At operation two tumors were excised from the right parotid gland. The larger measured 3 by 4 by 3 centimeters, and occupied the middle and upper portions of the gland; the smaller was in the lower half of the gland and measured 2.5 by 2 by 2 centimeters. There was no definite plane of cleavage.

Examination of the specimens showed normal salivary gland incorporating firm pale gray rubbery well vascularized, homogeneous tumor tissue. Histologic study showed some residual parotid gland but the significant change was the extensive replacement by mature and immature lymphoid elements. The widespread invasion by young and old lymphocytes with many cells in mitosis indicated a diagnosis of lymphosarcoma (Fig. 9).

CASE 1. O. H., a 68 year old white woman was first seen because of a mass at the right angle of the

Fig. 8 A. J. S., 35-A-8. Leiomyosarcoma of parotid gland. Phosphotungstic acid and hematoxylin stain, $\times 475$.

jaw closely attached to the lower portion of the parotid gland. It had been painful on occasions. The mass was first noted 5 months previously after recovery from a respiratory infection. Physical examination revealed a fixed, nontender oval mass, 12 by 9 by 8 centimeters lying beneath the angle of the jaw on the right side. Intraoral examination was negative. A clinical diagnosis of lymphoma or metastatic tumor was made. Biopsy was performed. At operation the new growth lay within the right parotid gland and there was no obvious line of demarcation. Gross and microscopic study substantiated the clinical impression of lymphoma. The final diagnosis was malignant lymphocytoma. No evidence of recurrence following radiation therapy was reported in a follow up examination 2 years later.

CASE 13. C. B., a 51 year old white woman, was seen because of a tumor near the angle of the right side of the jaw which had been present for 3 months and had recently been increasing in size. On examination the mass was fixed to the tissues, lay in or near the submaxillary gland and was described as being the size of a "hen's egg." Some enlarged cervical nodes were found in the supraclavicular

Fig. 9. Lymphosarcoma of parotid gland. Eosin and methylene blue stain, $\times 90$.

Fig. 10. C. B., 36783. A typical Hodgkin's disease of submaxillary gland. Phosphotungstic acid and hematoxylin stain, $\times 210$.

region anterior to the sternocleidomastoid muscle. Clinical impression was malignant tumor of the submaxillary gland or a primary bony neoplasm arising in the mandible. At operation a firm reddish-gray neoplasm 4 by 4 by 3 centimeters was shelled out of the right submaxillary gland. The surgeon's diagnosis was mixed tumor.

A pathologic diagnosis of atypical Hodgkin's disease was made on the basis of neoplastic destruction of normal submaxillary gland pleomorphism, abundance of reticulum cells, young and old lymphocytes and eosinophils, fibrosis, necrosis and the presence of large multinucleated giant cells suggestive of the Reed-Sternberg type (Fig. 10).

Follow up 4 1/2 years later revealed the patient to be still living.

DISCUSSION

Adenomas of the salivary glands have been reported by several authors. McFarland (5) presented a critical review of a large number of cases reported as adenoma of salivary gland and added 1 case of his own.

He regarded most of the so-called adenomas as variants of the mixed tumor showing a preponderance of glandular tissue and questioned the evidence in favor of their originating from salivary gland *per se*. Harris (2) described the morphology of 1 case in detail. He concluded that the tumor in his case arose from duct epithelium. This view is an acceptable interpretation of the first 2 cases presented here since the histologic appearance of the neoplastic cells in both cases is suggestive of the duct epithelium of salivary glands. Additional evidence of the adenomatous nature of the tumors is the fact that both were encapsulated. Clinical information regarding these cases is inadequate and no diagnostic criteria for recognition of these tumors preoperatively can be deduced.

Salivary gland angiomas have been encountered infrequently. McFarland (6) mentions 2 of unspecified type. Both were seen in infants. In the present group 2 were of blood vessel type and 1 of lymphatic derivation. In 2 the duration was from childhood,

Follow-up 4½ years later revealed the patient to be still living.

DISCUSSION

Adenomas of the salivary glands have been reported by several authors. McFarland (5) presented a critical review of a large number of cases reported as adenoma of salivary gland and added 1 case of his own.

He regarded most of the so-called adenomas as variants of the mixed tumor showing a preponderance of glandular tissue and questioned the evidence in favor of their originating from salivary gland *per se*. Harris (2) described the morphology of 1 case in detail. He concluded that the tumor in his case arose from duct epithelium. This view is an acceptable interpretation of the first 2 cases presented here since the histologic appearance of the neoplastic cells in both cases is suggestive of the duct epithelium of salivary glands. Additional evidence of the adenomatous nature of the tumors is the fact that both were encapsulated. Clinical information regarding these cases is inadequate, and no diagnostic criteria for recognition of these tumors preoperatively can be deduced.

Salivary gland angiomas have been encountered infrequently. McFarland (6) mentions 2 of unspecified type. Both were seen in infants. In the present group 2 were of blood vessel type and 1 of lymphatic derivation. In 2 the duration was from childhood,

and the third occurred in an infant. Clinically the long duration of the tumor while not specific for angioma, would tend to exclude the diagnosis of mixed tumor. Furstenberg indicates that the appearance of mixed tumors of the salivary gland is most common in the third or fourth decades. At the time of operation the unusual bleeding of the hemangiomas was suggestive of the type of growth.

Perineural fibroma of the salivary glands is seen rarely. McFarland (6) reported 2 cases, 1 with recurrence. Its origin is from the main trunk or a branch of the seventh nerve. Thus it arises within but not actually from the parotid gland. Developing in childhood and growing slowly it usually results in the signs of tumor only. Occasionally there may be twinges of pain. The diagnosis may be surmised clinically but is actually based upon the microscopic picture. Some may undergo malignant change. After the material for this paper was gathered a 2 year old child was operated upon by Dr. R. B. Cattell because of a large mass involving the right parotid gland. This proved to be a perineural fibrosarcoma of low grade malignancy.

Lately there has been much interest in that bizarre tumor of the salivary gland the papillary adenocystoma lymphomatousum. In 1937 Harris (3) described the entity and reviewed the literature. Joyce and associates described a series of 4, one of which showed an early adenocarcinoma and another a squamous cell carcinoma. The characteristics of this new growth have been elaborated so clearly that further discussion is unnecessary. Case 8 is unusual in that the tumor occurred bilaterally. We believe that this tumor is not an uncommon one. In the past year we have encountered 6 additional examples including another case of bilateral tumors.

Leiomyoma of a salivary gland is so rare as to justify reporting it alone. In the case described it arose in the right submaxillary gland. It was encapsulated and easily excised. The histogenesis is unknown. None of the more extensive works has included this particular histologic form. Its clinical diagnosis would be improbable.

The malignant counterpart of the leiomyoma proved to be a confusing neoplasm

and the diagnosis was not established until an autopsy had been performed. An incorrect structural diagnosis had been made on the basis of an aspiration biopsy. The origin of such sarcoma in the parotid gland is obscure. It could conceivably arise in the walls of blood vessels. The response to radiation therapy was unsatisfactory and the clinical course corresponded to that of a carcinoma. Cytologic study showed a typical malignant smooth muscle neoplasm. Special stains were confirmatory. There are no criteria other than microscopic appearance for the diagnosis of this tumor.

Malignant lymphoid neoplasms may arise in the salivary glands. All 3 of the cases reported here were primary on the right side. Two originated in the parotid and 1 in the submaxillary gland. They were characterized by rapid enlargement in the fifth or sixth decades of life. In 1 case a clinical diagnosis of lymphoma was entertained because of associated cervical adenopathy. The diagnosis in all cases was established by microscopic study. Three types are represented—lymphosarcoma, malignant lymphocytoma, and atypical Hodgkin's disease.

SUMMARY

Thirteen uncommon tumors of the salivary glands have been presented: adenoma, 2 cases; hemangioma, 2; lymphangioma, 1; perineural fibroma, 1; papillary adenocystoma lymphomatousum, 2; leiomyoma, 1; leiomyosarcoma, 1; lymphomas, 3 cases—lymphosarcoma, malignant lymphocytoma, and atypical Hodgkin's disease.

An attempt has been made to give certain criteria which may aid in their clinical diagnosis.

Although the greatest number of neoplasms arising in the salivary glands are mixed tumors it should be remembered that other types of tumors may also arise in them.

STIMULATION OF OVARIAN FUNCTION AND INDUCTION OF PREGNANCY THROUGH INTRAVAGINAL IMPLANTATION OF ESTROGEN PELLETS

BERNHARD ZONDEK, M D., and SAMUEL ROZIN M D., Jerusalem, Palestine

THE problem of amenorrhea plays a very significant role in the treatment of sterility. When ovarian function is at a standstill ovulation does not occur, the building up of the uterine mucosa is inhibited and as a result, it becomes impossible for fertilization to take place. Since the discovery of the central regulation of ovarian function through the gonadotropic hormone of the anterior pituitary lobe (12, 13, 28) we distinguish between several types of amenorrhea: (20) (a) prolagenic or hypophyseal, (b) estrogenic, (c) progestogenic, (d) hypothalamic (4).

In groups b and c it is necessary to differentiate between ahormonal or oligohormonal and polyhormonal types (15). In the ahormonal and oligohormonal conditions comprising the majority of the cases amenorrhea is caused by the absence or the insufficient production of the ovarian hormones. With complete cessation of ovarian function (ahormonal condition) an excess of follicle-stimulating hormone is produced in the anterior pituitary lobe and is excreted in the urine (14). In a castrated woman the follicle stimulating hormone content of the urine rises from 10 to 100 mouse units per litre as early as 14 days after the operation and the same occurs physiologically at the climacterium (14). Low excretion of estrogens combined with deficient excretion of follicle stimulating hormone indicates hypophyseal amenorrhea, combined with increased excretion of follicle stimulating hormone ovarian amenorrhea and with normal excretion of follicle stimulating hormone hypothalamic amenorrhea (4). The polyhormonal conditions depend on a disturbance in the ovarian function leading to the persistence of the follicles

or of the corpus luteum with hypersecretion of estradiol and progesterone respectively.

Amenorrhea may be the symptom of a general disease such as diabetes, blood disease, hyperthyroidism or hypothyroidism or it may be the result of psychic or climactic factors. In such cases one must attempt to cure the amenorrhea through the elimination of the underlying disease. Actually however many amenorrheas are of endocrine origin reflecting a disturbance in the pituitary-ovarian relationship. We are employing a therapy of substitution when we first bring about proliferation of the uterine mucosa in an amenorrheic patient with the aid of estrogenic hormone, then induce mucosal function through the administration of progesterone and finally bring on a true menstruation by withdrawal of the hormones. On the other hand when we attempt to stimulate the ovarian function with gonadotropic hormone we are employing a hormonotropic stimulation therapy (Zondek). The final object of all treatment must be to initiate rhythmic function of the gonadotropic hormone in the anterior pituitary lobe.

The anterior pituitary gland is the motor of sexual function (12, 13, 28). Under the influence of gonadotropin estradiol is produced in the follicular theca cells and this hormone exerts a reciprocal effect on the anterior pituitary function. In 1931 the senior author summarized (18) his investigations as follows:

Estrogenic hormone acts both as a stimulator and an inhibitor of the function of the anterior pituitary lobe with the result that the estrogenic hormone produced in the ovary under the influence of the anterior pituitary has a regulating effect on its producer. The motor of the sexual function is thus regulated by the substance it produces since small doses of estrogens stimulate while large doses inhibit it.

From the Gynecologic-Obstetric Department of the Rothschild-Hadassah University Hospital and the Hormone Research Laboratory of the Hebrew University, Jerusalem.

and the third occurred in an infant. Clinically the long duration of the tumor while not specific for angioma, would tend to exclude the diagnosis of mixed tumor. STIMULATION OF OVARIAN FUNCTION AND INDUCTION OF PREGNANCY THROUGH INTRAVAGINAL IMPLANTATION OF ESTROGEN PELLETS

BERNHARD ZONDEK M.D., and SAMUEL ROZIN M.D., Jerusalem Palestine

THE problem of amenorrhea plays a very significant role in the treatment of sterility. When ovarian function is at a standstill ovulation does not occur, the building up of the uterine mucosa is inhibited and as a result it becomes impossible for fertilization to take place. Since the discovery of the central regulation of ovarian function through the gonadotropic hormone of the anterior pituitary lobe (12, 13, 28) we distinguish between several types of amenorrhea (20): (a) prolano-genic or hypophyseal (b) estrogenic (c) progestogenic (d) hypothalamic (4).

In groups b and c it is necessary to differentiate between ahormonal or oligohormonal and polyhormonal types (15). In the ahormonal and oligohormonal conditions comprising the majority of the cases amenorrhea is caused by the absence or the insufficient production of the ovarian hormones. With complete cessation of ovarian function (ahormonal condition) an excess of follicle stimulating hormone is produced in the anterior pituitary lobe and is excreted in the urine (14). In a castrated woman the follicle stimulating hormone content of the urine rises from 10 to 100 mouse units per litre as early as 14 days after the operation and the same occurs physiologically at the climacterium (14). Low excretion of estrogens combined with deficient excretion of follicle stimulating hormone indicates hypophyseal amenorrhea combined with increased excretion of follicle stimulating hormone ovarian amenorrhea and with normal excretion of follicle stimulating hormone hypothalamic amenorrhea (4). The polyhormonal conditions depend on a disturbance in the ovarian function leading to the persistence of the follicles

or of the corpus luteum with hypersecretion of estradiol and progesterone respectively.

Amenorrhea may be the symptom of a general disease such as diabetes, blood disease, hyperthyroidism or hypothyroidism or it may be the result of psychic or climactic factors. In such cases one must attempt to cure the amenorrhea through the elimination of the underlying disease. Actually however many amenorrheas are of endocrine origin reflecting a disturbance in the pituitary-ovarian relationship. We are employing a therapy of substitution when we first bring about proliferation of the uterine mucosa in an amenorrhoeic patient with the aid of estrogenic hormone then induce mucosal function through the administration of progesterone and finally bring on a true menstruation by withdrawal of the hormones. On the other hand when we attempt to stimulate the ovarian function with gonadotropic hormone we are employing a *hormonotropic stimulation therapy* (Zondek). The final object of all treatment must be to initiate rhythmic function of the gonadotropic hormone in the anterior pituitary lobe.

The anterior pituitary gland is the motor of sexual function (12, 13, 28). Under the influence of gonadotropin estradiol is produced in the follicular theca cells and this hormone exerts a reciprocal effect on the anterior pituitary function. In 1931 the senior author summarized (18) his investigations as follows:

Estrogenic hormone acts both as a stimulator and an inhibitor of the function of the anterior pituitary lobe with the result that the estrogenic hormone produced in the ovary under the influence of the anterior pituitary has a regulating effect on its producer. The motor of the sexual function is thus regulated by the substance it produces, since small doses of estrogens stimulate while large doses inhibit it.

From the Gynecological and Obstetric Department of the Rothschild Hospital and the Hormone Research Laboratory of the Hebrew University, Jerusalem.

Implantation may be successfully done in the posterior wall of the vagina about 2 centimeters beyond the vaginal orifice. Following infiltration with 0.5 per cent novocain a small incision is made in the mucosa and with the aid of a forceps this is very easily converted into a cavity in the submucosa in which several pellets may be implanted at different sites. Fuller details of the technique may be found in the original paper (27).

Dosage The question of the amount of hormone to be implanted is of decisive importance. If the dose is too small the effect is negligible. If it is too large the resulting stimulation of the uterine mucosa (peripheral effect) has a disturbing influence leading to unpleasant clinical symptoms such as bleeding which will be more fully discussed. The dosage must be independently determined in each case. In cases of secondary amenorrhea we may take as a base line a dose of no more than 30 to 35 milligrams of estrone or estradiol for the first implantation about 25 milligrams for the second implantation which follows after an interval of about 3 to 6 months and the same dose for a third implantation several months later. In primary amenorrhea the initial dose may be 35 to 50 milligrams maximum and implantations of 30 to 40 milligrams may follow.

Preparation of the pellets The pellets were produced as follows: 10 to 25 milligrams of hormone (estrone or estradiol) without the addition of any binding substance were pressed by hand into a brass tube 2.5 millimeters in diameter with the aid of a brass piston. The pellets thus produced had a diameter of 2.5 millimeters and were 1 to 3 millimeters thick. The pellets were sterilized by dry heat for 24 hours at 100 degrees C.

Effect of the pellets The constant resorption of estrogenic hormone from the pellets provides the body with a protracted hormonal stimulus which has the following effects:

Central effect i.e. stimulation of the gonadotropic function of the anterior pituitary gland with consecutive production of the ovarian hormones.

Peripheral effects (a) stimulation of uterine growth and of proliferation of the uterine mucosa (b) probable stimulation of the ovary.

Stimulation of the production of gonadotropins in the anterior pituitary lobe (follicle stimulating hormone and luteinizing hormone) leads to the production of sex hormones in the ovary specifically of estradiol in the theca cells and of progesterone in the granulosa cells (central effect). These substances in turn stimulate the uterine mucosa leading to proliferation of and secretion by the mucous membrane thus preparing it for the nidation of the fertilized ovum. Moreover the pellet containing estrogens causes a direct (peripheral) stimulation of the uterus of its vegetative function increased uterine growth as well as of its generative function proliferation of the uterine mucosa. Certain experimental studies suggest that the ovary may also be stimulated by the estrogenic hormone. Pencharz working with infantile hypophysectomized rats implanted diethylstilbestrol and followed this by treatment with chorionic gonadotropin thereby not only inhibiting the atrophy of the ovary but actually obtaining considerable increase in weight with enlargement of the follicles and the corpora lutea. Similar results obtained by other authors (3, 8, 9, 11) suggest the conclusion that the estrogenic hormone renders the ovary sensitive to the influence of hypophyseal gonadotropin. It is quite possible that this effect is implicated in our cases as well and that the restoration of the cycle may perhaps be favored by it in that the central effect of gonadotropic stimulation is combined with the peripheral effect on the ovary leading to further sensitization of the ovary to gonadotropin.

Too strong an induction of the peripheral effect on the uterine mucosa may result in hyperproliferation (glandular cystic hyperplasia) which is sometimes known to provoke bleedings often of a severe nature. We have observed this undesirable by-effect and have several times been obliged to perform curettage in cases of protracted or occasionally of violent bleeding. An attempt should first be made to check the bleeding through the administration of 10 milligrams of progesterone daily for 5 days and only if this proves unsuccessful should curettage be performed. Following curettage the cycle is sometimes spontaneously initiated but in other cases amen-

EXPERIMENTAL STUDIES

Experimental studies of the senior author have demonstrated (22-23) that uninterrupted treatment with large doses of estrogens is capable of inhibiting the function of the anterior pituitary lobe actually affecting certain specific functions one of the most sensitive of which is the gonadotropic function followed in that order by inhibited production of growth hormone. If rats or fowl are treated for several months with estrogens they develop into eunuchoid dwarfs. Body growth is inhibited in such animals by as much as 60 per cent, and the development of ovaries and testes by 95 per cent. Atrophy of the sex glands, absence of follicular maturation and of corpus luteum formation and inhibition of spermatogenesis are all complete. Estrogenic hormone may thus induce partial biological resection of the anterior pituitary, since the gonadotropic function and the production of growth hormone are thereby inhibited, while the other hormonotropic functions are only slightly or not at all affected. Whereas inhibition of the anterior pituitary by means of large doses of estrogens is easy to achieve, experimental stimulation is extremely difficult and may be carried out only with small doses of hormone. It is important that the hormone be constantly absorbed and that it exert a continuous effect on the anterior pituitary, a condition which was found not to be fulfilled when hormone was injected, since in this case over rapid resorption was followed by excessively rapid enzymatic inactivation in the liver (16-17-29-30). Deane and Parkes (1-2) demonstrated that the desired continuous resorption was achieved when hormone pellets were administered as only 1 to 5 per cent was resorbed daily when this method was employed. Stimulation of the anterior pituitary was obtained in rats and rabbits with the aid of the implantation technique (25-26). The production of growth hormone, gonadotropic hormone, lactotropic hormone and in other experiments of thyreotropic hormone were all stimulated thereby. To begin with the last mentioned effect it was thus possible to imitate the human syndrome of Graves disease in laboratory animals. The animals exhibited loss of weight, nervous irritability, increased basal metabolism, typical electrocardiographic

changes and extreme exophthalmos. Furthermore giant animals were produced with enormously enlarged mammary glands, markedly increased milk secretion and ovarian hypertrophy with marked development of luteal tissue. Thus it proved possible through continued exposure to small quantities of estrogenic hormone to stimulate the secretion of various hormonotropic factors of the anterior pituitary lobe.

CLINICAL STUDIES

On the basis of the experimental results, we attempted to stimulate the function of the anterior pituitary lobe by means of uninterrupted action of estrogenic hormone in man as well. Here too after attempts at injection had proved unsatisfactory, the implantation of pellets appeared promising. We then tried the implantation of pellets in the customary manner, subcutaneously or intramuscularly on the upper thigh or on the abdominal wall, but we were dissatisfied with the results thus obtained. The efficacy of this method varied from case to case, probably because the pellets implanted in subcutaneous tissue were readily encapsulated and were thus rendered inactive due to the fibrous growth whose intensity varies in different people. We then demonstrated experimentally that the activity of estrogenic hormone was greatly increased when the hormone was injected near its target organ, i.e. in the vaginal submucosa. The dose of estrone required to elicit estrus by the intravaginal route is only a fifth of the subcutaneous and intramuscular doses required. Therefore we chose the intravaginal pellet implantation (Zondek) which has the following advantages (27).

a. Absorption is much more constant than in the case of subcutaneous implantation, probably because the blood supply of the vagina is superior to that of the subcutaneous tissue.

b. The effective activity of pellets implanted submucosally in the vagina is about 5 times that of pellets implanted subcutaneously.

c. Expulsion of pellets such as sometimes occurs following subcutaneous implantation, is rare.

orrhea recurs necessitating a second implantation. The disagreeable by-effects should not discourage further implantations, since stimulation of the anterior pituitary must be the constant aim. We have arrived at this point of view on the basis of the following observations. Repeated intravaginal implantation was capable of inducing not only uterine growth producing an organ of normal size, but also restoring ovarian function and ultimately pregnancy in women who had been amenorrheic for years and had exhibited symptoms of complete inhibition of ovarian function such as very small, atrophic uterus atrophic mucosa complete absence of estrogenic reaction in vaginal smears, increased secretion of follicle stimulating hormone (110 mouse units or more per litre urine) symptoms of vasomotor insufficiency etc. We have been able in recent years almost completely to avoid the bleedings induced by implantation since we have determined the proper dosage. Bleedings were brought on by the implantation of 50 to 75 milligrams of estradiol doses which we have since rejected as excessive since we now consider 40 milligrams to be the maximal permissible dose.

Success of the treatment. Sixty two women were treated for amenorrhea by intravaginal implantation. The pellets consisted of either estradiol or in most cases of estrone. Seven of the patients suffered from primary amenorrhea i.e. they had never yet menstruated and 55 of them had secondary amenorrhea of 2 to 10 years duration. Of these 62 patients, 52 responded with bleedings and 38 of them reported several cyclic bleedings following a single implantation while 26 had regular bleedings up to 12 months. In 12 cases the cycle was completely established and 8 of these women became pregnant.

Fifty four of the 62 patients were married and since 8 of the patients became pregnant the treatment was entirely successful in 14.8 per cent of the cases. It should indeed, be emphasized that we did not consider any other possible causes of sterility as we were particularly concerned with the initiation of ovarian function and ovulation which is the prerequisite condition for fertilization. Some of our patients may have had occluded tubes or

other causes for sterility so that our 14.8 per cent would represent the minimal number of successful treatments.

In this study we will not describe in detail all of the 62 cases in which patients were treated by intravaginal implantation but only those which culminated in pregnancy.

The following case demonstrates the disadvantages of the method i.e., the marked local stimulation of the uterine mucosa with severe bleeding. It should be noted however that these accessory phenomena have been avoided in recent years, since the dosage has been more carefully worked out. As may be seen in the case history we implanted 50 milligrams of estrone a dose which we would now consider excessive since we do not now exceed doses of 25 to 30 milligrams in cases of secondary amenorrhea. In spite of the bleeding, which is certainly to be regarded as an unpleasant accessory phenomenon we successfully induced ovarian function and reinitiated the cycle in a woman amenorrheic for 6 years.

Case S. S. aged 29 years childless after 9 years of married life was completely amenorrheic for the past 6 years and suffered from symptoms of vasomotor insufficiency. The uterus was atrophic, the mucosa very thin, containing only a few scattered glands in a resting condition. Examination of a vaginal smear revealed estrogenic insufficiency. On March 16 1943 intravaginal implantation of 50 milligrams of estrone was done. Fifty two days later the patient bled for 3 days and a severe bleeding, necessitating curettage followed 23 days thereafter. Strip curettage revealed marked glandular cystic hyperplasia of the mucosa. Amenorrhea returned following the curettage.

A second intravaginal implantation of 50 milligrams of estrone was made in January 1943. After an interval of 4 months, severe bleeding again necessitated curettage. Marked glandular hyperplasia was again observed in the mucosa. However after this curettage menstruations lasting for 4 to 5 days set in at intervals of 28 days, and the patient was completely cured of her 6 years amenorrhea.

PREGNANCIES

In 8 cases implantation induced not only bleedings but regular cycles with ovulation, as demonstrated by the fact that the patients became pregnant. We treated only such patients as appeared to us clinically severe and with unpromising prognosis. All our patients exhibited marked degeneration of the genital organs details of the symptoms are presented

below All had already been unsuccessfully treated for extended periods of time One patient, a 26 year old woman had menstruated only a few times in her life in other words she actually represented a case of primary amenorrhea The 7 others were cases of secondary amenorrhea of between 2 and 5 years duration Sterility had lasted for 3 to 7 years with an average period of 4.6 years. The following are detailed histories of the cases

Primary Amenorrhea

CASE 1 Th G a 26 year old woman childless after 3 years of marriage first menstruated at the age of 15 Slight bleedings followed at intervals of several months for 2 years. Then menstruation ceased. The patient suffered from nervousness sometimes amounting to depression actually brought on by a feeling of sexual inferiority

Examination revealed an atrophic vagina and an extremely infantile uterus with complete atrophy of the uterine mucosa. Total estrogenic deficiency was revealed by vaginal smear and by abnormally high urinary excretion of follicle stimulating hormone (333 mouse units per litre) Basal metabolism was +7 per cent. The case appeared almost hopeless due to the marked atrophy of the genitals Repeated implantation was nevertheless undertaken in the hope that this treatment might induce uterine growth and might perhaps reinitiate ovarian function

January 20, 1941 intravaginal implantation of 50 milligrams of estradiol was done Slight bleeding occurred 43 days thereafter Strip curettage showed that the mucosa had already developed to a certain extent, corresponding approximately to the 12th to the 14th day of the cycle The follicle stimulating hormone titre units per litre of the urine had fallen from 333 to 86 mouse units per litre On May 13, 1941 i.e. 112 days after implantation bleeding again occurred and 4 cyclic bleedings followed at intervals of 28 days. The significant growth of the uterus which now appeared almost normal in size was striking The previously somewhat atrophic breasts were greatly enlarged and painful After ovarian function had continued rhythmically for 4 months with progressive development of the mucosa indicating ovulation (proved by strip curettage) an amenorrhoeic period of 3 months duration followed whereupon an additional intravaginal implantation of 40 milligrams of estradiol was administered Two months later the cycle was reinitiated and 12 regular bleedings occurred. In February 1943 the patient became pregnant and a normal birth followed. The cycle remained normal after the patient gave birth and she became pregnant a second and a third time

In this apparently almost hopeless case repeated implantation had resulted in complete functional success

Secondary Amenorrhea

CASE 2 Ch W a 34 year old woman, childless after 4 years of marriage first menstruated at the age of 16 followed by irregular menstruations at intervals of 4 to 6 months Amenorrhea had been complete for the past 2 years If the bleedings induced by hormone injections are included in the calculation the patient must be considered to have been amenorrhoeic for at least 6 years

The sex organs were markedly underdeveloped the uterus being small and the uterine mucosa very atrophic thin containing only a few glands. The breasts were very underdeveloped Conspicuous symptoms of vasomotor insufficiency were noted such as flushes and attacks of perspiration irritability and insomnia.

September 1, 1941 50 milligrams of estradiol were implanted intravaginally Several weeks later the patient felt a distinct subjective improvement the flushes diminished in severity the nervous irritability subsided and her breasts had developed to a certain extent. The patient noted particularly that the hitherto constant dryness of the vagina during cohabitation no longer persisted Eighty-eight days after implantation a 10 day bleeding period set in (November 27, 1941) and bleedings recurred in December 1941 and in January and February 1942 Since no bleedings occurred in March and April, a second implantation of 30 milligrams was administered Two months later bleeding recurred and the patient became pregnant during the following month Pregnancy and birth were normal

CASE 3 L Z 30 year old woman childless after 6 years of marriage first menstruated at 13 years Menstruation was regular until 2 years previous to examination since when no bleedings had occurred During this period the patient had been suffering from severe nervous symptoms headaches and depressive states.

Examination revealed a somewhat atrophic vagina and no estrogenic activity was revealed by vaginal smear The uterus was very atrophic, with a thin mucosa containing only a few glands in the postmenstrual stage

July 7, 1941 25 milligrams of estradiol were implanted intravaginally but this treatment remained ineffective whereupon a second intravaginal implantation of 50 milligrams of estradiol was carried out on October 24, 1941 In consequence a bleeding was induced which began on January 1, 1942 and became progressively more severe so that curettage became necessary by the end of the third week and a very hyperplastic mucosa was removed at this operation Bleedings recurred in February and March and these were followed by an amenorrhoeic period, necessitating a third intravaginal implantation of 35 milligrams of estradiol in January 1943 Bleeding was re-established in March 1943 and normal menstruations followed for 8 months when in December 1943 the patient became pregnant Birth was normal

(vaginal smear) diminution in size of the uterus atrophy of the uterine mucosa increased excretion of follicle stimulating hormone, and the secondary phenomena of vasomotor insufficiency characteristic of the climacterium.

In a former study (24 31 32) we demonstrated that it is possible to induce bleeding from the atrophic mucosa of amenorrhoeic patients by the injection on 2 successive days of 5 milligrams of estrone and 50 milligrams of progesterone¹. It is also feasible to induce this effect with a single injection when the hormones are administered not in an oily solution but in the form of a precipitation of microcrystals of a specific size (33).

If 3 or 4 bleedings are induced by treatments repeated at intervals of about a month, ovarian function may be restored in a certain number of cases, and rhythmic bleedings ensue. It must therefore be concluded as already pointed out by A. Westman² and G. V. Smith, (10) that the cyclic estrogen-progesterone withdrawal flow plays a physiological role in the cyclic pituitary-ovarian interaction. The present investigation demonstrates that the same effect may also be obtained by continuous stimulation with estrogenic hormone flowing from the pellet reservoir. Apparently the central stimulation of the gonadotropic function of the anterior pituitary lobe combines with the peripheral stimulation of the ovary sensitizing the latter to the influence of pituitary gonadotropin. As a result the central mechanism that of the anterior pituitary as the motor of sexual function appears to be reinitiated.

SUMMARY

1 Estrogen pellets were implanted intravaginally in severe cases of amenorrhea with consequent sterility.

2 Intravaginal implantation possesses the following advantages over subcutaneous administration. (a) The effect is more constant, since the connective tissue enveloping the introduced hormone in the vaginal submucosa

is much less dense than that in the subcutaneous tissue. (b) The effect is about 5 times as intense. (c) The tablets are seldom expelled.

3 The effects of implantation are manifested in improved vascularization of the vagina in changes in the vaginal epithelium (cornified cells) in uterine growth proliferation of the uterine mucosa uterine bleeding and enlargement of the breasts.

4 The average interval between implantation and the onset of bleeding is 78 days.

5 The cycle may be reinitiated by a single intravaginal implantation whereby the amenorrhea is relieved. Alternatively several cyclic bleedings may occur which are again followed by amenorrhea requiring a second implantation after a certain period, or even a third in obstinate cases. A second implantation is also indicated if no bleeding occurs within 3 to 4 months of the initial implantation. The effect of implantation may be estimated by vaginal smear and by the examination of the uterine mucosa obtained by a diagnostic strip curettage.

6 The dosage, which must vary with the severity of the clinical symptoms, is of paramount importance. Doses may range between 25 and 50 milligrams of estrone or estradiol. Doses higher than 50 milligrams are not to be administered.

7 An unwelcome accessory effect sometimes associated with our treatment is an excessively intense peripheral reaction involving glandular cystic hyperplasia of the uterine mucosa, sometimes accompanied by severe bleeding requiring treatment with progesterone or if necessary with curettage. This accessory effect should not discourage a repetition of implantation employing a smaller dose should amenorrhea reappear. Moreover excessive bleeding may be avoided if not more than 30 to 40 milligrams of estrogen be implanted.

8 Mechanism of the effect. Estrogenic hormone leads to central stimulation of the anterior pituitary lobe whereby the secretion of gonadotropin is induced. Furthermore, a peripheral effect on the ovary is probably also induced rendering the ovary more sensitive to the influence of gonadotropin.

9. We have carried out intravaginal implantation in 54 married women suffering from

¹The interval between hormone inoculation and bleeding consists of 1 to 3 days following the day administration of only solutions of hormones, and of 1 to 3 days following the administration of one injection of hormone microcrystals.

²Acta Obst. gyna. scand., 1935, 5.

amenorrhea of many years duration accompanied by severe secondary changes of the genital organs. Bleeding was induced in 84 per cent of the amenorrheic patients. In 8 of the treated cases (14.8 per cent) not only was the amenorrhea cured but pregnancy actually ensued. Since other possible factors leading to sterility were not taken into account as the amenorrhea was the condition most obviously requiring treatment it may be that the percentage of successful treatments of sterility ought to be estimated at a higher figure. For implantation only such cases were selected which were prognostically unpromising and which had previously been under other types of treatment for years without any success. It is worthy of note that 1 of our patients who had menstruated only a few times in her life and whose genital organs were as undeveloped as before puberty responded to our treatment with complete initiation of genital function culminating in pregnancy.

INTRAEPITHELIAL CARCINOMA (IN SITU) OF THE CERVIX UTERI

IN the absence of complete and specific knowledge of the cause of cancer we obviously cannot prevent its occurrence to any great degree. The second best thing that we can do is to recognize it in its incipency and perfect our therapy at that early stage. Cancer of the cervix uteri is the malignancy which occurs most frequently in the female pelvis. It is second only to breast carcinoma in frequency of malignancy in women. Hence any decisive blow that can be taken at it will materially reduce the death rate of women from cancer. Since the cervix is essentially a surface organ it lends itself readily to inspection and biopsy. Thus cervical cancer is an ideal lesion for early detection.

In 1912 Schottländer and Kermauner described cellular changes in the surface epithelium about the periphery of invasive cervical cancer that were identical to the cellular changes in the depth of invasive cancer. They

believed that invasive cancer sometimes spread on the surface in this manner. It remained for Schiller who began his studies in the twenties and continued them into the thirties to conceive the idea that true cervical cancer might begin as a surface lesion and remain such for a considerable period before entering the invasive stage. To substantiate his belief that these surface lesions were actually cancer Schiller presented histological evidence that was suggestive if not conclusive. He also published clinical facts which supported his views such as one recurrence after five years and two recurrences in less than five years after hysterectomy. At the present time there are approximately twenty cases in the literature in which death resulted after treatment of an apparent intraepithelial carcinoma or in which patients presented themselves with advanced cervical cancer several years after a recorded biopsy which showed carcinoma in situ. In some instances a period of as long as twelve years had elapsed between the time the biopsy was taken and clinical cancer appeared. Among these cases are those of Stevenson and Sciplades, Pund, Smith and Pemberton, Schnitz and Benjamin, Knight, Young, Taylor and Guyer, Scheffey, Galvin and Te Linde.

The last two authors have made a prolonged and intensive study to prove histologically the relationship between carcinoma in situ and invasive cervical cancer. All cervixes which had shown noninvasive cancer on biopsy and which were subsequently removed were cut into blocks and many sections made from each block of tissue. Of a total of 75 cases they were able to demonstrate invasive cancer histologically in 35. In 10 cases more intraepithelial

cancer was found in the removed cervix and in the remaining 10 no abnormality was found in the entire cervix, indicating that either all the carcinoma in situ was removed at biopsy or that further carcinoma was missed in spite of the many sections. From these studies and from clinical data it would seem that the term intraepithelial cancer or carcinoma in situ should be used to indicate a microscopic picture and that such a microscopic picture found in a biopsy may indicate three possible clinical conditions: (1) a gross invasive cancer the periphery of which was biopsied. This is the condition originally described by Schottländer and Kermauner; (2) a cervix in which subclinical but microscopic invasive cancer exists; (3) a cervix in which the neoplasm is still strictly intraepithelial.

Hence in each instance in which the pathological report of carcinoma in situ is made the woman should be examined gynecologically and the gross findings correlated with the microscopic evidence. It is only in this way that a proper decision regarding therapy can be made.

It is interesting that in Pund's cases of intraepithelial cancer the average age was 36.6 years and in Galvin and Te Linde's group 37.1 years. Since the average age of patients with cancer of the cervix in its clinical form is 48 years it would appear that the noninvasive form of the disease may exist for many years before becoming grossly invasive and clinically apparent. This is simply another way of saying that the symptomatic life of a cervical cancer is a relatively short part of its entire existence.

Since the subject of carcinoma in situ and the cytological diagnosis of cervical cancer have come to the attention of the profession more or less simultaneously the relation of one to the other should be given serious consideration. Although the available data regarding

the value of smears in detecting carcinoma in situ are relatively meager compared with the biopsy data sufficient have been accumulated to indicate that many preinvasive carcinomas may be discovered by the study of cytology smears. The relatively or absolutely normal appearance of the cervix may make the taking of biopsies rather difficult. The smear technique does not present this difficulty. Since histological studies have shown that practically all intraepithelial cancers start at the columnar stratified junction biopsies should be taken there as well as from any isolated suspicious areas. However smears may be incorrectly taken as well as biopsies. A smear made by the blind introduction of a swab into the vagina is more apt to lead to a false negative report than a smear taken directly from the cervix. When one considers that the percentage of false negative reports for smears in the presence of gross cervical cancer is in the neighborhood of 10 per cent the greater likelihood of a false negative in the presence of the small nonulcerating noninvasive cancer becomes apparent. Two points should be emphasized in relation to cytology: (1) a positive smear should always be confirmed by biopsy before beginning treatment for cancer; (2) one should never rest assured that cancer is not present on the basis of a negative smear if the cervix looks at all suspicious. Biopsy examination of such a cervix should be done and should be repeated if necessary before one can be satisfied that no cancer is present.

Concerning the treatment of carcinoma in situ there is rather general agreement that total abdominal hysterectomy should be done. Galvin and Te Linde have reported that 67 patients operated upon from 8 years to 6 months before the report were living and free from evidence of cancer. The operation which they performed was called a 'modified Wer

them. It consists of removal of the uterus with a centimeter or two of parametrium and a wide vaginal cuff. Lymph gland resection is not done, thus greatly reducing the magnitude of the operation. In the younger individuals an ovary was frequently spared and there were no recurrences among these patients. The authors stress the point that they do not advocate this modified Wertheim operation for clinical cervical cancer. There is little doubt that the percentage of cures of carcinoma in situ with irradiation would be high, but it is interesting that Galvin and Te Linde report one death among 8 patients treated by irradiation. This woman died in six months and autopsy showed metastatic cancer.

Our present knowledge of intraepithelial cancer based on sound clinical and pathological observations indicates that cervical cancer can be diagnosed at that stage and that the disease is then curable. An opportunity is thus offered to eradicate this serious and relatively frequent disease by the education of the public as to the value of periodic examinations and by the education of doctors to make the examinations which are necessary for the establishment of the diagnosis.

RICHARD W. TE LINDE

THE USE OF METHIONINE IN OBSTETRICS

ANIMAL experimentation has shown that nephrosis in combination with wide spread liver damage may be caused by severe dietary restrictions. These manifestations were demonstrated to be similar to those found in patients who died due to conditions which produced the clinical picture of the so called hepatorenal syndrome. Certain agents such as chloroform or phosphorus caused marked liver necrosis but this de-

struction was contingent on the fact that protein-deficient diet played the predisposing role. Furthermore experimental work showed that the nutritional necrosis which was found in the liver of these animals had some similarity to the pathological changes of the liver in eclamptic patients. Investigators proved that these conditions in animals could be prevented by the administration of choline plus cystine or by the use of methionine.

Hypoproteïnism is a common finding in these conditions. This protein depletion may be the common factor which renders the liver and kidneys more susceptible to hepatotoxic agents. Glycogen has been established as a protective agent to the liver and kidney but it is only recently that protein has been proved to play an important role in the protection of all tissues of the body. In fact, it is possible for normal liver and kidney function to be maintained only if there is adequate protein intake.

When protein depletion does occur correction to the proper levels may be facilitated by the intravenous administration of plasma, protein hydrolysates, or by the use of methionine. It is estimated that approximately three grams of methionine is the normal daily intake for an adult. Due to the fact that methionine is an essential amino acid it is not synthesized in the body but must be provided from foods or be given as a supplement to the diet.

Experimental work has shown methionine to be lipotropic in its action. In spite of low protein intake, the administration of this substance prevents fatty infiltration of the liver even in the presence of toxic agents such as phosphorus, carbon tetrachloride or chloroform anesthetics.

It should be realized that experiments in animals do not always coincide with clinical results found in the human but definite clinical

cal evidence demonstrates that some acute degenerative lesions of vital organs are affected beneficially by the administration of methionine. Recent investigators state that wound healing has been stimulated by its use. In addition administration of this drug has played a part in prevention of wound disruption in some protein-depleted individuals. Opinions have been expressed both for and against the use of methionine in chronic cirrhotic lesions of the liver and its value in this regard must be studied further.

Certain obstetrical patients develop complications which cause widespread liver and kidney damage. These conditions have many features relative to protein metabolism and the use of methionine which should be studied. In two recent publications¹ four obstetrical complications which were investigated in this regard were discussed. In patients who showed predisposition to liver damage methionine was given as a supplement to the diet or it was administered intravenously when the patients were too ill to receive it orally. Obstetrical patients suffering from the following complications were treated: patients with severe toxemia with acute infectious jaundice with hepatorenal syndrome following surgical shock and rhesus factor iso-immunized women.

Beneficial results were obtained by the use of methionine in severe pre-eclamptic and eclamptic patients. The improvement was manifested by estimations of liver function chiefly by means of the cephalin cholesterol test. Clinical improvement was evident by a striking increase in urinary output which was accompanied by diminishing edema in the majority of cases. There was no improvement in those patients who had true chronic nephritis.

Methionine and choline were given to pregnant women with acute infectious jaundice. There was no claim made that this procedure would shorten the disease as it had been demonstrated previously that immediate improvement did not occur with this treatment. However it was given with the surmise that subsequent cirrhotic changes might be prevented. The reported cases are too few and the length of study too brief to permit any conclusions.

Interesting results were obtained in cases of the hepatorenal syndrome which followed surgical or obstetrical shock. All these individuals showed persistent hypotension, anuria, coma and increasing jaundice. Liver tests denoted impaired liver function in every case. In addition to plasma and whole blood transfusions intravenous methionine was given apparently with good results.

In the last group of cases there was hemolytic disease of the newborn due to rhesus factor iso-immunization. These cases showed a most convincing effect of methionine as a hepatic protective. Studies were made of pregnant women who showed definite elevation in antibody titrations. Women with the higher antibody levels were placed on methionine every day throughout the remainder of the pregnancy. The remaining cases were used as controls; these patients did not receive the drug but treatment otherwise was identical.

The rationale in giving methionine to the mothers was that if methionine was given in sufficient quantity a good portion would cross the placental barrier into the fetal circulation. Thus it would have a possible protective action on the fetal liver. It was not claimed that methionine could prevent hemolysis of blood but it was given in an attempt to protect the fetal liver which is frequently damaged in this disease. These workers state that it is not

¹MacArthur J. L. *Am. J. Obst. Gyn.* 94:3, 5, 382. Phillips
W. *Am. J. Obst. Gyn.*, 94: 57, 1, 3.

difficult to treat anemia but it is almost impossible to have a baby who is born with a severely damaged liver remain alive and well. The procedure used was to give methionine to the immunized pregnant women throughout the pregnancy. The babies were given smaller doses for the first twelve days of life. Liver function tests which were made on fetal blood showed far less damage when methionine was used. The fetal survival rate also was much improved.

Results have been promising but not conclusive. In the treatment of toxemia and hemolytic disease of the newborn methionine is a valuable adjunct to other proved types of therapy. The hepatorenal syndrome, which occasionally follows surgical or obstetrical shock, can be treated most efficiently by the combined administration of plasma, whole blood and intravenous methionine. The problem merits further study.

NEWELL W. PHILLIPS

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

IN the volume *Surgical Pathology*¹ the author's aim is to develop a text which may serve as a useful source of information for those general surgeons or members of their allied fields by which they may have ready access to the fundamentals of pathology for active use or for preparation in the various board examinations.

The material has been carefully selected condensed, and presented without redundant verbiage. The theoretical receives little attention. Debatable subjects are discussed briefly and succinctly. There is a definite objective trend at all times. The writer describes the pathologic changes of each entity differently from other entities gives its incidence, quickly incorporates adequate clinical data and avoids prolonged discourse as to why it developed. He is more interested in the end result than in the proper book on pathology than a distribe about questionable unproved etiologic agents.

The format is simple. Without hesitation he begins by discussing the skin and ends with the bones and the joints in other words he starts on the out summary of embryology anatomy and histology. This reacquaints the reader with ideas which may have become dulled during the passing years.

Although the rare lesions are discussed, the greater amount of space is allotted to the anatomic changes seen most frequently. Both the gross and the microscopic descriptions are complete. Where indicated, there is clinical correlation. The photographs in black and white, are well selected and appropriate. Further they are representative of the various lesions.

The print is clear and the paper smooth. There is no glare as one reads. By means of various shades and forms of type little space is lost in paragraphing and still the various divisions and sections are accentuated.

Emphasis in the bibliography is on the more recent articles and texts of the English speaking countries. In general there is an extensive amount of information provided by a writer who has had a wide experience in pathology as seen in the operating room.

This reviewer has only one suggestion to include a section on neuropathology despite the reason for deisiting as given in the preface

¹*SURGICAL PATHOLOGY*. By Peter Herbst, M.D. Philadelphia: Lea & Febiger, 1948.

The book may be recommended without reservation
M. C. WHITLOCK.

AN English translation of *Patologia da gestacao* by Raul Briquez² would be welcome. It is a thoroughly modern treatise on pathologic conditions associated with gestation. It differs from most books by presenting practically entirely current opinions and tenets. A glance at the bibliography impresses one with this fact. Seldom is there a work referred to dated before 1930 and references in the early forties are the general rule.

It is a synopsis of diseases of pregnancy written succinctly, clearly, understandably. Its scope is complete and no subject of importance is left unconsidered. The illustrations are good, well chosen and technically the book is well done. As far as this reviewer knows there is not a similar work in the English language.

The contents may be divided into four sections. In the preliminary chapters are considerations of the migration of the ovum, nidation, hormones, allergies and avitaminoses. Subjects not specifically pathologic states of pregnancy are then discussed. Various diseases, 19 in all, are given a chapter each. The more prominent are pulmonary tuberculosis, syphilis, chronic autointoxication, acidosis, allmentation liver, kidney blood and heart diseases, thropathies, lower genital tract infections and trauma during gestation.

The specific pathologic states of gestation are treated under such headings as intractable vomiting, hypertension, and eclampsia. The remaining chapters deal with pathologic conditions directly or indirectly associated with the ovum such as faulty implantation, abortion, intrauterine death, hydatiform mole, and chorioepithelioma. There is appended a chapter on sterilization.

Anyone interested in reviewing pathology of pregnancy will find in this text a complete coverage of the subject set down with a modern touch.

STEPHEN A. ZIEMAN

IN the book *The Clinical Management of Varicose Veins*³ the author has stressed the important factors in the clinical management and treatment of varicose veins. He agrees with most authorities that

²*PATOLOGIA DA GESTACAO*. By Raul Briquez. Sao Paulo: Editora Remanencia, S. A., 1948.
³*THE CLINICAL MANAGEMENT OF VARICOSE VEINS*. By David Woodfolk Barrow, M.D. With foreword by Arthur W. Allen, M.D. New York: Paul B. Hoeber Inc., 1948.

varicose veins represent a degenerative condition and that the patient will have more varicose veins as time goes on regardless of what method of treatment is used.

The author has discussed very well the subjects of anatomy, physiology and pathology. Under symptomatology he has discussed in detail the subject of carbon dioxide concentration in the tissues and the association of stasis and edema with the various complications that develop in the lower leg.

In the chapter on examination of the patient he has stressed the importance of the communicating veins. He attributes his good results to careful attention to the communicating veins, and prefers to treat all extensive cases by ligation and stripping and at times with retrograde injection of the sclerosing solution. A high saphenofemoral ligation is followed by thorough stripping and subsequent injection of the remaining vein.

Under Complications he expresses the opinion that most complications associated with varicose veins are due to the congestive factor and to the accumulation of toxic products in the tissues. Treatment is directed toward the elimination of this congestive stasis and edema. To accomplish it he carries out a careful ligation of all the perforating veins. Injection of the remaining vein which persist and supportive treatment of the extremity.

Although thrombophlebitis is not discussed as fully as the condition might warrant this volume can be recommended to any surgeon who treats and who is studying the problem of varicose veins.

H. O. McPHERSON

THE T. Book of Genito-Urinary Surgery by Winsbury White is the most important system of urology since Cabot's *Modern Urology* the last edition of which appeared in 1936. It is an up-to-date book written by leading British urologists. Chapters have been written by such men as Swift, Joly, Terence Millin, Clifford Morson, Jocelyn Swan and numerous other similarly well known urologic surgeons. Winsbury White himself has also contributed a number of chapters. The book is complete and suitable not only for the student or part time urologist, but also for the trained full time urologic surgeon. The chapters on transurethral resection describe the different instruments, the technique of their use and the results obtained with different methods. Complete chapters are also devoted to the different types of open prostatectomy including an up-to-the-year discussion by McMillin on his retro-pubic operation and a discussion on perineal prostatectomy by Winsbury White. Data on the sulfonamides and antibiotics which are complete and detailed, are not confined to a single chapter, but are spread through the book and discussed in relation to various different pathologic conditions and surgical procedures.

TEXTBOOK OF GENITO-URINARY SURGERY Edited by H. P. Winsbury White, M.B., Ch.B., F.R.C.S. (Edin.), F.R.C.S. (Eng.). Baltimore: The Williams & Wilkins Co., 1944.

A number of important, commonly occurring but rarely described, conditions are discussed thoroughly. The chapter on cystitis and associated lesions of the bladder neck is of great value and the discussion and description of bladder neck polyps and enlarged urethral glands are exceptionally clear cut and instructive. There are numerous illustrations, many in color and all good depicting surgical technique and pathologic specimens. The clarity and detail of many of the colored drawings of pathologic conditions as seen through the cystoscope are reminiscent of those seen in earlier German urologic texts.

Due to the multiplicity of subjects many conditions and procedures are necessarily dealt with rather briefly, occasionally inadequately. The book is printed with clear type on good paper and is very readable but it is bulky, difficult to handle and would fit the resting doctor's hand and tilted chair more conveniently if divided into two volumes.

The book is excellent and every urologic surgeon should have it in his library as a source of review and reference text.

A. J. SCHWARTZ

One cannot refrain from expressing a word of admiration on the appearance of a beautiful atlas of anatomy² coming from a country that was for so long a time under the shadow of war and devastating enemy occupation. The volume includes 512 illustrations, many of them full page and some in color depicting the osteology, the articulation and the musculature of the human body. There is no descriptive text but each illustration is carefully labelled in accordance with B.N.A. nomenclature to permit accurate and quick recognition of the structure shown.

An interesting innovation is the author's method of indicating muscle position and attachment by showing the muscles in colored diagram overlying the bony structure underneath in black and white.

This volume *Atlas of Human Anatomy* by M. W. Woerdeman should prove exceedingly helpful both to the medical student working in the dissecting room and to the surgeon refreshing his memory on the details of the operative field he is planning to explore.

SCOTT L. KOCK

THE annual publication of the Association for Research in Nervous and Mental Disease, the 27th in the series, represents the proceedings of the Association of the December 1947 meeting. Unquestionably this rich volume *The Frontal Lobes* has a front rank position among the other distinguished Research publications of this association.

The book is divided into four sections: biology of the frontal lobes, experimental studies, clinical studies and frontal lobotomy. In each of these

ATLAS OF HUMAN ANATOMY, DESCRIBED AND REPRODUCED by M. W. Woerdeman, M.D., F.R.N.A.S., Vol. 1. Baltimore: The Williams & Wilkins Co., 1944.

THE FRONTAL LOBES Edited by John F. Talbot, M.D., Charles D. Aring, M.D., and E. Bernard Warrick, M.D. Proceedings of the Association for Research in Nervous and Mental Disease, Vol. 27. Baltimore: The Williams & Wilkins Co., 1948.

parts the subjects are treated authoritatively by an imposing list of authors whose names represent the top flight laboratory and clinical investigators in neurology in this country at the present time. It is reassuring to know that on the basis of such solid information a rational and safe approach to the clinical problem of the treatment of the psychoses and intractable pain is possible. Regardless of what ever personal feeling the reader may have toward such surgical attack upon the frontal lobes at least he cannot say that the advocates of such treatment are forcing ahead without sufficient fundamental knowledge of the anatomical physiological psychological properties of the frontal lobes. The presentation of the material in this book is therefore the most timely.

The book is well printed solidly bound well illustrated readable for all the weight of the subject matter and as usual in these publications is supplemented by an extensive cumulative bibliography.

JOHN MARTIN

THE well printed and beautifully illustrated small volume *The Modern Management of Gastric and Duodenal Ulcer*¹ edited by Deller is designed to present to general practitioners physicians and surgeons an account of the modern trends in diagnosis and treatment of gastric and duodenal ulcer. In addition to the principal author there are five co-authors and as is to be expected in a book of multiple authorship this volume is decidedly uneven in quality. The chapters on the applied anatomy and physiology of the stomach and on the pathogenesis of gastric and duodenal ulcer are entirely inadequate and suggest that the authors of these sections are unaware of the large amount of experimental work that has been done in these fields during the past 25 years. While the discussion of the clinical picture of the disease is good the attempt to explain the cause of ulcer pain reveals that the author of this section is unaware of the extensive studies of W. L. Palmer and of Bonney and Pickering. The section on special investigations and radiology is good and the illustrations are uniformly excellent. By far the best parts of the little book are the sections dealing with surgical therapy. These alone make the volume a valuable addition to the library of both the internist and the surgeon. An excellent description is provided of those surgical procedures that have won a place in the treatment of this disease in the best hospitals and clinics of the world. There is also a good description and discussion of vagotomy and its place in the treatment of duodenal ulcer. The authors point out that whereas the results so far obtained by this newer method of treatment have been almost uniformly good the period of observation is still too short to permit a final conclusion with respect to its ultimate place.

LESTER R. DRAGSTEDT

¹THE MODERN MANAGEMENT OF GASTRIC AND DUODENAL ULCER. Edited by I. Croxon Deller, M.D. M.R.C.P. Baltimore: The Williams and Wilkins Co., 1948.

THE enlarged and revised edition of Bunnell² reflects the progress made in the treatment of wounds and injuries of the hand during the war years and the greatly increased interest that has been aroused in this field of surgery in military and civilian centers. In both of these movements Dr. Bunnell has played a leading and stimulating role and the entire surgical profession is indebted to him for his contributions to the surgery of the hand and his tireless efforts to work out improved methods of surgical treatment and to make them more widely known.

Many of the men working in military hospitals under Dr. Bunnell's guidance as consulting surgeon have contributed case reports and illustrations to this new edition. In Chapter 5 on Skin and Flexion Contractures Chapter 6 on Bones Chapter 7 on Joints Chapter 10 on Intrinsic Muscles of the Hand and Loss of the Thumb and Chapter 12 on Injuries of the Hand particularly are many new diagrams and illustrations some in color which graphically present the problems involved the various methods of treatment advised and the results that have been accomplished.

In Chapter 5 methods of employing the skin of a functionless finger the tubed flap—at times with utilization of the same flap for the repair of different and separate defects and the broad apron flap from the abdominal wall are illustrated with numerous excellent photographs many of them generously credited to the men who were carrying out these procedures in widely separated military hospitals. The importance of adequate excision of scar, of wide separation of digits and avoidance of binding scars at the webs are repeatedly emphasized both in the application of pedunculated flaps and of free grafts.

Chapter 6 on Bones has been enlarged from 12 to 36 pages. A number of methods of restoring the bony framework injured by accident or as a result of gunshot wounds are described with the aid of diagrams photographs and x-ray films. These methods include the use of cancellous and cortical bone grafts substitution of a metatarsal for a metacarpal bone shifting of an uninjured metacarpal to replace an adjacent bone and the use of multiple metal pins or Kirschner wires to help provide fixation and immobilization. Iliac bone rib grafts tibial grafts have all been used successfully and a number of ingenious methods for employing them to advantage are indicated in diagrammatic sketches.

Chapter 10 on Intrinsic Muscles of the Hand and Loss of the Thumb has also been enlarged by 30 pages and a number of complicated problems are discussed with well illustrated examples. Fowler's method of repair of injured extensor tendons, methods of securing abduction of the index finger following loss or injury of the first dorsal interosseus of securing flexion of the proximal phalanges in patients with ulnar and median palsy and of securing rotation and adduction of the thumb are considered at length.

²SURGERY OF THE HAND. By Sterling Bunnell, M.D. 2d ed. Philadelphia, London and Montreal J. B. Lippincott Co. 1948.

varicose veins represent a degenerative condition and that the patient will have more varicose veins as time goes on regardless of what method of treatment is used.

The author has discussed very well the subjects of anatomy physiology and pathology. Under symptomatology he has discussed in detail the subject of carbon dioxide concentration in the tissues and the association of stasis and edema with the various complications that develop in the lower leg.

In the chapter on examination of the patient he has stressed the importance of the communicating veins. He attributes his good results to careful attention to the communicating veins and prefers to treat all extensive cases by ligation and stripping and at times with retrograde injection of the sclerosing solution. A high saphenofemoral ligation is followed by thorough stripping and subsequent injection of the remaining veins.

Under Complications he expresses the opinion that most complications associated with varicose veins are due to the congestive factor and to the accumulation of toxic products in the tissues. Treatment is directed toward the elimination of this congestive stasis and edema. To accomplish it he carries out a careful ligation of all the perforating veins injection of the remaining veins which persist and supportive treatment of the extremity.

Although thrombophlebitis is not discussed as fully as the condition might warrant this volume can be recommended to any surgeon who treats and who is studying the problem of varicose veins.

THE MODERN MANAGEMENT OF GASTRIC AND DUODENAL ULCER. Edited by F. Croxon Deller, M.D. M.R.C.P. Baltimore: The Williams and Wilkins Co., 1948.

THE enlarged and revised edition of Bunnell's² splendid contribution on the surgery of the hand reflects the progress made in the treatment of wounds and injuries of the hand during the war years and the greatly increased interest that has been aroused in this field of surgery in military and civilian centers. In both of these movements Dr. Bunnell has played a leading and stimulating role and the entire surgical profession is indebted to him for his contributions to the surgery of the hand and his tireless efforts to work out improved methods of surgical treatment and to make them more widely known.

Many of the men working in military hospitals under Dr. Bunnell's guidance as consulting surgeon have contributed case reports and illustrations to this new edition. In Chapter 5 on Skin and Flexion Contractures Chapter 6 on Bones Chapter 7 on Joints Chapter 10 on Intrinsic Muscles of the Hand and Loss of the Thumb and Chapter 12 on Injuries of the Hand particularly are many new diagrams and illustrations some in color which illustrate graphically the problems involved the various methods of treatment advised and the results that have been accomplished.

In Chapter 5 methods of employing the skin of a functionless finger the tubed flap—at times with utilization of the same flap for the repair of different and separate defects and the broad apron flap from the abdominal wall are illustrated with numerous excellent photographs many of them generously credited to the men who were carrying out these procedures in widely separated military hospitals. The importance of adequate excision of scar, of wide separation of digits and avoidance of binding scars at the webs are repeatedly emphasized both in the application of pedunculated flaps and of free grafts.

Chapter 6 on Bones has been enlarged from 12 to 36 pages. A number of methods of restoring the bony framework injured by accident or as a result of gunshot wounds are described with the aid of diagrams photographs and x ray films. These methods include the use of cancellous and cortical bone grafts substitution of a metatarsal for a metacarpal bone shifting of an uninjured metacarpal to replace an adjacent bone and the use of multiple metal pins or Kirschner wires to help provide fixation and immobilization. Iliac bone rib grafts tibial grafts have all been used successfully and a number of ingenious methods for employing them to advantage are indicated in diagrammatic sketches.

Chapter 10 on Intrinsic Muscles of the Hand and Loss of the Thumb has also been enlarged by 30 pages and a number of complicated problems are discussed with well illustrated examples. Fowler's method of repair of injured extensor tendons, methods of securing abduction of the index finger following loss or injury of the first dorsal interosseus of securing flexion of the proximal phalanges in patients with ulnar and median palsy and of securing rotation and adduction of the thumb are considered at length.

²SURGERY OF THE HAND. By Sterling Bunnell, M.D. 3d ed. Philadelphia, London and Montreal: J. H. Lippincott, Co. 1948.

and with clear, well conceived diagrams of operative procedures and numerous illustrations of the results obtained. A considerable amount of new material has also been added on methods of providing a substitute for the lost thumb.

The first edition of Bunnell's *Surgery of the Hand* was an outstanding contribution to surgical literature. In the second edition the author has added new material and new concepts of repairing the injured hand that should lead to definite improvement and still greater interest in the surgical management of injured hands. The entire surgical profession is indebted to him for this comprehensive study of a important and often neglected field of surgery.

SEYMOUR L. KOCHE.

THE book *Practical Bacteriology Hematology and Parasitology* needs no introduction to laboratory workers and physicians as its usefulness has been well demonstrated by its revisions since its first appearance in 1900. Each new edition has allotted more space to the interpretation and diagnostic significance of various laboratory procedures. The greatest emphasis has been placed on bacteriology, hematology and parasitology as the title indicates, however all types of laboratory work are included.

Part 1 the section on bacteriology has been almost entirely rewritten and brought up to date by Dr. Branham who replaces Dr. Mildred Clark Clough as coeditor. It is impossible to list all the additions but a few may be mentioned such as newer laboratory methods of diagnosing diseases due to Rickettsia, filterable viruses and fungi. The chapter on mycology is well illustrated and includes a section on antibiotics. The methods of assay of penicillin in blood and the determination of the sensitivity of the organism to penicillin are given in the chapter on staining methods and special procedures.

Part 2 the section on hematology has been revised less extensively than the others. Methods for the determination of prothrombin and the Rh-Hr factors have been added, as well as the significance of the Rh factor in erythroblastosis fetalis.

Part 3 the section on parasitology has been rewritten and a great deal of new material added, including new work on malaria, schistosomiasis, filariasis, DDT and arthropod transmission of disease. There are many new illustrations especially good are those giving the life cycle of the various parasites.

Part 4, entitled *Clinical and Pathological Examination of Body Fluids and Organs*, covers a large number of subjects in relatively small space. It includes methods for the examination of urine, feces, sputum, gastric contents, cerebrospinal fluid, and the chemical examination of blood. Chapter 44 of this section on vitamins as specific food factors has a brief bibliography appended. The last section

of the appendix lists, according to diseases, laboratory procedures useful in their diagnosis.

The editors, as well as the many contributors to this book are to be congratulated on keeping this edition up to the high standards of the previous ones. This book for the many years of its existence has been a constant source of information to laboratory workers. It contains material not available in other textbooks. This edition is full of the latest work on subjects vital to the diagnosis of disease by laboratory methods.

OWEN E. HENRIK.

THE book *Preoperative and Postoperative Care of the Surgical Patient* by Hugh C. Ilgenritz has covered rather thoroughly the major developments of the war and of the past decade which have contributed most to the pronounced reduction in mortality and morbidity in surgical patients. The importance of the proper attention to nutrition, fluid and electrolyte balance and whole blood requirements before, during, and after surgery has been stressed throughout the book.

Chapters on fluid and electrolyte balance, and metabolism and nutrition constitute a concise but informative review of these important subjects.

Shock and blood transfusion are considered in separate chapters. While most of the theories as to the etiology of shock are discussed, evidence that whole blood loss is the prime etiological factor and that whole blood replacement is the chief weapon in combating shock is emphasized. Plasma and plasma substitutes are discussed and their limitations as blood substitutes are well outlined.

Sedative medications and choice of anesthetic agent are discussed in one chapter. There are chapters on general preoperative and postoperative measures.

Other chapters deal with systemic complicating factors, organic diseases, chemotherapeutic and antibiotic drugs, major and minor postoperative complications, intestinal obstruction and peritonitis, care of the wound, and burns. The latter third of the book is devoted to preoperative and postoperative care in surgery of the chest, the stomach, the small intestine and appendix, the large bowel, the biliary tract, the thyroid, the extremity and the female pelvis.

In his presentation of all these subjects the author has not limited himself to the discussion of one recommended procedure. Different methods of management are evaluated. All sides of controversial issues are presented.

Considerable attention has been given to detail, essential in the preoperative and postoperative care of surgical patients. Essential laboratory tests are described, so that with the necessary material available these tests can be performed without other reference data.

PREOPERATIVE AND POSTOPERATIVE CARE OF SURGICAL PATIENTS. By Hugh C. Ilgenritz, A.B., M.D., F.A.C.S. St. Louis: The C. V. Mosby Co., 1948.

PRACTICAL BACTERIOLOGY, HEMATOLOGY, AND PARASITOLOGY. By E. R. Sikt, M.D., Ph.D., Sc.D., LL.D., Paul W. Clough, M.D., Sara E. Branham, M.D., Ph.D., Sc.D., and contributors. 10th ed. Philadelphia: The Blakiston Co., 1948.

There is little in the book which might be criticized. Cardiorespiratory embarrassment, pentoneal contamination, and sepsis are not discussed as etiological factors in shock. Perhaps not enough consideration has been given to the management of the patient who develops anuria following blood transfusion reaction, crush syndrome, and traumatic shock. The exceeding importance of limiting fluids once the anuria is known to exist, so as not to overload the circulation is not mentioned. The discussion of gas gangrene does not include diagnostic criteria for the differentiation of true gas gangrene or clostridial myositis from anaerobic cellulitis which were outlined by MacLennan, and later by Jergesen and Simeone.

These minor criticisms do not detract from the general worth of the book as a reference text on pre-operative and postoperative care. The author has told not only what to do, but how to do it and why it should be done. The book can be recommended for interns, residents and all practicing surgeons.

HOWARD E. SNYDER.

THE book *Successful Marriage*¹ is a symposium of discussions dealing with every aspect of modern marriage. The 515 page book is written by a panel of physicians, sociologists and psychologists, each an expert in his field. Dr. Fishbein and Dr. Burgess have carefully correlated the material to present an outstanding treatise on marital relationships of today. While the book is written primarily for the layman, the physician who may be called upon to act as a marriage counselor will do well to familiarize himself with its contents and recommend it as authoritative reading to those who consult him about marital problems.

The book is divided into 5 parts. Part 1, entitled "Preparation for Marriage," consists of 6 chapters encompassing important advice such as the determination of true love and the wise choice of a mate. A thorough understanding of these subjects before marriage is indeed vital to marital success.

Part 2, "The Marriage," is concerned chiefly with anatomical, physiological and psychological factors in marital adjustment not generally available to the newlywed. Sexual technique and adjustment is frankly discussed and easily comprehended. A chapter on home management and finance is filled with excellent suggestions. The discourse on marital maladjustments due to psychological factors should be of great value to perplexed marital partners. It stresses the importance of seeking psychiatric advice as soon as such advice is needed and at a time when a remedy will be most easily effected. The inclusion here of an excellent chapter on miscarriage and abortion seems to be incongruous, for it belongs more correctly with the subject following.

Part 3, "Conception, Pregnancy and Childbirth," deals with heredity, facts on pregnancy mechanism

of childbirth, and economic problems attendant on parenthood. There is an excellent chapter on factors favoring fertility and the basal temperature graph as an aid to conception. Contraceptive methods are also discussed.

Part 4, "The Child and the Family," includes 9 chapters pertaining to such subjects as physical and psychological growth of the child, sex problems and education and adolescent preparation for successful marriage. Since the presence of children is a dominant factor in marital happiness, the benefits of adoption are cited in instances where natural child bearing is impossible. The chapter on parent-child relationships is outstanding.

Part 5, "Social Problems of Sex and Marriage," concerns itself with social subjects a few of which are of questionable value in a book on marital success. The chapter on prostitution in the United States is one of these. Since many groups are reluctant to accept the dissolving of marriage as a solution to marital problems, the chapter on divorce is bound to be controversial.

In general, the book is frank, thorough and exceedingly well written. Practically applied the suggestions and advice set forth within this book should tend to make available the attainment of a completely happy marriage. THEODORE J. MORRIS.

FOR a practitioner with any interest in anesthesia, the book *Pediatric Anesthesia*² will certainly be a well used addition to his library. The problems of pediatric anesthesia are completely discussed from the general requirements for handling children, through the preanesthetic consultation and premedication to an exhaustive, clear and stepwise discussion of techniques involved in pediatric anesthesia, and finally to the postoperative care with the possible complications, how to avoid them and their treatment if necessary.

A chapter involving the special physiology of the infant is included in an effort to emphasize the particular nature of the responses of the child and new born to the administration of anesthetic drugs.

The authors are detailed in their explanations. As they state, "the specialist has reached eminence by mastering detail." They leave no important consideration to chance.

In the chapter concerning inhalation anesthesia the choice of agent, methods and techniques generally are reviewed. The endotracheal section is of practical importance to adult anesthesia as well since it lucidly explains methods which are certainly valid in all usage of these devices. The steps of intubation if followed will certainly facilitate smooth performance of this maneuver. The use of intravenous anesthetic agents in children is discussed and particularly valuable in this chapter is the section concerning the use of curare both as to the surgical or major relaxation effect and its aid to the anesthesiologist in reducing the induction period for

¹SUCCESSFUL MARRIAGE. Edited by Morris Fishbein, M.D. and Ernest W. Burgess, Ph.D. Garden City N.Y. Doubleday and Co. Inc., 1948.

²PEDIATRIC ANESTHESIA. By M. Dixby Leigh, M.D. and M. Kathleen Bellon, M.D. New York: The Macmillan Co., 1948.

intubation. The importance of adequate curarization is just as important in children as in adults. The most lengthy chapter of the book presents a dissertation of anesthetic agents and techniques which affords an excellent guide particularly for the student. This chapter lists the more common surgical procedures and discusses the several anesthetic methods suitable for them. It is not dogmatic but explains

the reasons for such choice and includes examples of risk involved.

This volume does not introduce any spectacular new considerations but it does present the entire picture of the field of pediatric anesthesia and re-emphasizes the use of skill and judgment in the application of anesthetic drugs to any patient.

FRANK M. SELLERS.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

DALLAS B. PHEMISTER, Chicago *President*
FREDERICK A. COLLIER, Ann Arbor Michigan *President Elect*

PRELIMINARY PROGRAM FOR THE 35th CLINICAL CONGRESS THE STEVENS CHICAGO, OCTOBER 17 to 21, 1949

THE thirty fifth Clinical Congress of the American College of Surgeons will be held in Chicago from October 17 to 21, 1949 with hotel headquarters at The Stevens. The Clinical Congress in addition to its usual five-day program will be host to the Sixth Inter American Congress of Surgery which will open on Friday morning October 21 and hold sessions through Sunday October 23. The plans for the Inter American Congress are described in a separate article.

Some twenty hospitals in the Chicago area which are approved for graduate training in surgery will participate in the clinical program. Operative and nonoperative clinics will be held in the hospitals each day in general surgery, obstetrics and gynecology, fractures, orthopedic surgery, thoracic surgery, neurosurgery, genitourinary surgery and ophthalmology and otorhinolaryngology. The schedule of clinics will be published in a *Daily Clinical Bulletin* which will be issued each day during the Congress.

Arrangements are under way to telecast operations to the hotel from one or more of the hospitals. The successful demonstrations of television at the Clinical Congress in New York in 1947 and at the Clinical Congress in Los Angeles in 1948 make it highly desirable to continue the use of this medium. Television has proved itself to be a superlative instrument to further the Show me purpose which was the main incentive for the founding of the Clinical Congress in 1910 three years before the American College of Surgeons was organized.

The program of meetings at the headquarters hotel will be varied and comprehensive. The opening session on Monday morning October 17, will be a general assembly for both surgeons and hospital personnel. Scientific sessions, official meetings and hospital conferences will follow

during the five days and many will undoubtedly wish to remain for the sessions of the Sixth Inter American Congress of Surgery on Saturday and Sunday. Delegates and visitors to the latter meeting will likewise be welcome at clinical and scientific sessions of the Clinical Congress.

PRESIDENTIAL MEETING

The opening evening session of the Clinical Congress will be devoted to the Presidential Meeting at which the officers-elect consisting of Dr. Frederick A. Collier of Ann Arbor, president, Dr. Donald G. Tollefson of Los Angeles, first vice president, and Dr. Robert M. Moore of Galveston, second vice-president will be installed. Dr. Dallas B. Phemister of Chicago, outgoing president, will preside and will deliver the Presidential Address. The fourth Martin Memorial Lecture will be delivered by Sir James R. Learmonth of Edinburgh, whose subject will be Colateral Circulations, Natural and Artificial.

CONVOCATION

The annual Convocation will be held on the final evening Friday. The formal initiation ceremonies for the new Fellows will be a colorful feature of the occasion. The Fellowship Address will be given by Lord Webb-Johnson of London, President of the Royal College of Surgeons.

EVENING SCIENTIFIC SESSIONS— GENERAL SURGERY

The program and speakers for the Tuesday evening general surgery session will be as follows: Acute Surgical Emergencies in Gynecology and Obstetrics.

General Introduction. NEWELL W. PHILPOTT
M.D., F.A.C.S., Montreal.
Tubal Pregnancy Its Diagnosis and Treatment
LEWIS C. SCHEFFETZ M.D. Philadelphia.

Pelvic Peritonitis Occurring in the Obstetrical or Gynecological Patient. FRANK GLENN M.D. F.A.C.S. New York.

Emergency Cesarean Section. WILLIAM E. STURDIFORD M.D. F.A.C.S. New York.

The program and speakers for the Wednesday evening general surgery session will be as follows:

Fracture Oration

Blood Coagulation and the use of Anticoagulants

The Significance of Different Methods for Prothrombin Estimation and their Relative Values. JOHN H. OLWIN M.D. Chicago

Studies on Antithrombin and Etiologic Factors in Phlebotromboses. JOHN H. KAY M.D. New Orleans.

A Further Report on Dicumarol Prophylaxis against Venous Thrombosis in Women Undergoing Surgery. GEORGE VAN S. SMITH M.D. F.A.C.S. Brookline, Massachusetts.

The program and speakers for the Thursday evening general surgery session will be as follows: Chemotherapy in Malignant Neoplastic Disease. CARL V. MOORE, M.D. St. Louis.

Hormone Therapy of Cancer. CHARLES B. HUGGINS, M.D. Chicago

The Use of Radioactive Iodine in Studying the Pathologic Physiology of Thyroid Cancer. RULON W. RAWSON M.D. New York.

What We Have Learned from Isotopes Concerning Depletion and Repair in Surgical Patients. FRANCIS D. MOORE M.D. F.A.C.S. Boston.

GENERAL SURGERY PANEL DISCUSSIONS

General surgery panel discussions will be held on Monday, Tuesday and Wednesday afternoons, from 1:30 to 3:00 and from 3:30 to 5:00 o'clock. The subjects and names of moderators follow:

Monday—1:30 to 2:00 p.m.

Surgical Lesions of the Breast. GEORGE G. FINNEY M.D. F.A.C.S. Baltimore

3:30 to 5:00 p.m.

Fractures of the Skull. ELDREDGE H. CAMPBELL, M.D. F.A.C.S. Albany

Tuesday—1:30 to 3:00 p.m.

Massive Upper Abdominal Hemorrhage. JOHN H. MULHOLLAND M.D. F.A.C.S. New York.

3:30 to 5:00 p.m.

New Surgical Technique in Drug Treated Infections. S. CHAIR LYONS, M.D. F.A.C.S. New Orleans.

Wednesday—1:30 to 3:00 p.m.

The Management of Acute Emergencies Occurring During Operations. I. MIMS GAGE, M.D. F.A.C.S. New Orleans.

3:30 to 5:00 p.m.

Preoperative and Postoperative Care and Anesthesia for Infants. THOMAS H. LAMMAN M.D. F.A.C.S. Boston.

SPECIALTY SESSIONS

Plans will be announced later for the sessions in ophthalmology, otorhinolaryngology, orthopedic surgery, plastic surgery, urology, thoracic surgery, neurological surgery and obstetrics and gynecology. Friday afternoon will be devoted to panel discussions in the surgical specialties, but a definite schedule has not yet been completed for other sessions.

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems will be held on Tuesday through Friday mornings, and from 1:30 to 3:00 o'clock on Thursday afternoon. Brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties will be presented, under the general direction of Dr. Owen H. Wangensteen, chairman of the committee. Forum on Fundamental Surgical Problems.

HOSPITAL CONFERENCES

The twenty-eighth Hospital Standardization Conference will be held during the first four days of the Clinical Congress. Its opening meeting will constitute the first formal session of the Clinical Congress and will be for both surgeons and hospital representatives. Dr. Dallas B. Phenister, president of the College, will preside.

Hospital administrators, trustees, members of medical staffs, nurses, technicians, dietitians, and heads of the various hospital departments and their personnel, are invited to participate in the discussions at the hospital conferences which will be directed by leading authorities in the hospital field in the United States and Canada. The program will include formal sessions, panel discussions, round table conferences, symposia, and forums.

MEDICAL MOTION PICTURES

The showing of medical motion pictures each day will again be a popular feature of the Clinical Congress. The latest available films on surgery and related subjects will be presented. Special

showings will be arranged of medical motion pictures in the fields of ophthalmology and otorhinolaryngology. Both sound and silent films will be shown all of which will have been approved by the Committee on Motion Pictures. Some of the newer medical motion pictures which are now under production will be completed by the time of the Clinical Congress.

COMMITTEE ON ARRANGEMENTS

The Chicago Committee on Arrangements for the Clinical Congress is actively at work on arrangements for the program. The membership follows:

Warren H. Cole, M.D. F.A.C.S. Chairman
 Michael L. Mason, M.D. F.A.C.S. Secretary
 William E. Adams, M.D. F.A.C.S.
 Fremont A. Chandler, M.D. F.A.C.S.
 Edward H. Christofferson, M.D. F.A.C.S.
 Vernon C. David, M.D. F.A.C.S.
 M. Edward Davis, M.D. F.A.C.S.
 Loyal Davis, M.D. F.A.C.S.
 Lester R. Dragstedt, M.D. F.A.C.S.
 Paul W. Greeley, M.D. F.A.C.S.
 Paul H. Holinger, M.D. F.A.C.S.
 Sumner L. Koch, M.D. F.A.C.S.
 Herman L. Kretschmer, M.D. F.A.C.S.
 Walter G. Maddock, M.D. F.A.C.S.
 Foster L. McMillan, M.D. F.A.C.S.
 Karl A. Meyer, M.D. F.A.C.S.
 Harry A. Oberhelman, M.D. F.A.C.S.
 Dallas B. Phemister, M.D., F.A.C.S.
 Willis J. Potts, M.D. F.A.C.S.
 Charles B. Puestow, M.D. F.A.C.S.
 Herbert E. Schmutz, M.D. F.A.C.S.
 Derrick T. Vail, M.D., F.A.C.S.

The Clinical Congress general committee which operates under the Administrative Board of the College, consists of Dr. Malcolm T. MacEachern, chairman, Miss Eleanor K. Grumm, secretary, Doctors Bowman C. Crowell, Charles F. Branch, George H. Miller and H. Prather Saunders, and Mr. Edward G. Sandrok, Mr. James S. Shannon and Miss Laura G. Jackson.

The Clinical Congress Committee on Programs consists of Dr. Frederick A. Collier, chairman and Doctors Henry W. Cave, Evarts A. Graham, and Alton Ochsner.

The Advisory Committee on Programs consists of Dr. George H. Miller, chairman and Doctors Warren Cole, Sumner Koch, Michael Mason,

Charles Puestow, Bowman C. Crowell, H. Prather Saunders, Charles F. Branch and Malcolm T. MacEachern.

TECHNICAL AND SCIENTIFIC EXHIBITION

The Technical and Scientific Exhibits will be held in the Exhibition Hall on the lower level of The Stevens. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, and pharmaceuticals, and publishers of medical books will be represented.

ADVANCE REGISTRATION

Surgeons who wish to attend the Congress should register in advance. Advance registration will greatly expedite the procedure of registering. No registration fee will be charged. Fellows whose dues are paid to December 31, 1948. For endorsed Junior and Senior Candidates, the fee will be \$5.00. Non-Fellows who after individual consideration are permitted to register will pay a fee of \$10.00. No registration fee will be required of initiates of the class of 1949.

HOTEL RESERVATIONS

It is desirable to make hotel reservations as early as possible. In making these communications should be addressed to the Convention Housing Bureau, 105 West Adams Street, Chicago, stating that you will be attending the Clinical Congress of the American College of Surgeons. All hotel reservations, both for surgeons and hospital representatives are to clear through this Bureau. No correspondence should be sent directly to the hotels. A form for reservations was enclosed in the letter recently sent to Fellows. Choice of hotels may be designated.

A list of the major hotels follows:

CHICAGO HOTELS

Blumark, 171 W. Randolph Street
 Blackstone, Michigan Avenue at 7th Street
 Congress, 500 S. Michigan Avenue
 Drake, Michigan and Lake Shore Drive
 Harrison, 57 E. Harrison Street
 Lake Shore Drive, 181 Lake Shore Drive
 LaSalle, 10 N. LaSalle Street
 Morrison, 70 W. Madison Street
 Palmer House, 15 E. Monroe Street
 Sheraton, 505 N. Michigan Avenue
 Sherman, 106 W. Randolph Street
 Stevens, 720 S. Michigan Avenue

showings will be arranged of medical motion pictures in the fields of ophthalmology and otorhinolaryngology. Both sound and silent films will be shown, all of which will have been approved by the Committee on Motion Pictures. Some of the newer medical motion pictures which are now under production will be completed by the time of the Clinical Congress.

COMMITTEE ON ARRANGEMENTS

The Chicago Committee on Arrangements for the Clinical Congress is actively at work on arrangements for the program. The membership follows:

Warren H. Cole, M.D. F.A.C.S. Chairman
 Michael L. Mason, M.D., F.A.C.S. Secretary
 William E. Adams, M.D. F.A.C.S.
 Fremont A. Chandler, M.D. F.A.C.S.

SIXTH INTER AMERICAN CONGRESS OF SURGERY

THE thirty fifth Clinical Congress of the American College of Surgeons will be host to the sixth Inter American Congress of Surgery when it convenes in Chicago on October 21, 22 and 23. On its first day it will overlap with the Clinical Congress. The delegates and visitors from Latin American countries will be welcome to attend all sessions of the Clinical Congress, and the operative clinics at the hospitals.

The American College of Surgeons joined the Association of Inter-American Congresses of Surgery by vote of the Board of Regents on June 27, 1944. This action was preceded by an invitation from Dr. Luis Vargas Salcedo of Santiago, Chile, dated July 21, 1942, to send two delegates as guests of honor to the first Inter American Congress of Surgery in Santiago held November 14 to 19, 1942. Dr. Leo Eloesser attended as delegate, and it was upon his enthusiastic recommendation that the College accepted the invitation to join. He also attended the second Congress held in Buenos Aires, October 10 to 15, 1943. Dr. Alton Ochsner was delegate to the third Congress, held in Rio de Janeiro from September 6 to 15, 1947. The fifth Congress was held in La Paz, Bolivia, October 17 to 21, 1948, with Dr. E. Payne Palmer of Phoenix and Dr. Hu Crim Myers of Philippi, West Virginia as delegates and co-relators.

The surgical societies of the following countries, in addition to the United States, are members of the Association of Inter American Congresses of Surgery: Argentina, Brazil, Bolivia, Chile, Cuba, Ecuador, Mexico, Panama, Paraguay, Peru, and

Uruguay. Dr. Arnaldo Cavaglia of Buenos Aires is the Secretary General.

A preliminary outline of the program for the Sixth Inter American Congress of Surgery follows:

Friday morning, October 21

Inaugural Ceremony

Friday afternoon, October 21

Delegates may attend the specialty panels of the Clinical Congress

Saturday morning, October 22

Main Theme: Acute Cerebrocerebral Trauma

Relator: E. Jefferson Browder, M.D.

F.A.C.S. Brooklyn

Co-relators: To be appointed by each country

Saturday afternoon, October 22

Main Theme: Treatment of Injuries in the Region of the Ankle with Complications and Sequelae

Relator: Harrison L. McLaughlin, M.D.,

F.A.C.S. New York

Co-relators: To be appointed by each country

Saturday evening, October 22

Official Banquet

Sunday morning, October 23

Business Session

Sunday afternoon, October 23

Main Theme: Pulmonary Carcinoma

Relator: E. Everts Graham, M.D., F.A.C.S.,

St. Louis

Co-relators: To be appointed by each country

SUBJECT INDEX TO VOLUME 88

- ABDOMEN** ventral wall, Anatomic and clinical re-evaluation of Camper's, Scarpa's, and Colles fasciae, 545
- Abnormalities**, Technique of surgical division of patent ductus arteriosus, 62 congenital, One hundred cases of of vagina, 79 congenital, Craniofacial morphology in cleft palate and cleft lip deformities, 359 congenital, Physiologic methods in diagnosis of heart disease, ed 399, congenital Exstrophy of bladder ed 401 congenital anorectal, Imperforate anus, case series and preliminary report on one stage abdominoperineal operation 623
- Abscess**, paracolic Carcinoma of cecum complicated by appendicitis or 501
- Ac-globulin** Stability of and of prothrombin in citrated human plasma, 370
- Adenocarcinoma**, Carcinoid tumors of intestine, 317
- Ameliasia**, Thoracic complications of 753
- Amenorrhea**, Stimulation of ovarian function and induction of pregnancy through intravaginal implantation of estrogen pellets, 783
- American College of Surgeons**, Clinical Congress, Preliminary program for 35th the Stevens, Chicago October 17 to 21 1949 803
- Amino acids**, Effect of intravenous glucose and, on glycosuria and urinary output in humans, 97
- Anastomosis**, One stage end-to-end, of colon analysis of complications in 79 cases with comparison of open and aseptic types of 209, One stage resection and, of colon, ed 364 ureteroileocolic Exstrophy of bladder ed 401 Ureteroileocolic, 441 Double jejunal lumen gastrojejunal, pantaloon, 453
- Anatomy** Inguinal and femoral hernioplasty 473 Anatomic and clinical re-evaluation of Camper's, Scarpa's, and Colles fasciae, 545 Anatomic variations of extrahepatic biliary system as seen by cholangiographic studies, 577
- Anesthesia**, spinal, Prolonged use of intrathecal vasoconstrictor substances, 528
- Anticoagulants**, Evaluation of various clinical signs of thrombophlebitis and experience in therapy with 337
- Antiseptics**, Evaluation of hexachlorophene and detergents as substitutes for surgical scrub biological technique 639
- Anus**, Imperforate, case series and preliminary report on one stage abdominoperineal operation, 623
- Aorta**, Technique of surgical division of patent ductus arteriosus, 62 Methods for preservation and transplantation of arterial grafts, observations on arterial grafts in dogs, report of transplantation of preserved arterial grafts in 9 humans, 689
- Appendicitis**, Carcinoma of cecum complicated by or paracolic abscess, 501
- Appendix**, Carcinoid tumors of intestine, 317
- Arteries**, Experimental pulmonary embolism, 33 pulmonary Technique of surgical division of patent ductus arteriosus, 62 Methods for preservation and transplantation of arterial grafts, observations on arterial grafts in dogs, report of transplantation of preserved arterial grafts in 9 human cases, 689
- Asepsis**, Evaluation of hexachlorophene and detergents as substitutes for surgical scrub, biological technique, 639
- Atropine**, Use of beta methylcholine urethane in post operative urinary retention, 196
- BETA METHYLCHOLINE** urethane, Use of in post operative urinary retention 196
- Bile**, Stratification of in gall bladder and cholelithiasis, 731
- Biliary system**, extrahepatic, Anatomic variations of as seen by cholangiographic studies, 577
- Bladder** Vesicovaginal fistula and its management, with description of intravesical operation for certain difficult cases, 155 Etiology of stress incontinence, 237 Exstrophy of ed 401 Correction of stress incontinence by simple vesicourethral suspension, 509
- Bleeding** abnormal uterine Carcinoma of endometrium in young women, 332
- Blood**, proteins, Nature of postoperative hypoproteinemia in patients with gastrointestinal cancer 185 coagulation, Effect of sulfathiazide on bleeding and clotting time of and prolongation reduction by administration of vitamin K, 201 anticoagulants, Evaluation of various clinical signs of thrombophlebitis and experience in therapy with, 337 coagulation, Stability of ac globulin and of prothrombin in citrated human plasma, 370 anticoagulants, Pulmonary embolism, its incidence, significance, and relation to antecedent vein disease, 373 Hemolysis during transurethral prostatic resection 389 flow Physiologic methods in diagnosis of congenital heart disease, ed 399 coagulation thrombin level, Trypsin and thrombin induced venous thrombosis and its prevention with dicumarol 33 methylenebis (4 hydroxycoumarin) 635 Dextran, experimental plasma substitute, 661 circulation, Study of peripheral vascular disease with radioactive isotopes, part II 711
- Blood pressure**, Microplethysmography as criterion for sympathectomy in hypertension, 170
- Blood transfusion** Effects of sublethal hemorrhage in normal dogs and in dogs previously transfused with whole blood 178
- Blood vessels**, disease, Study of peripheral vascular disease with radioactive isotopes, part II 711 Vascular changes of skin in pregnancy vascular spiders and palmar erythema, 739
- Bone**, Intramedullary fixation in pathologic fractures, 519
- Book Shelf** John Coakley Lettson and his literary friends, 154 Gentlemen from Tennessee, 405 Case of eccentric lexicographer 681
- Breast**, carcinoma of, Apocrine tissue chronic cystic mastitis and sweat gland, 1 cancer of Evaluation of skin grafting in technique of radical mastectomy in relation to local recurrence of carcinoma, 45 Clinical response of metastatic lesions of carcinoma of female to hormonal therapy as related to histologic grade of malignancy 301 "Vertical epidemic" of mammary carcinoma in mice, its possible implications for problem of cancer in general 295 Testosterone propionate in treatment of advanced carcinoma of 702
- Bronchus**, Carcinoma cells in sputum and bronchial secretions, study of 150 consecutive cases in which results were positive, 273 secretion, Cytologic examination of sputum and in diagnosis of bronchogenic carcinoma, ed 676
- Burns**, radiation, Surgical treatment of 609
- CALCULUS** Stratification of bile in gall bladder and cholelithiasis, 731
- Cancer** Nature of lateral "aberrant" thyroid tumors, 31 Nature of postoperative hypoproteinemia in patients

- with gastrointestinal, 83 histologic grade, Clinical response of metastatic lesions of carcinoma of female breast to hormonal therapy as related to, 291; heredity "vertical epidemic" of mammary carcinoma in mice, its possible implications for problem of cancer in general, 293 Carcinoid tumors of intestine, 3 7 Intraepithelial carcinoma in situ of cervix, 1er1, ed. 79
- Carbohydrate metabolism, Pancreatic physiology in light of recent surgical experiences, ed. 266
- Carcinoma, as cat gland, of breast Apocrine tissue, chronic cystic mastitis an l, local recurrence, Evaluation of skin grafting in technique of radical mastectomy in relation to, 45 developing in chronic draining cutaneous sinuses and fistulas, 87 Bronchiogenic, ed. 29 bronchiogenic, Mediastinal tumors, ed. 3 cells, in sputum and bronchial secretions, study of 50 consecutive cases in which results were positive 73 of breast, Clinical response of metastatic lesions of female, t hormonal therapy as related t histologic grade of malignancy 29 mammary "vertical epidemic" of in mice, its possible implications for problem of cancer in general, 295 Role of peritoneal reflection in prognostic of of rect m and sigmoid colon, 226 of endometrium in young women 33 f vulva, report of 3 3 cases, 435 of cecum complicated by appendicitis or paracolic hernia, 50 bronchiogenic, Cytologic examination of sputum and bronchial secretions in diagnosis of ed. 676 of breast, Testosterone propionate in treatment of advanced, 70 of nasopharynx, report of 50 cases, 703 of cervix, 1er1, I intraepithelial, in situ of, ed. 79
- Catheterization, venous, Physiologic methods in diagnosis of congenital heart disease, ed. 399
- Cecum, Carcinoma of complicated by, appendicitis or paracolic abscess, 50
- Cells, see Carcinoma, cells
- Cervical stump, analysis of 3 cases, 465
- Cervix uteri, see Uterus cervix
- Cesarean section, Fetal mortality and morbidity in, 3
- Chest, Mediastinal tumors, ed. 3
- Cholangiography Anatomic variations of extrahepatic biliary system as seen by 577
- Cholelithiasis, Anatomic variations of extrahepatic biliary system as seen b cholangiographic studies, 577
- Cholelithiasis, Stratification of bile in gall bladder, nd, 731
- Colitis, ulcerative, Surgical management of 351
- Colon, surgery One stage end-to-end anastomosis of analysis of complications in 79 cases 1th comparison of open and aseptic types of anastomosis, 209 surgery One stage resection and anastomosis of, ed. 264, Subincision lipoma of 309, cor 683 Role of peritoneal reflection in prognosis of carcinoma of rectum and sigmoid colon, 226 Surgical management of ulcerative colitis, 151 Uterostigmoid anastomosis, 44 Sliding inguinal hernia of abnormal peritoneal folds and simple self method of restoration, 495
- C) tole, Vaginal operations for prolapse of uterus and stress incontinence,
- Cysts, Pseudocysts of pancreas, report of 3 cases, 2 p
- DEAVER, John B. Simplicity in surgery, ed. 330
- Detergent, Evaluation of hexachlorophene and, as substitutes for surgical scrub, biological technique, 639
- Dextran experimental plasma substitute, 66
- Diabetes mellitus, Pancreatic physiology in light of recent surgical experiences, ed. 266
- Diagnosis, early Intraepithelial carcinoma in situ of cervix, 1er1, ed. 79
- Disseminated, E situation of various clinical signs of thrombophlebitis and experience in therapy 1th anticoagulants, 337 Effectiveness of prophylaxis against thromboembolic complications following major surgery 4 year survey 3,304 cases, 486 Trypsin and thrombin induced venous thrombosis and its prevention with, 53 methyleneblue (4 bromoxyantra), 635
- Distress, Effect of intravenous glucose and amino acids on glycosuria, nd urinary output in humans, 97
- Duct, cystic, hepatic, Anatomic variations of extrahepatic biliary system as seen by cholangiographic studies, 577
- Ductus arteriosus, Technique of surgical division of patent, 62 Surgical treatment of patent, 57
- Duodenum, carcinoma of Consequences of section of pancreatic duct, experimental study 254
- Dysmenorrhea, Endometriosis—its surgical significance, critical analysis of 179 cases, 30
- ELBOW Fractures of upper end of radius and ulna, 69
- Electromyography Anterior poliomyelitis, early and late electrical stimulation of muscles, 213
- Embolism, pulmonary Experimental, 31 pulmonary Evaluation of various clinical signs of thrombophlebitis and experience in therapy with anticoagulants, 337 Pulmonary Its incidence, significance, and relation to antecedent vein disease 373 Effectiveness of dicumarol prophylaxis against thromboembolic complications following major surgery 4 year survey 3,304 cases, 486
- Empyema, Carcinoma developing in chronic draining cutaneous sinuses and fistulas, 87
- Endometriosis, its surgical significance, critical analysis of 79 cases, 30
- Endometrium, Carcinoma of in young women, 332
- Epithelium, pale, Apocrine tissue, chronic cystic mastitis and sweat gland carcinoma of breast, 1
- Esophagus, Gastric resection for esophagitis and strictures of acid-peptic origin, 500
- Estrogen pellets, Stimulation of ovarian function and induction of pregnancy through intravaginal implantation of 783
- L tremities, injuries, Posttraumatic vasomotor disorders, with particular reference to late manifestations and treatment 4 7 blood supply Study of peripheral vascular disease 1th radioeth isotopes, part II, 7
- FASCIA, Camper's, Colles Scurpa's, Anatomic and clinical re-evaluation of, 545; external oblique Repair of inguinal hernia 1th, critical evaluation of results, 603
- Femoral canal, Inguinal and femoral hernioplasty 473
- Femur Intramedullary bone fixation in pathologic fractures, 5 9

Neck Nature of lateral "aberrant" thyroid tumors 31
Carcinoma of nasopharynx, report of 150 cases, 763

- Sulfathiazidine, Effect of, on bleeding and clotting time of blood and prolongation reduction by administration of vitamin K 201
- Surgery plastic, Evaluation of skin grafting in technique of radical mastectomy in relation to local recurrence of carcinoma, 45 plastic, One hundred cases of congenital absence of vagina, 79 plastic, Craniofacial morphology in cleft palate and cleft lip deformities, 359 technique, Partial gastrectomy in war years, 447 technique, Double jejunal lumen gastrojejunal anastomosis, pantaloon anastomosis, 453 plastic, Lingual and femoral hernioplasty 473 postoperative care Effectiveness of dicumarol prophylaxis against thromboembolic complications following major 4 year survey 3,304 cases, 486 plastic, Sliding inguinal hernia of colon, abnormal peritoneal folds and simple safe method of restoration, 495 abdominal, Prolonged spinal anesthesia, use of intrathecal vasoconstrictor substances, 528 pulmonary Value of respiratory function studies in ed. 537, preoperative and post-operative care, principles of surgical practice, Simplicity in, ed. 539 McArthur's technique, Repair of inguinal hernia with external oblique fascia, critical evaluation of results, 603 plastic, Surgical treatment of radiation burns, 609, surgical scrub, Evaluation of hexachlorophene and detergents as substitutes for biological technique, 639 technique, Tendon transplants for irreparable radial nerve paralysis, 643 Risk of surgical operation, ed. 678, plastic, Methods for preservation and transplantation of arterial grafts, observations on arterial grafts in dogs, report of transplantation of preserved arterial grafts in 9 human cases, 689
- Sympathectomy Microplethysmography as criterion for in hypertension 170 Posttraumatic vasomotor disorders, with particular reference to late manifestations and treatment, 417
- T**ENDON transplantation for irreparable radial nerve paralysis 643
- Testosterone, Clinical response of metastatic lesions of carcinoma of female breast to hormonal therapy as related to histologic grade of malignancy, 591
- Testosterone propionate, in treatment of advanced carcinoma of breast 703
- Thorax, Thoracic complications of amebiasis, 755
- Thrombin Trypsin and, induced venous thrombosis and its prevention with dicumarol 3,3 methylenebis (4 hydroxycoumarin), 635
- Thrombophlebitis, Evaluation of various clinical signs of and experience in therapy with anticoagulants, 337
- Thrombosis, Iliofemoral, Evaluation of various clinical signs of thrombophlebitis and experience in therapy with anticoagulants 337 venous, Effectiveness of dicumarol prophylaxis against thromboembolic complications following major surgery, 4 year survey 3,304 cases, 486 venous, Trypsin and thrombin induced, and its prevention with dicumarol, 3,3 methylenebis (4 hydroxycoumarin) 635
- Thyroid, aberrant, Nature of lateral, tumors, 31
- Tissue, Apocrine, chronic cystic mastitis and sweat gland carcinoma of breast, 1
- Transfusion, whole blood Effects of sublethal hemorrhage in normal dogs and in dogs previously transfused with 178
- Trauma, Posttraumatic vasomotor disorders, with particular reference to late manifestations and treatment, 417
- Trypsin and thrombin induced venous thrombosis and its prevention with dicumarol, 3,3 methylenebis (4 hydroxycoumarin) 635
- Tumor Nature of lateral aberrant thyroid 31 Medial astinal, ed. 331 Carcinoma of intestine, 317 Uncommon of salivary glands, 776
- U**LCER, of leg Indurated leg and, clinical study of their etiology and treatment, 115 chronic, Posttraumatic vasomotor disorders, with particular reference to late manifestations and treatment 417 duodenal gastric, Partial gastrectomy in war years, 44 Double jejunal lumen gastrojejunal anastomosis, pantaloon anastomosis, 453 duodenal, Gastric resection for esophagitis and stricture of acid-peptic origin 560 duodenal Rationale for surgical treatment of 585
- Ulna, Fractures of upper end of radius and, 69
- Ureter Ureteroileoid anastomosis, 441
- Ureterointestinal anastomosis, Vesicovaginal fistula and its management, with description of intravesical operation for certain difficult cases, 155
- Urethra Correction of stress incontinence by simple vesico-urethral suspension 509
- Urine, Effect of intravenous glucose and amino acids on glycosuria and urinary output in humans, 97 retention postoperative Use of beta-methylcholone urethane in postoperative urinary retention 196 Etiology of stress incontinence, 337 Correction of stress incontinence by simple vesico-urethral suspension 509
- Uterus, prolapse of Vaginal operations for cystocele, and stress incontinence, 11 Endometriosis—its surgical significance, critical analysis of 179 cases, 230 Carcinoma of endometrium in young women, 332 Ruptured report of 42 cases, 652
- Uterus cervix, Obstructed, 50 Cervical stump, analysis of 183 cases, 465 Intraepithelial carcinoma in situ of ed. 792
- V**AGINA, anatomy of surgery of Vaginal operations for cystocele, prolapse of uterus and stress incontinence, 11 One hundred cases of congenital absence of 79 Vaginal and ovarian metastases from hypernephroma, report of case and review of literature, 145 Vesicovaginal fistula and its management, with description of intravesical operation for certain difficult cases, 155
- Varicose veins, Indurated leg and leg ulcers, clinical study of their etiology and treatment, 115
- Vascular spiders, Vascular changes of skin in pregnancy and palmar erythema, 739
- Vasomotor system Posttraumatic disorders, with particular reference to late manifestations and treatment 417
- Veins, Experimental pulmonary embolism, 23 Ligation Evaluation of various clinical signs of thrombophlebitis and experience in therapy with anticoagulants, 337 disease, Pulmonary embolism its incidence, significance, and relation to antecedent, 373 external iliac, hypogastric, Resection of great, on lateral pelvic wall 498
- Vent, proximal, One stage end to end anastomosis of colon analysis of complications in 79 cases with comparison of open and aseptic types of anastomoses, 309
- Vesico-urethral suspension, Correction of stress incontinence by simple, 509
- Vitamin K Effect of sulfathiazidine on bleeding and clotting time of blood and prolongation reduction by administration of 201
- Vulva, Carcinoma of report of 313 cases 455
- W**RIST drop Tendon transplants for irreparable radial nerve paralysis, 643

COLLECTIVE REVIEW

Protein Metabolic Response to Trauma. JOHN W BRAASCH M.D Chicago Illinois	473
---	-----

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

Head	
Mandibular Bone Grafts. W B MACOMBER, R. A. SHEPARD and V E. CROFT	484
Eye	
Ectropion Corrected by Bridge Pedicle Craft. H. B STALLARD	485
Atrophia Gyrata Choroidae et Retinae. JOHAN SAEMJ	486
The Prognosis of Sarcoma of the Choroid J BRUCE HAMILTON	486
Ear	
Otosclerosis in Childhood. WILLIAM MCKENZIE	486
Nose and Sinuses	
Columnella Reconstruction. MORTIMER H. SHAW and STEPHEN R. FELL	487
Osteoma of the Frontal and Ethmoid Sinuses. H. BRUNNER and I G SPIESMAN	487
Mouth	
Mandibular Fractures in Children. GEORGE W MATTHEWS and THOMAS V MAGRUDER JR	488
Pharynx	
Associated Symptomatology of Diseases of the Epipharynx. WALTER H. THROBOLD	488
Neck	
The Significance of the Protein-Bound Blood Iodine in Patients with Hyperthyroidism. GEORGE M. CURTIS and ROY E. SWENSON	488
Complications following Irradiation of the Thyroid Gland. R. M. LUKENS	489
The Open Approach to Arytenoidectomy for Bilateral Abductor Paralysis, with a Report of 2 Cases. DE GRAAF WOODMAN	489
Further Operative Results of Carcinoma of the Larynx. TZ. D. DEMETRIADES and D. IOAN NOVICU	489
Cancer of the Larynx. Five Year Results of Radiotherapy. MAX CUTLER	554

SURGERY OF THE NERVOUS SYSTEM

Brain and Its Coverings Cranial Nerves	
Follow Up Study of Men with Penetrating Injury to the Brain. JOHN A. AITA	491
Sturge Weber Syndrome. ARCHIBALD D. MCCOY and HAROLD C. VORIS	491
A Pneumographic Study of the Temporal Horn, with Special Reference to Tumors in the Temporal Region. ERIC LUNDGREN	491
Trigeminal Tractotomies in the Treatment of Facial Neuralgia. JACQUES LE BEAU S. DAUM and S. FORJAZ	492
Ten Years Experience with Trigeminal Tractotomy OLAV SJOOVIST	493
Paralysis of Deglutition Surgical Correction. HOWARD C. NAFFZIGER, COOPER DAVIS, and H. GLENN BELL	493
Spinal Cord and Its Coverings	
Surgical Experiences with Extramedullary Tumors of the Spinal Cord. FRANCIS G. GRANT	494

SURGERY OF THE THORAX

Chest Wall and Breast	
Primary Rib Tumors. RALPH A. DORNER and DEANE S. MARCY	495
Breast Reduction and Lactation. A. RAGNELL	495
Early Diagnosis and Treatment of Carcinoma of the Breast. VICTOR RIDDELL	495
Simultaneous Evolution and Involution of Breast Carcinoma and Warts of the Mammary Region. ANDRÉ JOSSEBRAND MARCEL DARGENT and MARCEL MAYER	496
Carcinoma of the Breast and Its Treatment. SIR CECIL WAKELEY	496
Cancer of the Breast and Gestation. JEAN FERRO-TIN	497
Trachea, Lungs, and Pleura	
Congenital Tracheoesophageal Fistula without Esophageal Atresia. CAMERON HAIGHT	497
The Management of the Pulmonary "Coin" Lesion. E. J. O'BRIEN WILLIAM M. TUTTLE, and JOSEPH E. FERRANTE	497

Primary Pulmonary Malignancy. ALTON OCHSNER, MICHAEL DEBAKEY, CHARLES E. DUKLAP and IRVING RICHMAN	498	The Prognosis and Treatment of Malignant Hemorrhage from Gastric and Duodenal Ulcers. ERIC D. BARTZIS	505
The Role of Pleural Exudation in Infection Following Pneumectomy. JOHN T. SMALL and GEORGE M. HIGGINS	498	Considerations on 941 Interventions for Gastro-duodenal Perforations. LEONIDA MANROCCI	505
Some Observations on the Roentgen Diagnosis of Nonopaque Foreign Bodies Aspirated into the Bronchus. SOLVE WILDER	551	Gastric Resection. The Schoemaker-Bilroth I Operation. JOHN F. HIGGINS and O. THORNDYKE	506
Streptomycin Treatment of Pulmonary Tuberculosis. MEDICAL RESEARCH COUNCIL INVESTIGATION	558	Appraisal of Patients after Gastric Resection during War. R. BOLLER and D. MITCHELL	506
Heart and Pericardium		Pyloric Stenosis Caused by the Ingestion of Corrosive Substances. Report of a Case. HOWARD K. GRAY and CHRISTIE L. HOLMES	507
Battle Wounds and Injuries of the Heart and Pericardium. PAUL C. SAMMONS	499	Acute Pseudomembranous Enteritis or Enterocolitis. Complication after Intestinal Surgery. CLAUDE F. DIXON and RODGER E. WEINBERG	507
Revascularization of the Heart. CLAUDE S. BECK	500	Duodenitis. A. TAVELMAR	508
Neoplastic Metastases to the Heart. AARON M. LEFKOVITZ	500	J. Junctional Insufficiency: Its Relation to the Sprue Syndrome. E. LEONARD POSEY, JR., and J. ARNOLD BARGER	508
Chronic Constrictive Pericarditis Over the Left Heart Chambers and Its Surgical Relief. PAUL D. WHITE, FRED ALEXANDER, EDWARD D. CHURCHILL, and RICHARD H. SWIFT	500	The Surgical Treatment of Congenital Megacolon. CLAUDE F. DIXON and DAVID B. JUDS	509
The Surgical Treatment of the Infantile Type of Coarctation of the Aorta. JULIAN JOHNSON and CHARLES K. KIRBY	500	Hemorrhoids and Cancer. NELS CARSTEN	510
Pregnancy and Subacute Bacterial Endocarditis. CURTIS L. MICHIELSON	518	Anterior Resection for Malignant Lesions of the Upper Part of the Rectum and Lower Part of the Sigmoid. CLAUDE F. DIXON	51
Esophagus and Mediastinum		Experiences with Operation for Rectal Carcinoma with Preservation of the Sphincter. A. BRUNGER	51
The Treatment of Congenital Atresia of the Esophagus from Technical Point of View. PH. SANDERSON	50	Studies of Roentgenologic Images of the Gastrointestinal Mucosa. Particular Appearances of the Mucosa of the Cecal Portion of the Ascending Colon in the Syndrome of the Right Lower Abdomen. ANDREA CARATI	551
Spontaneous Rupture of the Esophagus. JULIAN A. MOORE and JAMES D. MURPHY	50	Tuberculosis of the Stomach and Duodenum. HERMAN W. OSTERUM and WILLIAM SCHERER	51
Benign Pedunculated Tumors of the Esophagus. RAYMOND C. BEXLER, JAMES N. COLLIER, and MARVIN F. HALL	503	Tumors of the Upper Third of the Stomach. MANUEL MELLENCHAM and JAMES ROCA	553
		The Mucosal Pattern of the Terminal Ileum in Children. Preliminary Report. JOSEPHINE WELLS	55
		Roentgen-Ray Diagnosis of Malignant and Potentially Malignant Lesions of the Colon and Rectum. JOSEPH C. BILL and JAMES B. DOUGLAS	553
		The Gastroscopic Picture in Postirradiation Gastritis. EDDY D. PALMER	554
SURGERY OF THE ABDOMEN			
Abdominal Wall and Peritoneum		Liver Gall Bladder Pancreas, and Spleen	
The Treatment of Primary and Recurrent Inguinal Hernia by Skin Graft. VINCENZO F. PATAFO and DIEGO E. ZAVALLERA	503	Hepatic Coma. T. LYNN MURPHY, THOMAS C. CHALKERS, RICHARD D. ECKHART and CHARLES S. DAVIDSON	51
A Review of Femoral Hernias. ANDREW G. BUTTINS	503	Operative Treatment of Gall Stone Disease in the Light of Ultimate Results. VICTOR HOFFMAN	5
Repair of Femoral Hernia by "Postage Stamp Fascial Graft. H. A. KROH	503	The Pancreatic Fistulas and Their Treatment. MICHAEL PARASKEVAS	51
Gastrointestinal Tract		Hydatid Disease of the Liver and Lung and Its Surgical Treatment. GEORGE MARANO	558
Polypoid Adenomatosis of the Entire Gastrointestinal Tract. MARK M. RAVITCH	503		
Follow-Up of Vagotomy Plus Gastroenterostomy or Pyloroplasty for Ulcer. E. N. COLLIER, GEORGE CHILL, JR., and J. H. DAVIS	504	Miscellaneous	
Management of Massively Bleeding Peptic Ulcer. JOHN D. STEWART, STREET M. SCHAEFER, WILLIAM H. POTTER, and ALFRED J. MASSEY	504	The Significance of Calcareous Tuberculous Glands in the Abdomen in Relation to the Urinary Tract. JAMES A. ROSE	53

GYNECOLOGY

- Uterus**
- Age, Incidence, and Distribution of 4,652 Cases of Carcinoma of the Cervix. MARVIN G. SADDUCK and JAMES P. PALMER 513
- The Ovary in Endometrial Carcinoma. EPHRAIM WOLL, ARTHUR T. HERTIG, GEORGE VAN S. SMITH, and LEWIS C. JOHNSON 513

COLLECTIVE REVIEW

PROTEIN METABOLIC RESPONSE TO TRAUMA

JOHN W. BRAASCH, M.D., Chicago, Illinois

WITHIN the last few years, Selye (91, 92) Cuthbertson (21, 23, 24, 25) and others have done much to focus the attention of not a few investigators on the important problem of the protein metabolic response to trauma. Some workers have approached this problem hoping to use its elucidation as a key to the workings of various endocrine problems, and others have hoped that some practical application to the treatment of various traumatic states might be found. The latter have been disappointed the former have not. Through these efforts we are now on the threshold of uncovering many of the mechanisms involved.

The importance of this problem has not been overemphasized. When one considers the part protein plays in edema formation, wound healing, gastrointestinal function, gastric and duodenal ulcers, epidermal ulcers, surgical, traumatic, and burn shock, resistance to infection, and liver damage as has been recently outlined by Kremen, one is impressed with the strategic nature of the subject under scrutiny.

It is the writer's purpose in this article to review the field pertaining to the changes in protein metabolism incident to nonspecific damage, to discuss the possible etiology of such changes, and to bring in any other relevant material. In so doing it is hoped that some of the confusion surrounding this subject will be clarified.

To avoid the confusion which might arise in the description of these metabolic changes, each tra-

umatic situation will be reviewed separately. It is considered important by this worker that these separate entities be thought of as such until more definite evidence is discovered which allows them to be included in one syndrome.

Fractures. Cuthbertson credited Wertheimer *et al.* with making the first studies on this phenomenon. These workers found high urinary nitrogen excretion levels following battle injuries and shock. Cuthbertson (21, 23, 24) was the first worker to make extensive studies on the protein metabolic response to fracture. He found that the urinary nonprotein nitrogen was increased after fracture, remaining elevated for periods up to 30 days. Howard *et al.* (48, 50, 51) confirmed and extended Cuthbertson's observations, demonstrating that following osteotomy patients excreted an increased amount of nitrogen in the urine, but the increase was not of the same magnitude or duration as that following traumatic fracture. In addition, fecal nitrogen levels were found to bear no constant relation to the stage of the reaction to fracture. As to any correlation between the amount of trauma and the height of increase in urinary nonprotein nitrogen, there seems to be some confusion. In 1936, referring to patients, Cuthbertson (23) stated that the loss of nitrogen in the urine varied with the amount of soft part injury incident to the fracture, but in 1942, referring to experimental studies in rats, he (24) stated that there was apparently no correlation between the amount of trauma and the amount of nitrogen lost.

Partition studies of the nitrogen fractions of urine by Cuthbertson (23, 24) revealed that most of the increase was in urea and ammonia with a slight increase in the creatine fraction. Concom-

Abridgment of part of a thesis submitted to the Faculty of the Graduate School of the University of Illinois in partial fulfillment of the requirement for the degree of M.S. in Physiology.

Itantly the excretion of sulfur potassium, and phosphate was found to follow roughly the nitrogen excretion.

There is some disagreement in the literature regarding the efficacy of high protein or high caloric diets, or of both, for establishing a positive nitrogen balance after fracture. Cuthbertson (23) found that giving a large amount of protein (up to 33 gm. of nitrogen a day) and a moderate number of calories (up to 3,400 calories a day) did not appreciably affect the negative balance as the extra nitrogen administered appeared in the urine. On other occasions he administered up to 4,100 calories, but still the negative nitrogen balance persisted. Howard *et al* (48, 50, 51) and Browne (9, 10, 11) are of the same opinion. Opposed to these views is Werner who cited a case of fractured femur with multiple soft part injuries. The patient's course after fracture was marked by a positive nitrogen balance throughout on from 21 to 53 gm. of nitrogen daily administered orally and intravenously in the form of amino acids and amigens. This worker failed, however to mention the patient's previous dietary history which as we shall point out later is of vital importance.

The urinary excretion of cortinlike substances and 17-ketosteroids has been studied by Browne *et al* (8, 9, 10, 11, 12, 13). Unfortunately their cases yield no definite information because some of them are complicated by intercurrent infection, isolated determinations, fluctuating intakes, mixed types of trauma, and other factors. However the following generalities can be drawn from this work and that of Forbes *et al* (1) after fractures and other types of trauma the urinary 17-ketosteroid output is raised for from 24 to 48 hours, then it falls below normal for a period approximating the "catabolic reaction" and (2) the urinary excretion of the cortinlike substances appears to be increased for this same quite variable length of time. No definite inferences as to a correlation between the return to normal of these substances and the return to normal levels of the nitrogen excretion can be drawn.

This metabolic response which has just been described can be reproduced in the rat. Cuthbertson *et al* (25) studied the urinary nonprotein nitrogen, creatinine, creatine, sulfur sodium, potassium, and phosphorus from adult rats after fracture of the femur at open operation. They found that the sodium and creatinine levels remained fairly constant, but those of nitrogen, sulfur potassium, and phosphorus were increased. This response lasted 6 days with a peak on the third day. It is interesting to note that some of the animals were given extra carbohydrate in their diets, and

it was the authors' opinion that their nitrogen loss was not as great.

BURNS. Turning our attention now to the effects of thermal injury we find that this type of damage is followed by the same consequences as fracture with one or two exceptions. Davidson was the first worker to notice that the total urinary nitrogen excretion was elevated after burns. Lucido followed the nitrogen excretion in a single case of 40 to 50 per cent third degree burn and found that the urinary nitrogen excretion remained elevated for approximately 30 days. Taylor *et al* (95) studied these chemical phenomena extensively in patients and found an increase in urinary nonprotein nitrogen for a period corresponding to the severity of the burn, from 14 to 21 days. Urinary nitrogen partition studies revealed a relative and absolute increase in the undetermined nitrogen fraction. These authors surmised that this fraction was made up of polypeptide nitrogen as it yielded both amino and amide nitrogen. This undetermined nitrogen fraction remained elevated for as long as the study continued in the data presented. The patients on whom the urinary partition studies were made were severely burned, showing hemoglobinuria and suppression of urine formation. In fact, the total nitrogen in the urine of the patients whose data were presented ranged from normal to high normal. However no data on the intake were given therefore the significance of the last statement is open to question. The remaining components of the total urinary nitrogen were normal with the exception of the presence of small amounts of creatine. Plasma nitrogen partitions were found to mirror those of the urine. Hirschfeld *et al* and Abbott *et al* confirmed the work of Taylor *et al* (95) in so far as the increase in total urinary nonprotein nitrogen was concerned. They however were unable to demonstrate any appreciable increase in the undetermined nitrogen fraction. On the other hand Walker *et al* studying urinary and plasma nitrogen partitions following severe burns were able to confirm Taylor's finding relative to the undetermined nitrogen. They also showed that the urinary creatinine contributed moderately and the creatine minimally to the rise in urinary nonprotein nitrogen. The ureic acid fraction remained relatively constant.

As in the case of fractures, there is not complete unanimity of opinion as to the constancy of the phenomenon under discussion. For Cope *et al* found, following burns, only a small negative nitrogen balance which "was easily correctible by increasing the protein and caloric intake. Electrolyte studies also revealed a constantly positive

potassium and phosphate balance. These authors surmised that the discrepancy between their work and the studies of other workers was on the basis of the absence of infection in their series. It occurs to the writer that this difference might be explained by the extent of the burns. Cope's patients were victims of the Coconut Grove fire and suffered mainly from inhalation burns. Examination of the protocols reveals that the patients with extensive surface burns, as a rule, lost from 20 to 30 gm. of nitrogen a day in the urine. The balance in these cases became positive only after 10 or 12 days with nitrogen intakes of approximately 20 gm. The writer has no explanation for the positive electrolyte balances.

Urinary cortinlike substances and 17 ketosteroids have been studied after burns as well as after fractures. Cope *et al* found the 17 ketosteroid excretion to be raised for from 3 to 7 days after burns, then subnormal until the end of convalescence. Forbes *et al* confirmed these observations as did Brown *et al* (8, 9, 10, 11, 12, 13). The latter workers found the sequence of events in urinary cortinlike substance excretion the same after burns as after fractures. Usually as pointed out after fracture, the urinary excretion level of this substance returned to normal approximately with the nitrogen balance. However these authors described some cases in which the cortinlike substance remained elevated in the urine long after nitrogen equilibrium was attained under the dietary factors described.

The important problem of nutrition as it relates to the urinary nitrogen excretion after burns has been investigated by Taylor *et al* (96). He found that 3,000 calories and from 100 to 125 gm. of protein per day were often necessary to correct the negative nitrogen balance in their burn patients. These findings were confirmed by Abbott *et al*.

Experimental burns have yielded much the same information as have the clinical studies. Meyer *et al* (75) using dogs found a negative nitrogen balance lasting 15 days after the burn on diets similar to those of the control period. They noted a rise in urinary nitrogen without change in the urinary nitrogen partition and without change in the total fecal nitrogen. These findings were generally substantiated by Clark *et al* in rabbits. However in these animals the percentage of ammonia and creatinine remained constant but that of urea as well as of creatine was increased. No increase in undetermined nitrogen was found.

Clark *et al* studied the blood urea concentration after burns in rats and rabbits and found as would be expected, that it was elevated. These observations were confirmed and extended by Rosenthal

et al who found that in the case of burns of 50 per cent lethality there was only a slight rise in the undetermined nitrogen fraction comparable to the rise in the amino nitrogen fraction which returned almost to normal levels in 12 to 16 hours after the burn. On the other hand burns of 100 per cent lethality caused markedly increased undetermined nitrogen values in the blood. The amino nitrogen levels were elevated but to a minor degree. Both changes persisted until death after 12 to 16 hours.

Other forms of trauma. The forms of trauma giving the metabolic response of greatest magnitude are burns and fractures but it is well recognized that operative procedures, soft part injuries (12) bedrest (27) infections (41) and other surgical or medical conditions may under certain circumstances produce much the same metabolic events as do burns and fractures.

Brunschwig *et al* (14) and Brunschwig and Corbin (15) extensively studied postoperative nitrogen excretion. During the immediate postoperative period the giving of intravenous nitrogen in amounts which before operation would be sufficient to maintain a positive nitrogen balance, was found usually to result in a negative balance. These authors noted further that as a rule the patients who were subjected to the most extensive operative procedures showed the larger loss of nitrogen in the urine per unit of nitrogen intake.

The work of Werner and of Mulholland *et al* is not in agreement with the previous statements. The former worker presented the data on 8 cases and referred to 17 others, mostly intra abdominal operations. Of 2 partial gastrectomy patients on whom complete nitrogen excretion data were presented one showed a positive balance on nitrogen intakes which in the normal subject would just be sufficient to maintain nitrogen equilibrium. The other patient showed a negative balance with a high urinary nitrogen excretion. Werner concluded that with a sufficient intake of protein the nitrogen balance can be kept positive throughout the immediate postoperative period. It is the writer's belief that this conclusion cannot be drawn from the inadequate evidence presented. Then too the lack of preoperative evaluation of the patient's nutritional status is an important omission in the light of the observation of Browne *et al* (11) regarding the failure of the catabolic response in debilitated individuals. The latter workers, Mulholland *et al* report the maintenance of a positive nitrogen balance after partial gastrectomy with oral alimentation. Again these patients were subjected to partial gastrectomy for peptic ulcer. In view of the fact that their nutri-

tional status was unknown, and considering the marked individuality in response to trauma, the significance of the 4 cases presented is in doubt.

Well and Browne and Venning *et al* (98, 99) have shown that, as after burns and fractures, the excretion of cortinlike material in the urine is increased after surgical procedures. A peak is reached at the third to fifth day and following this the excretion gradually declines to normal values. According to Forbes *et al* the 17 ketosteroid output also follows the general pattern found in the previously described traumatic conditions.

COMMENT

Before comment is made on the concepts herein presented the shortcomings of the present methods of studying protein metabolism should be discussed. Clinical investigations have been carried out with emphasis on the nitrogen balance, and by means of urinary partition studies, plasma nitrogen concentrations, electrolyte balance studies, and hormone metabolic excretion levels. Therefore, it should be recognized that the knowledge gained thereby is of limited value and interpretations as to the actual tissue nitrogen metabolism may be too deviously drawn. The fact that these same methods, with the emphasis distributed in the same way are relied upon quite extensively in the laboratory investigation of the phenomena in question forces one to accept the conclusions derived therefrom with the same qualifications.

Largely through the efforts of Cathbertson are we acquainted with the sequelae of major fractures. Cathbertson has shown in patients and experimental animals, an increase of urinary nitrogen, sulfur, potassium, and phosphorus, the nitrogen increase being due mainly to an increased urea fraction. Accompanying these changes, but without the establishment of a definite correlation, is an increase in the urinary excretion of cortinlike substance and a brief increase followed by a rapid drop to subnormal, of the 17 ketosteroid urinary output. There appears to be some disagreement as to the efficacy of a large amount of protein with or without a high caloric diet, in returning the nitrogen balance to positive, but there is definite agreement that after a major trauma such as a severe burn, raising the nitrogen intake to approximately 25 gm. daily with a comparable caloric increase does not alter the over-all balance to a significant degree.

The metabolic results of thermal burns with a few exceptions are similar to those following fracture. In the experimental animal the response to burning is more marked and more prolonged than

that to fracture. In the only electrolyte study after burn no negative balance was noted, and some of the investigators noted a brief rise of the undetermined nitrogen fraction in the urine and blood. After uncomplicated surgical procedures and other miscellaneous damaging stimuli, the over-all nitrogen balance is similar to that following burns and fractures, as is the urinary excretion of cortinlike substance and 17-ketosteroids.

One of the more important factors controlling the metabolic changes after damage is obviously the extent of the damage. An equally important influence is the nutritional state of the individual at the time of the trauma. The debilitated individual has been noted by Browne *et al* (12) to be much different in his response to trauma, burns, fractures, and surgical procedures from the normal. These workers have failed to obtain rises in urinary nonprotein nitrogen following damage in these cases. This phenomenon has been noted in experimental animals on low protein diets by Munro and Cuthbertson, Cohen and Browne, and Madden and Clay. In addition to failing to show the increase in urinary nonprotein nitrogen, these individuals do not have an increased urinary cortinlike substance excretion in response to damage (9).

The implications of these metabolic phenomena are far from clear. The prevailing opinion is that the reaction is concerned with the transport of proteins and minerals from elsewhere in the body to the wound or any other area in need of protoplasmic building blocks. However if this reaction is prolonged it leads to protein depletion with all its consequences. This opinion is based on a rather insecure foundation. Sanders and Garrison placed adult rats on a 1 per cent protein diet for from 10 to 13 days before producing an abdominal wound and beginning sodium ricinoleate administration intramuscularly. This agent is an irritant producing an increase in urinary nonprotein nitrogen in normal rats and, theoretically, the reaction described for burns and fractures. These authors found that the experimental animals had wounds of higher tensile strength after the fifth postoperative day. They did not determine the urinary nonprotein nitrogen levels. It has been shown that a period of low protein feeding prevents the protein metabolic response to damage; therefore, their results are invalidated. Ravdin *et al* found that sodium xanthine and other irritants producing the so-called catabolic reaction protected rats' livers from injury by chloroform. They postulated that the split protein products set free from tissue by the irritant protected the liver cells from the chloroform damage.

It has been suggested that the body initiated a generalized catabolism to provide the wounded area with some missing substance found in low concentrations in normal tissue. In other words, there existed a relative deficiency at the site of the damage. Accordingly Croft and Peters supplied rats with added amounts of methionine in their diets after scalds and failed to find the usual increase in total urinary nitrogen. However Meyer *et al* (74) using dogs, and Chanutin and Laudewig using rats, have attempted to repeat these studies without success.

A further important practical consideration concerns itself with the use of high protein diets following burns and other trauma. If this additional nitrogen is excreted almost quantitatively in the urine, its value is open to question. Using the method of self-selection feeding in rats during infection and after burns Holt and Kajda have shown that the animals tended to avoid protein food while suffering from the depressing effects of the infection. With recovery they tended to eat a higher protein diet than normally. These workers also mentioned work with burns using this same method. Immediately after the burning the rats usually chose a high protein diet.

This conflicting evidence is not particularly clarifying and until new methods are developed to study this enigma its solution will remain obscure. Until this time comes, it is the consensus that tested methods of clinical management should prevail.

PATHOGENESIS

Within the last several years the writings of Selye (91, 92) have provided much of the impetus behind the attempt at elucidation of these phenomena. He has combined and integrated much previous work and added some of his own to formulate a concept concerning a response to nonspecific trauma which he calls the adaptation syndrome. This syndrome concerns itself with the development of a resistance to various damaging stimuli and the various underlying chemical and structural alterations taking place. The protein metabolic response to damage is included by Selye in the adaptation syndrome as but a small part of it. It is largely through his influence that the eyes of investigators in this field have been focused on the endocrines in general and on the adrenal gland in particular as playing a part in the etiology of the nitrogen metabolic response to trauma. However before we examine the evidence concerning the role of the adrenal and other endocrine glands, it behooves us to deal with the nonendocrine aspects of the problem.

Source of nitrogen. Cuthbertson *et al* (25) wondered at the source of the nitrogen lost after trauma. He studied the response in rats after fracture and found that the changes in weight of the quadriceps of the injured limb did not account for the total loss in protein as represented by the excessive nitrogen excreted in the urine. To attempt to elucidate the problem further he also studied the sulfur phosphorus, and potassium balance in the same group of animals. He found that the ratio of excess sulfur and phosphorus to excess nitrogen in the urine was approximately that found in muscle tissue. It was his impression that the potassium to nitrogen ratio was higher than that of muscle tissue which discrepancy he explained by postulating a change in cell permeability related to the healing process. He based this supposition on the work of Andresen and Tammam who found an increase of the potassium concentration in the tissue fluids of aseptic wounds.

Further work has not particularly clarified the situation. Howard (47, 48, 49) studied potassium and nitrogen balances following abdominal operations, hypophysectomies, fever from malarial inoculations, and fractures. He could not demonstrate a correlation between the potassium to nitrogen ratio in muscle and the ratio of excess potassium to excess nitrogen in the urine following these procedures. In 1943 Albright stated that the potassium, sulfur, and phosphorus to nitrogen urinary ratios approximated that of normal muscle tissue during the first and second half of fasting or following thyroxine administration. But in 1945 Reifstein *et al* found that the calculated potassium balance on the basis of the nitrogen balance did not agree with the actual balance after operative trauma. They postulated this discrepancy to be due to an error in calculating the nitrogen to potassium ratio of muscle tissue or a difference in the nitrogen to potassium ratio of catabolized tissue as compared with anabolized tissue.

The inference gathered from this work, although conflicting at times, seems to point to the general body protein stores as the source of the excess nitrogen excreted following nonspecific damage.

Influence of adrenal cortex. As stated previously, the work of Selye (92) has pointed to the endocrine glands as playing an important part in the response to nonspecific trauma. This worker showed that in response to damage there was hypertrophy of the adrenal glands, atrophy of the thymus and lymph nodes, a set pattern of blood chemistry and electrolyte changes and changes in the specific and nonspecific resistance to the trauma. These changes were not reproducible in the adrenalectomized or hypophysectomized animal.

These observations suggest a relationship on a pathogenetic basis of the protein metabolic response to damage to the foregoing observed changes.

This concept is especially pertinent in the light of the influence of the adrenal gland on protein metabolism. Britton and Silvette were among the first workers to demonstrate metabolic abnormalities following adrenalectomy finding low blood and tissue carbohydrate levels after this procedure. Evans found that fasting phlorhizinized adrenalectomized rats without treatment excreted 25 per cent less nitrogen than did normal rats under similar conditions. This observation has since been confirmed by Harrison and Long without the use of phlorhizin.

As a corollary to these findings, Long *et al.* (67) showed that adrenocortical extracts increased the glycogen content of the liver, the urinary sugar and the glycogen of the body fluids with a concomitant increase in urinary nitrogen either in normal or adrenalectomized animals. These same workers failed to increase the nitrogen excretion in the urine of partially pancreatectomized animals on a 53 per cent protein and 11 per cent carbohydrate diet with 10 c.c. of cortical extract or 313 mgm. of corticosterone. Ingle (52, 54, 57) has investigated the results of 17-hydroxy 11-dehydrocorticosterone, 17-hydroxycorticosterone and corticosterone administration to rats. All of these compounds, if given in sufficient doses, were capable of inducing a glycosuria and an increase in nitrogen excretion. In the case of 17-hydroxy 11-dehydrocorticosterone the increase in nitrogen excretion did not appear to be sustained.

In a review by Long (64) of the possible locus of action on protein metabolism of the cortical hormones, most of the evidence came from tissue slice studies. Among these was the demonstration by Jimenez Diaz of lower rates of deamination in the kidneys of adrenalectomized cats. Fraenkel-Conrat *et al.* (38) have noted a decreased liver arginase concentration in adrenalectomized rats which was restored to normal by corticosterone, 11-dehydrocorticosterone and 11-dehydro 17-hydroxycorticosterone. These compounds were found also to increase the arginase content of livers in normal rats. The same workers (39) have demonstrated that hypophysectomy leads to a marked decrease in liver arginase, and that adrenocorticotrophic hormone reverses this change.

This considerable amount of evidence implicates the adrenal cortex and its secretions as being partially responsible for the control of protein metabolism and the excretion level of urinary nonprotein nitrogen. This control remains to be proved especially in the light of the following evidence.

It was shown by Wells and Kendall (102) that phlorhizinized rats developed a lower urinary sugar output when adrenalectomized. However these same rats were able to utilize fed casein to maintain a stable glucose urinary output after adrenalectomy. These workers suggested the possibility of differential control of the metabolism of food and body proteins. Ingle and Oberle (55) found that force-fed and fasted, saline-treated, adrenalectomized rats excreted as much nitrogen in the urine as did controls. They postulated that the rat has mechanisms regulating nitrogen balance other than the adrenocortical hormones and that adjustment in the metabolism of proteins can occur without the adrenals. These results are not contradictory to those of Evans or Harrison and Long as their animals were not allowed access to saline.

Sayers and Sayers *et al.* (88) have shown that the rat's adrenal cholesterol content is lowered and then rises in response to injection of the adrenotropic hormone of the anterior pituitary. The same response curve was noted after damage to the organism such as exposure to a cold environment. Exposure to low barometric pressures (63) the injection of B chloroethyl vesicants (69) and hemorrhage (90) were followed by the same response which was abolished by hypophysectomy. Furthermore, the same changes were found in the ascorbic acid content of the adrenal gland (70, 89, 90). Following hypophysectomy the total adrenal cholesterol is lowered, but not the concentration (Sayers *et al.* 88). In all of these papers the lowering of adrenal cholesterol and ascorbic acid with subsequent increase was interpreted first as depletion of the original reserves and subsequent increased formation by the hyperactive gland. Sayers and Sayers *et al.* (88) correlated these chemical studies with the histochemical appearance of the adrenal gland, suggesting that the ascorbic acid and cholesterol curves were compatible with the change in amount of lipid-staining substances in the adrenal cortex.

The recent development by Talbot *et al.* of a colorimetric, quantitative test for the 11-oxy corticosteroids has provided Hemphill and Reiss with a technique with which to measure the 11-oxy corticosteroid level of the adrenal tissue and blood. These workers followed the adrenal and blood content of these substances in rats after adrenocorticotrophic hormone administration and after exposure to cold. After the injection of adrenocorticotrophic hormone they found a transient decrease followed by a steady increase in the adrenal content and a steady increase without decrease in the blood. In the case of cold exposure the adrenal

content did not decrease but increased steadily for 72 hours. These results are compatible with those of the vitamin C, cholesterol and histochemical studies previously mentioned.

The control of the adrenal gland is therefore exercised by the anterior pituitary gland through its elaboration of the adrenocorticotrophic principle. Ingle *et al* (54) have produced an atrophy of the adrenal cortex by the continued administration of cortical extract. These same workers showed that the administration of adrenocorticotrophic hormone prevented this same atrophy. Furthermore, the usual adrenal hypertrophy was not found following 12 hours of exercise as a stressing agent if cortical extract was given previous to these observations, showing that pretreatment with corticosterone prevents the usual fall in adrenal ascorbic acid and cholesterol of rats exposed to cold or subjected to unilateral adrenal ectomy. They postulate that exposure to stress increases the tissue utilization of cortical hormone lowering its level in the blood which in turn brings about activation of the anterior lobe of the pituitary gland.

Long and Fry (66) and Long (65) have recently presented evidence concerning the control of this system by epinephrine. These workers found that the intramuscular injection of this agent into rats caused a decrease in adrenal ascorbic acid in the normal but not in the hypophysectomized animal. A just criticism of the assumption that epinephrine might play a part in the metabolic response to damage is the fact that this drug may be just another nonspecific agent. In answer to this criticism Long (65) points out that recently it has been demonstrated that the administration of the drug increased the height of thyroid epithelium (82) increased the blood level of thyrotrophic hormone in normal dogs (93) and rabbits, it caused ovulation in a significant number of animals (72).

In the preceding papers we have seen the thesis developed that the adrenocortical hormones are intimately concerned with nitrogen metabolism and that the administration of these hormones in excessive amounts can cause an increase in urinary nonprotein nitrogen. Evidence has been cited showing that certain changes take place in the adrenal cortex following the exposure of the organism to a damaging situation and the mechanisms involved in controlling these changes have been reviewed.

Recently however there has been published some evidence which tends to make the foregoing

speculations rather insecure. Toby and Noble and Ingle *et al* (58) studied the response to lumb clamping and fractures in adrenalectomized rats. These animals failed to show the expected rise in urinary nonprotein nitrogen following trauma but if they were given a constant dose of cortical extract which in itself failed to increase nitrogen excretion the rise in urinary nonprotein nitrogen occurred. The adrenal glands, therefore seem to be necessary for the mechanism to function but it can go on without an increased secretion from them because in the animals whose adrenals were replaced by a constant parenteral dose of cortical extract trauma was attended by the usual consequences in nitrogen excretion.

Role of the thyroid gland. The action of the secretions of the thyroid on the urinary nitrogen excretion are familiar namely an increase in nitrogen excretion follows the administration of thyroxine. Wells and Kendall (103) from studies on phlorhizinated and adrenalectomized thyroidectomized rats, were under the impression that the adrenal cortex and thyroid acted synergistically in their control of nitrogen excretion. The pioneer studies of Dougherty and White (28) have been most informative. These workers demonstrated that mice caused a regression of lymphoid tissue. Since then they (29, 30) have demonstrated the control of circulating lymphocytes and antibody titer exhibited by the adrenal cortex and the corticotrophic hormone of the anterior pituitary. Recently they (106) have added greatly to our knowledge of the control of nitrogen metabolism by experiments on fasted mice. In these animals they showed that the adrenal cortex seemed to control the rate of lymphoid nitrogen depletion and the thyroid the rate of carcass nitrogen depletion. These conclusions were reached on the basis of the following observations: adrenalectomized mice lost no lymphoid nitrogen when starved for 48 hours and cortical steroid administration to these animals increased the loss above that in intact animals. Thyroidectomized mice which had fasted for 48 hours showed no loss of carcass nitrogen and adrenalectomized and thyroidectomized mice did not show a loss of lymphoid or carcass nitrogen on fasting for 48 hours. To show that the secretions of these two glands seemed to regulate the ebb and flow of protein between various body systems the following evidence was offered in adrenalectomized fasted mice there was an actual increase in lymphoid nitrogen in thyroidectomized fasted mice there was a larger decrease in lymphoid nitrogen than in the intact fasted mice. Apparently the secre-

tions of the thyroid gland tend to promote the movement of carcass nitrogen to the lymphoid structures. Furthermore, these workers offered evidence which tended to support the opinion of Wells and Kendall (103) that the adrenal cortex and the thyroid act synergistically in the control of protein metabolism. Noting that the adrenalectomized, fasted, steroid-treated mice lost more carcass nitrogen than did the adrenalectomized fasted mice they suggested that the adrenocortical hormones might augment the thyroid in its control of carcass nitrogen. It might also be noted at this point that the difference of the means of these two groups of animals was equal to between 2 and 3 times the standard error of the difference and so is of questionable significance. In addition, when it is noted that the adrenalectomized, fasted animals did not lose as much carcass nitrogen as the intact, fasted animals (difference of means slightly less than 3 times standard error of differences) these observations become more important.

The significance of these observations is at once evident, the only question being that of the application of findings in a fasting mouse to the phenomenon of increased nitrogen excretion following trauma in the rat and human being. Perhaps the necessity of the presence of the adrenocortical hormones for the protein metabolic response to fracture (58) limb clamping (97) and for the diabetogenic activity of stilbestrol (53) is based on the potentiation of the thyroid gland in its control of carcass nitrogen. In any case these concepts await their application to the deranged protein metabolism following damage.

Basal metabolic rates have been measured by Cuthbertson (32) in patients after fractures which produced increases in urinary nitrogen excretion. These studies do not clarify the situation, however as examination of the author's data reveals no marked change in oxygen consumption when the nitrogen excretion returns to normal, nor any high rates of oxygen usage in cases uncomplicated by fever. The possibility exists that the actions of thyroxine on protein metabolism and on oxygen consumption are dissociated. It is of interest to note that Dunlop found dinitrophenol to increase the basal metabolic rate but not the nitrogen excretion in the urine.

Other possible influences It is also interesting to speculate on the role played by other possible influences on the protein metabolic response to trauma. Of particular importance is the effect of shock per se on protein metabolism. Wilhelm (107) has recently outlined the subject most thoroughly. Kline (59,60) demonstrated that a sustained increase in the output of amino acids from

the muscles and an increase in the uptake of amino acids by the liver occurred in the dog after non-fatal hemorrhage. Furthermore, Engel and Engel (31) found that there was a high rate of urea accumulation in the blood for 3 hours following paracental aminoacid infusion in the nephrectomized rat which had been subjected to a nonfatal hemorrhage. In nephrectomized controls the urea blood levels were high only for the first hour. The fact that the livers of these animals were able to form urea from the excessive amino acid nitrogen offered is supported by the evidence of Russel *et al.* and Wilhelm *et al.* (108). They found the rates of oxygen uptake, deamination, and urea synthesis by liver slices, and the concentrations of ammonia, amide, and amino nitrogen in liver tissue were nearly normal in the rat after nonfatal hemorrhage.

These same workers, however, have shown that the liver shows some impairment of deamination and urea synthesis in the more severe hemorrhages. Furthermore, Engel *et al.* (33) have shown that hepatic anoxia due to arrest of the circulation *in vivo* leads to progressive failure of the liver to remove amino acids from the blood. If the period of anoxia was longer than 40 minutes, the 3 hour recovery period, during which the circulation was re-established, led to only partial return of normal function. The explanation of these phenomena may be based partly on the observations of Greg and Alexander who found destruction of co-carboxylase, cozymase, and aflaxazine adenine dehydrogenase and inactivation of the protein moieties of amino acid oxidase and lactic dehydrogenase following severe hemorrhage.

Harkins and Long found a marked increase in plasma amino nitrogen following a severe burn in the rat. There was a concomitant increase in the whole blood ammonia nitrogen without change in liver ammonia nitrogen, or liver amide nitrogen, and without impairment of the oxygen uptake of liver slices. The question is still open, therefore, as to the part played by these mechanisms in human burns, with or without shock. In any case, hepatic anoxia might possibly explain the high undetermined nitrogen excretion levels in the burn patients of Taylor *et al.* (93). Perhaps the undetermined nitrogen represented some cellular protein breakdown product which was excreted in the urine because it was unable to be deaminated and converted to urea by the damaged liver.

The role of various proteolytic enzymes in human burns is also open to question. Beloff and Peters have demonstrated a decrease in a skin proteinase following burns. Zamecnik *et al.* have found an increase in peptidase activity of serum and lymph coming from a burned area in the dog.

Leach *et al* have called attention to the zone of damaged cells surrounding the severely burned area as a possible site of origin of toxins which in view of the preceding work, might be interpreted to include proteolytic enzymes. Any further statement as to the application of these findings is, of course, hazardous. However it might be pertinent to the discussion to mention that the presence of a proteolytic enzyme liberated from the burned area, and the effects of burn shock on liver metabolism might be added to the effects of the endocrine imbalance and explain the difference noted between the response to burns and to other damaging stimuli.

The reaction of debility The clinical observations of Browne *et al* (12) that the debilitated patient fails to show an increase in urinary nitrogen following fracture and also does not exhibit the increase in urinary cortinlike substances is of interest but is unexplained by any of the foregoing considerations. Neufeld *et al* studied blood non-protein nitrogen following nonspecific trauma as applied in a revolving drum. Rats previously exposed to this trauma, and which appeared to be resistant to its effects in terms of mortality failed to show the rise found in the untreated animals. This finding is in accord with those of Selye (92) as to the nonspecific resistance of animals exhibited in the stage of resistance of his adaptation syndrome. It might perhaps be thought that the failure of debilitated patients to show the catabolic reaction might be explained on the basis of this acquired resistance to long-continued non-specific trauma.

Of interest to this discussion also are the effects of various diets on the experimental animal's response to trauma. Munro and Cuthbertson observed that after feeding a protein-free diet to rats until steady nitrogen excretion levels were reached fracture was not attended by the usual rise in urinary nitrogen. This finding was interpreted by them to mean that the excessive output of nitrogen which follows injury arises from storage protein and not from essential tissue substance. Cohen and Browne repeated these observations but found that, although fracture was unattended by a rise in nitrogen excretion lowering of the caloric intake was followed by a prompt increase. They therefore concluded that failure to respond to the fracture was not due to exhaustion of the supply of readily available protein. These workers then administered 1 c.c. of adrenocortical extract five times a day to these animals on the low protein diet and again no rise in urinary nitrogen occurred. This last finding is, of course, of extreme importance in view of the work of Ing

(58) and Toby and Noble, who found that the giving of constant amounts of adrenocortical extract to adrenalectomized animals allowed a rise in urinary nitrogen following fracture. One might infer from these experiments that the effect of the alteration of the diet was not on the adrenal *per se* but rather on the substrate of the adrenal hormones, or the other factor or factors influencing the protein metabolic response to damage, or both. The work of Mulinos *et al* (77-78) is also of importance. These workers found adrenal weight loss and decreased adrenal vitamin C concentrations in rats chronically underfed. As this adrenal weight loss was larger on a percentage basis than the loss in body weight, and because the histologic picture of the adrenal cortex was similar to that following hypophysectomy they postulated that chronic underfeeding produced a pseudohypophysectomy. It is not unreasonable to think that the pseudohypophysectomy if produced, might alter the functions of other endocrine glands namely the thyroid. This mechanism could conceivably be the basis for the peculiar reaction to trauma of the debilitated individual.

COMMENT

Further investigations dealing with the differentiation of the response following fracture from that following burns would be profitable. Electrolyte balance studies after burns in the experimental animal in an attempt to confirm Cope's clinical observations and total urinary nitrogen studies following burns in the adrenalectomized animal would be of interest. The elucidation of the relative parts played by the thyroid and adrenal glands in response to trauma would be of great aid. The suggestion by White and Dougherty that the thyroid might serve to funnel protein from the general body tissues to the lymphoid structures which are then broken down and yield an increased nitrogen excretion in the urine is of fundamental importance. As it is well known that lymphoid tissue is high in uric acid the following points are quite pertinent. Babad using adrenocortical extract in rats, and Forsham *et al* (36) using 11-dehydrocorticosterone acetate in patients found that the excretion of uric acid was more consistently raised in the urine than was the total nitrogen. Forsham *et al* (37) found this to be true also following adrenocorticotrophic hormone administration. In spite of the fact that the rare uric acid excretion studies after trauma (24, 95-100) do not show this fraction of the total nitrogen to be particularly increased relative to the others, this concept is indeed an attractive one and bears further scrutiny.

tions of the thyroid gland tend to promote the movement of carcass nitrogen to the lymphoid structures. Furthermore these workers offered evidence which tended to support the opinion of Wells and Kendall (103) that the adrenal cortex and the thyroid act synergistically in the control of protein metabolism. Noting that the adrenal ectomized, fasted, steroid-treated mice lost more carcass nitrogen than did the adrenalectomized, fasted mice they suggested that the adrenocortical hormones might augment the thyroid in its control of carcass nitrogen. It might also be noted at this point that the difference of the means of these two groups of animals was equal to between 2 and 3 times the standard error of the difference and so is of questionable significance. In addition when it is noted that the adrenalectomized, fasted animals did not lose as much carcass nitrogen as the intact, fasted animals (difference of means slightly less than 3 times standard error of difference) these observations become more important.

The significance of these observations is at once evident, the only question being that of the application of findings in a fasting mouse to the phenomenon of increased nitrogen excretion following trauma in the rat and human being. Perhaps the necessity of the presence of the adrenocortical hormones for the protein metabolic response to fracture (58) limb clamping (97) and for the diabetogenic activity of stilbestrol (53) is based on the potentiation of the thyroid gland in its control of carcass nitrogen. In any case, these concepts await their application to the deranged protein metabolism following damage.

Basal metabolic rates have been measured by Cuthbertson (22) in patients after fractures which produced increases in urinary nitrogen excretion. These studies do not clarify the situation, however as examination of the author's data reveals no marked change in oxygen consumption when the nitrogen excretion returns to normal, nor any high rates of oxygen usage in cases uncomplicated by fever. The possibility exists that the actions of thyroxine on protein metabolism and on oxygen consumption are dissociated. It is of interest to note that Dunlop found dinitrophenol to increase the basal metabolic rate but not the nitrogen excretion in the urine.

Other possible influences. It is also interesting to speculate on the role played by other possible influences on the protein metabolic response to trauma. Of particular importance is the effect of shock per se on protein metabolism. Wilhelm (107) has recently outlined the subject most thoroughly. Kluge (59,60) demonstrated that a sustained increase in the output of amino acids from

the muscles and an increase in the uptake of amino acids by the liver occurred in the dog after non-fatal hemorrhage. Furthermore Engel and Engel (32) found that there was a high rate of urea accumulation in the blood for 3 hours following peritoneal aminoacid infusion in the nephrectomized rat which had been subjected to a nonfatal hemorrhage. In nephrectomized controls the urea blood levels were high only for the first hour. The fact that the livers of these animals were able to form urea from the excessive amino acid nitrogen offered is supported by the evidence of Russell *et al.* and Wilhelm *et al.* (108). They found the rates of oxygen uptake, deamination, and urea synthesis by liver slices, and the concentrations of ammonia, amide, and amino nitrogen in liver tissue were nearly normal in the rat after nonfatal hemorrhage.

These same workers, however have shown that the liver shows some impairment of deamination and urea synthesis in the more severe hemorrhages. Furthermore, Engel *et al.* (33) have shown that hepatic anoxia due to arrest of the circulation *in vivo* leads to progressive failure of the liver to remove amino acids from the blood. If the period of anoxia was longer than 40 minutes, the 2 hour recovery period, during which the circulation was re-established, led to only partial return of normal function. The explanation of these phenomena may be based partly on the observations of Greg and Alexander who found destruction of co-carboxylase, coenzyme, and allomaxine adenine nucleotide and inactivation of the protein moieties of amino acid oxidase and lactic dehydrogenase following severe hemorrhage.

Harkins and Long found a marked increase in plasma amino nitrogen following a severe burn in the rat. There was a concomitant increase in the whole blood ammonia nitrogen without change in liver ammonia nitrogen or liver amide nitrogen, and without impairment of the oxygen uptake of liver slices. The question is still open, therefore, as to the part played by these mechanisms in human burns, with or without shock. In any case, hepatic anoxia might possibly explain the high undetermined nitrogen excretion levels in the burn patients of Taylor *et al.* (95). Perhaps the undetermined nitrogen represented some cellular protein breakdown product which was excreted in the urine because it was unable to be deaminated and converted to urea by the damaged liver.

The role of various proteolytic enzymes in human burns is also open to question. Beloff and Peters have demonstrated a decrease in a *skin* proteinase following burns. Zamecnik *et al.* have found an increase in peptidase activity of serum and lymph coming from a burned area in the dog.

The significance of the changes in 17-ketosteroid output in the urine after trauma is far from clear. Mason *et al* and Forsham and Thorn *et al* (37) have recently reported increased excretion of both 17-ketosteroids and 11-oxyteroids in the urine following the administration of purified anterior pituitary corticotrophic hormone to man. Whereas, following trauma when the corticotropin secretion of the anterior pituitary hormone is thought to be increased, the 17-ketosteroid output falls as the 11-oxyteroid output rises.

These are just a few of the defects in our complete understanding of this subject. Perhaps with their elucidation this complex group of events which *in toto* make up the protein metabolic response to trauma will be better correlated. Then too, with the recent advent of the laboratory use of isotopes, perhaps new and important information regarding the internal machinery of the body following damage will become available. This information would be a preferable basis for assumptions concerning this phenomenon than are balance studies.

SUMMARY

Following fractures, burns, operations, and other types of trauma there occurs an increased excretion of urinary nonprotein nitrogen. In the majority of the clinical studies after burns, the increase is found in the undetermined nitrogen fraction, whereas after experimental fractures, the urea-ammonia fraction accounts for most of the increase. Associated with this phenomenon is an increased urinary excretion of adrenal corticosteroid substances and a decreased excretion of the 17 ketosteroids.

The assumption that the source of this nitrogen is general body tissue is supported by the observations that the weight lost by a fractured limb of a rat does not account for the excessive nitrogen excreted in the urine, and that following fractures there occurs an increased excretion of the intracellular electrolytes.

The various explanations of these phenomena are centered around a hypophyseal-adrenocortical-thyroid mechanism. It is suggested by studies in adrenalectomized rats that the adrenal glands are necessary for the response following fracture but that this response can go on without an increased secretion from these glands. Determinations of carcass and lymphoid nitrogen of fasting mice suggest that the secretions of the thyroid are important in conjunction with those of the adrenal cortex in controlling nitrogen depletion. Whether this mechanism operates following trauma in human beings is at present unproved.

CHART II — ANALYSIS OF FAILURES

Type of original graft	Reason for failure	Type of secondary graft	Time for clinical union	Comments
Rb	Resorption and decalcification of graft	Osteoperiosteal	—	Residual bony defect too extensive for osteoperiosteal graft. Ilac graft finally used successfully to produce union
Rb	Resorption and decalcification of distal end of graft	Tibial block and osteoperiosteal	weeks	None
Rb	Resorption and decalcification of graft	Osteoperiosteal	—	Residual bony defect too extensive for osteoperiosteal graft. Ilac graft finally used successfully to produce union
Rb	Resorption and decalcification of graft	Osteoperiosteal	—	Residual bony defect too extensive for osteoperiosteal graft. Ilac graft finally used successfully to produce union
Ilac	Inadequate immobilization of proximal fragment	Osteoperiosteal	weeks	None
Ilac	Infection	Ilac	—	Failure of union at distal end of second graft, probably due to inadequate circulation, since graft was placed under skin and subcutaneous tissue obtained from neck chest ribbed pedicle Osteoperiosteal feeder graft finally produced good union
Ilac	Inadequate immobilization of proximal fragment	Osteoperiosteal	weeks	Original ilac graft extended from right to left tarsus
Ilac	Failure of union at distal end of graft, cause unknown	Osteoperiosteal	7 weeks	None
Ilac	Infection probably due to Kirschner wire used to stabilize symphysis	Osteoperiosteal	weeks	Both the original graft and the osteoperiosteal "feeder" were bilateral to replace major loss of the body
Tibial block	Unknown	Ilac	weeks	Bilateral graft
Osteoperiosteal	Infection	None	—	Patient transferred to another plastic center before secondary graft could be done

Defects of facial contour were corrected by the use of dermal fascial fat grafts obtained from the abdomen or by cartilage implants.

The authors conclude that the important factors affecting bony union are (1) complete absence of residual infection (2) adequate splinting (3) adequate preoperative and postoperative care and (4) a meticulous surgical technique.

FREDERICK W. MERRIFIELD, M.D., D.D.S.

EYE

Ectropion Corrected by Bridge Pedicle Graft

H. B. STALLARD, *Brit J Plast Surg* 1948 1 77

The author presents the report of a case of severe ectropion of both lower lids with the everted palpebral conjunctiva hypertrophied and infiltrated with plasma cells in the subconjunctival connective tissue. The eversion and inflammation of the lower lids had been present for 8 years. Excision of a wedge-shaped piece of the tarsal plate and overlying palpebral conjunctiva had been performed on the ectropion of the right lower lid 3 years previously with complete cure employed by the author in this case is described.

1. The everted conjunctiva was excised after incision at the junction of healthy and diseased conjunctiva along a line above and parallel to the lower fornix carried around the medial and lateral canthi and along the posterior line of the lid margin. The excision was carried down to the tarsal plate and subconjunctival tissue was removed with the conjunctiva.

2. The remaining palpebral conjunctiva was entirely undermined.

3. An incision was made in the lower lid parallel to its margin, at a distance of 4 mm. extending from a point medial to the inner canthus to one beyond the outer canthus, the points being at the medial and lateral bases of the upper lid bridge pedicle. The incision was undermined 2 mm upwards and 3 mm downwards. The healthy conjunctival margin was sutured to the lid margin with horizontal mattress sutures of No. 6 black silk, knots being placed on the skin surface.

4. A paramedian tarsorrhaphy was performed with No. 1 white silk vertical mattress sutures passed through squares of oil silk.

5. A bridge pedicle from the upper eyelid, wide enough to fill the raw area in the lower lid was swung forward and then downward and sutured in place. The bridge pedicle supplied extra skin for the shortened lower lid and a sling for holding it in its correct position.

6. The incision in the upper lid was undermined and sutured. The tarsorrhaphy was left for 3 months and then divided.

A photograph which was taken 9 months after operation on both lower lids shows a satisfactory functional and cosmetic result.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Mandibular Bone Grafts. W. B. MacCOMBER, R. A. SHEPARD and V. E. CROOK. *Plast Reconstr Surg* 948, 3: 370.

The authors present the results of their experience with mandibular bone grafts in a plastic center to which men with facial injuries were assigned. A large number of battle casualties with injuries to the mandible were admitted. Several types of bone grafts were used, and the successes and failures in some 92 cases are recorded.

Tribute is paid to the maxillofacial teams which operated in evacuation, field, and general hospitals in overseas theaters.

The concepts of minimal débridement, adequate early repair of facial wounds, and adequate immobilization and maintenance of normal occlusal relationships were invaluable in the long range care of these patients.

An average period of 3 months had elapsed between the time of injury and admission of the patient to the center and in practically all cases localized bone and soft tissue infection was present, with extraoral or intraoral drainage, or both.

Early definitive care consisted of (1) adequate oral hygiene, (2) control of infection with penicillin and sulfadiazine, (3) incision for drainage and conservative sequestrectomies, (4) conservative but adequate treatment of fractured and infected teeth, (5) adequate splinting and immobilization of the jaw, (6) trismus therapy and (7) high caloric and vitamin therapy.

Late definitive treatment consisted of (1) replacement of lost soft tissue, and (2) restoration of continuity of the mandible. An average period of 9½ months elapsed between admission of the patient and bone grafting, and a minimum of 3 months freedom from infection and drainage was insisted upon before proceeding with the operation. In soft tissue replacements, 2 months were allowed for stabilization of local circulation.

CHART I.—TYPES OF GRAFTS USED

Type of graft	Number used	Interval between injury and graft	Average time for clinical union	Failure of union
Osteoperiosteal	36	months 5-7	weeks 10	
Iliac crest			12	2
Rib	5		11 ½	
Thiell block		10		
Total	41			

Evaluation of tibial rib and iliac grafts. Osteoperiosteal grafts were obtained from the tibia, and used for minimal defects of 0.5 cm. or less. They were used as primary grafts and also as "feeder" grafts in cases in which there had been failure of union or resorption of a previously placed rib or iliac graft. Infection caused failure of one primary graft, and the "feeder" graft failed to produce union in 3 cases.

Combination grafts of a block of cortical bone from the tibia, overlaid with an osteoperiosteal graft, were used in defects of moderate size not involving the symphysis or the angle. Nine such grafts were used, with but one failure.

Rib or iliac crest grafts were used for all large bony defects of the mandible, the choice of graft being a relatively personal preference. Of 35 rib grafts, 4 failed to produce union because of resorption of a part of the graft with replacement by fibrous tissue.

Grafts from the ilium provide a good source of cancellous bone for replacement of mandibular defects. In 22 cases, only 5 failed to provide union.

Operative technique. Nasotracheal anesthesia was used routinely. Adequate exposure of operative sites, designed to fully expose the defect and the proximal and distal fragments, was considered essential.

Superficial scar tissue was mobilized, scar tissue over the bone fragments or in the defect was completely excised. Special attention was given to the preparation of the proximal and distal ends of the bone. The development of active bleeding of bone ends over as large a surface as possible is emphasized. The bone ends were beveled, or mortised joints were used. Tantalum wire was used for fixation. The control of bleeding by the ligation of vessels was considered essential, and prevented the occurrence of postoperative hematomas. Care was taken to avoid oral communication and wound closure was accomplished by the use of subcutaneous and cutaneous sutures of 5.0 and 3.0 catgut. Occasionally 24 hour superficial drains were used and pressure dressings were applied routinely.

Postoperative care is emphasized. The authors believe that constant observation is necessary for 24 to 48 hours, and aspiration to clear mucous secretions. Nurses trained in the postoperative care of these patients are a boon.

Penicillin and sulfadiazine are administered routinely for one week and a high caloric diet is started as soon as it can be tolerated. The first dressing is done on the fourth or fifth postoperative day.

Following satisfactory completion of the bone graft, the development of sulci in the oral vestibule may be necessary to facilitate the construction of dentures. This procedure was accomplished by means of Z-plastics or skin grafts over stent molds.

CHART II—ANALYSIS OF FAILURES

Type of wound	Reason for failure	Type of secondary graft	Time for clinical cure	Comments
LB	Resorption and decalcification of graft	Osteoperiosteal	—	Residual bony defect too extensive for osteoperiosteal graft. Ilac graft finally used successfully to produce union.
RB	Resorption and decalcification of distal end of graft	Tibial block and osteoperiosteal	weeks	None
LB	Resorption and decalcification of graft	Osteoperiosteal	—	Residual bony defect too extensive for osteoperiosteal graft. Ilac graft finally used successfully to produce union.
RB	Resorption and decalcification of graft	Osteoperiosteal	—	Residual bony defect too extensive for osteoperiosteal graft. Ilac graft finally used successfully to produce union.
Ilac	Inadequate immobilization of proximal fragment	Osteoperiosteal	weeks	None
Ilac	Infection	Ilac	—	Failure of union at distal end of second graft, probably due to inadequate immobilization, since graft was placed under skin and subcutaneous tissue obtained from neck. Best tubed pedicle osteoperiosteal "fender" graft finally produced good union.
Ilac	Inadequate immobilization of proximal fragment	Osteoperiosteal	weeks	Original Ilac graft extended from right to left radius.
Ilac	Failure of union at distal end of graft, cause unknown	Osteoperiosteal	7 weeks	None
Ilac	Infection, probably due to Kirschner wire used to stabilize symphysis	Osteoperiosteal	weeks	Both the original graft and the osteoperiosteal "fender" were bilateral to replace a major loss of the body.
Tibial block	Unknown	Ilac	weeks	Bilateral graft.
Osteoperiosteal	Infection	None	—	Patient transferred to another plastic center before secondary graft could be done.

Defects of facial contour were corrected by the use of dermal fascial-fat grafts obtained from the abdomen or by cartilage implants.

The author concludes that the important factors effecting failure are: (1) complete absence of residual infection; (2) adequate splinting; (3) adequate preoperative and postoperative care; and (4) a meticulous surgical technique.

EYE

Ectropion Corrected by Bridge-Pedicle Graft

H. B. STALLARD, *Bull. U. S. A. Surg.* 1945, 1

The author presents the report of a case of severe ectropion of both lower lids with the everted palpebral conjunctiva hypertrophied and infiltrated with plasma cells in the subconjunctival connective tissue. The eversion and inflammation of the lower lids had been present for 5 years. Excision of a wedge-shaped piece of the tarsal plate and overlying palpebral conjunctiva had been performed on the ectropion of the right lower lid 3 years previously, with complete failure to correct the deformity. The operative procedure employed by the author in this case is described.

1. The everted conjunctiva was excised after incision at the junction of healthy and diseased conjunctiva along a line above and parallel to the lower fornix carried around the medial and lateral canthi and along the posterior line of the lid margin. The excision was carried down to the tarsal plate and subconjunctival tissue was removed with the conjunctiva.

2. The remaining palpebral conjunctiva was entirely undermined.

3. An incision was made in the lower lid parallel to its margin at a distance of 4 mm., extending from a point medial to the inner canthus to one beyond the outer canthus; the points being at the medial and lateral bases of the upper lid bridge pedicle. The incision was undermined 2 mm. upwards and 3 mm. downwards. The healthy conjunctival margin was sutured to the lid margin with horizontal mattress sutures of No. 6 black silk, knots being placed on the skin surface.

4. A paramedian tarsorrhaphy was performed with No. 1 white silk vertical mattress sutures passed through squares of oil silk.

5. A bridge pedicle from the upper eyelid, wide enough to fill the raw area in the lower lid, was swung forward and then downward and sutured in place. The bridge pedicle supplied extra skin for the shortened lower lid and a sling, for holding it in its correct position.

6. The incision in the upper lid was undermined and sutured. The tarsorrhaphy was left for 3 months and then divided.

A photograph which was taken 9 months after operation on both lower lids shows a satisfactory functional and cosmetic result.

JOSEPH S. DYRLAKI, M.D.

Atrophía Gyrate Choroides et Retinae. JOWAN SAEBO *Brit J Ophth* 1913, 32, 824.

In analysis of the 30 previously reported cases of choroideremia and gyrate atrophy reveals no essential difference between them, and Saebo concludes they are the same entity. He presents a thorough study of 4 additional cases in brothers ranging in age from 27 to 46 years who came from a family of 9 children. Evidence of consanguinity was absent, nor was the condition present in a descendant nor in three generations of ascendants. The mother aged 70, had normal eyes except for white atrophic halos around the optic discs.

The fundus picture in the 4 brothers was strikingly uniform and symmetrical in both eyes, the only variation being due to the progress of the disease. The optic discs and retinal vessels were unaffected. The macular region was represented by a reddish island which was surrounded by glistering white atrophy. Within this island were scattered pigment dots, most densely set within the macula proper. With age this area became reduced until merely a grayish-brown patch remained the zone of atrophy widened and the choroidal vessels going from macula to periphery decreased both in number and caliber. The pigment disappeared from the atrophic zone being deposited along the borders. In all these cases, there was a fairly normal chorioretinal rim, the crystalline lenses were clear and a typical annular scotoma was seen.

The symptoms are first light blindness, present from early youth, inconvenience later from the reduced field of vision and eventually a lessening of central acuity which may be reduced to light perception at the age of 40. The color sense remains normal. Myopia has been found in three-quarters of all cases reported.

This familial condition indicates a recessive mode of heredity. JAMES E. LEBENSON, M.D.

The Prognosis of Sarcoma of the Choroid. J. B. WILSON *N Z Med J* 1913, p. 25, Supp.

Hamilton reports 1 case of choroidal sarcoma from his personal practice in Southern Tasmania which has been watched for years or more. He agrees with Martin Jones that malignant cells in the venous outlets from the globe do not necessarily denote a bad prognosis. Of his 7 patients with extensions into the sclera 4 are still alive.

He hazards the opinion that in early excision the growth may be less encapsulated than somewhat later. Since von Hippel found that excision in the pre-glaucomatous stage resulted in a mortality of 25 per cent while excision in the glaucomatous stage produced a mortality of 19 per cent.

JAMES E. LEBENSON, M.D.

EAR

Otosclerosis in Childhood. WILLIAM McKENZIE. *J Lar Otol Lond* 1913, 6, 66.

The author reports the results of fenestration performed in 3 cases of otosclerosis in which the history

of hearing impairment began in childhood. In his preliminary discussion he states that at the Deafness Clinic of the Middlesex Hospital, 8 patients of a total of 300 suffering from otosclerosis gave a history of deafness before the age of 15 years.

In the experience of the author the diagnosis of deafness in children is difficult because the child does not complain of deafness, he cannot remember hearing well and so has no standard for comparison. The parents usually complain of disobedience and inattention in the child rather than deafness. However he believes that the history depends on the accuracy of the parents' observation.

Cardinal points of diagnosis of otosclerosis in childhood are a family history and a noticeable deafness for some years becoming deaf without earache or otorrhea, in contrast to a history of repeated deafness with colds and the absence of a profound deafness in the presence of infected otitis media. The majority of cases of perceptive deafness can be ruled out by the presence of normal speech and by the fact that perceptive deafness in children does not increase steadily.

In the realm of objective testing, the tests with tuning forks yielding a negative Rinne for 256 and 512 cycles with a profound loss of hearing, suggest otosclerosis. Another test used is the valve amplifier and if a deaf child speaks normally and can understand speech with a valve amplifier the diagnosis is conductive deafness. According to the author the air conduction audiogram shows a characteristic curve corresponding to that which may be expected in young people with otosclerosis.

The author believes, however, that the diagnosis of otosclerosis is so difficult in a child that the distinction from middle ear deafness due to adenoids may be impossible. In all his cases the postnasal space was examined and adenoids were removed in the course of investigation.

As to making the difficult decision about fenestration the author states that it must be made by the parents and the otologist and the author's advice in each case was for operation.

Case 1 was that of a child 1 year of age who had a 2 year history of deafness which was not improved by tonsillectomy and adenoidectomy and subsequent inflation of the eustachian tubes. In the speech frequencies the hearing in the right ear was 35 decibels and in the left ear 53 decibels. At fenestration on the left ear the stapes was found to be fixed. Three months after operation the speech level in the left ear was 20 decibels a gain of 33 decibels.

Case 2 was also one of a girl 12 years of age with the complaint of deafness since the age of 7 years and a history of otorrhea in both ears 6 months before examination lasting 2 weeks. There had been no improvement following tonsillectomy and adenoidectomy elsewhere 6 months previously. The hearing levels in the speech frequencies were 40 decibels in the right ear and 48 decibels in the left ear. The stapes was fixed at fenestration on the left ear. The postoperative audiogram at 1 month

showed a speech level of 33 decibels a gain of 15 decibels

Case 3 was a patient 22 years of age who was first seen because of deafness of 1 year's duration at the age of 12 years. Removal of adenoid remnants followed by eustachian tube inflation had produced no improvement. The preoperative audiogram showed a speech level of 27 decibels in the left ear and 40 decibels in the right ear. A fenestration operation was performed on the right ear and the stapes was found to be fixed. The postoperative audiogram at 8 months showed a speech level of 23 decibels a gain of 17 decibels.

In conclusion the author states that fenestration has improved the hearing in each case although it is too early to say whether this improvement is permanent.

EUGENE L. DERLACKI, M.D.

NOSE AND SINUSES

Columella Reconstruction MORTIMER H. SHAW and STEPHEN R. FELL, *Brit J Plast Surg* 1948, 1: 111

The authors present a report of the plastic reconstruction effected in a case of nasal deformity resulting from syphilis. The deformity was an extensive course of specific treatment in 1940. The following destructive changes had occurred in the nose: (1) the columella was represented by a thin bridge of scar tissue; (2) the tip of the nose to the right of the midline was drawn backwards into a deep cleft and was adherent to the remains of the nasal septum; (3) the cartilaginous septum had been almost entirely destroyed with a resultant large perforation; (4) the lining of the vestibule of the nose and alae was scarred and the mucous lining of the nose was destroyed and replaced by scar tissue.

The reconstructive surgery was carried out in stages as follows:

Stage 1 Through an oronasal opening made in the upper buccal sulcus the whole skin covering of the nose was freed from the septal remains and from the pyriform opening. The resulting raw surface was grafted by a thin dermatome graft from the arm on a stent mold which overdistended the cavity. This was replaced by an acrylic mold at the tenth day dressing.

Stage 2 Twenty three days later under brachial plexus block a tubed pedicle 4.5 cm. by 3 cm. was raised on the dorsal aspect of the left hand over the finger and between metacarpals to the thumb and index. The defect in the hand was filled by a Thiersch graft.

Stage 3 Thirty five days later under local anesthesia the columellar remnant was excised and the proximal end of the tubed pedicle from the hand was implanted under the nasal tip. The hand was maintained in position by "handle bar" attachment between a plaster of paris headcap and a plaster cuff on the left wrist. The nose was supported by an acrylic "plumper" on two curved bars attached to an upper dental cap splint with a central locking plate.

Stage 4 Seventeen days later the columellar implant was detached from the hand under local anesthesia. The rest of the procedure was done under general anesthesia. The columellar graft was implanted in the upper lip over the anterior nasal spine. The oronasal opening was closed after excision of the excessive portion of skin graft by suturing the buccal mucosa. The nose was supported by the extraoral appliance with the two acrylic plumpers.

Stage 5 Three months later under general anesthesia a bone graft from the iliac crest was inserted through a tip incision between the covering skin and the lining graft of the nasal cavity extending to the glabella after denuding the nasal bridge of perosteum. A plaster slab splint was applied and the supporting appliance discarded.

An illustration shows the present appearance of the patient with the final scar excision between tip and columella yet to be performed.

EUGENE L. DERLACKI, M.D.

Osteoma of the Frontal and Ethmoid Sinuses. II BRUNNER and I. G. SPIESMAN, *Ann Otol Rhinol* 1948 57: 714

The authors present 4 very complete case reports of frontal or ethmoid sinus osteomas. The findings in these cases prove that in the paranasal sinuses (1) osseous tumors occur which bulge into the sinuses and are covered by the sinus mucosa; (2) in elderly individuals particularly they may remain small and may cause no symptoms and should therefore be called osseous hyperplasias or exostoses rather than neoplasms; (3) in younger individuals however they may become very large and form typical osteomas with more severe symptoms depending upon whether the tumor invades the orbit and causes diplopia, or whether it extends upward and backward to invade the brain.

The authors believe that evidence of extension of these lesions should be waited for but that an osteoma which appears to be growing should be removed surgically at once because osteomas of the paranasal sinuses may destroy surrounding tissue not only by an increase in the size of the tumor but also by the formation of mucocoeles from obstruction of the nasofrontal duct. There appear to be no definite signs or symptoms which would indicate when the osteoma has extended to the dura.

The 4 cases presented include (1) an elderly individual with localized osteoma of the frontal sinus which was asymptomatic and did not increase in size during a 5 year period; (2) a 17 year old white male with an osteoma of the frontal sinus which had extended down into the orbit and was successfully excised surgically; (3) a 34 year old white male with an osteoma of the left ethmoid and the sphenoid sinuses, which extended upward and backward, breaking through the dura of the anterior fossa and causing a malacia of the base of the frontal lobe and death from meningitis (by exposing the brain to infection from the nasal cavity); (4) a 49 year old white male with an osteoma of the frontal sinus ex-

tending posteriorly to erode the dura of the frontal lobe, with superficial necrosis of the brain, and a large intracranial and cerebral pneumatocephalus.

Mandibular Fractures in Children. GEORGE W. M. TITMUS and THOMAS V. MAGRUDER, JR. *J. Pediatr. S. Louis*, 94:3, 33-40:5.

The management of mandibular fractures in children presents unusual difficulties not found in similar fractures in adults. This is because the deciduous teeth, the 6 year molars and the permanent incisors make very poor anchors for intermaxillary wiring. There is little to be found in the literature or in authoritative text books concerning the management of mandibular fractures in children. Skeletal fixation is of little value because of the danger of inserting pins into tooth buds. In uncomplicated cases without much displacement, a head cap with an elastic bandage under the chin or a canvas aviator's helmet with the same elastic bandage may be effective. However in cases in which there is wide separation of segments necessitating considerable traction and very firm fixation the authors have found open reduction with direct wiring of the bone with tantalum wire to be the best procedure. With this method of treatment, strict asepsis and postoperative protection with penicillin to avoid infection are important, as well as the observance of special care to prevent the occurrence of any damage to the tooth buds of the permanent teeth.

WILLIAM K. WRIGHT M.D.

PHARYNX

Associated Symptomatology of Diseases of the Epipharynx. WALTER H. THEOBALD. *Ann. Otol. Rhinol.* 94:8 57-67.

Examination of the epipharynx is too often neglected in the routine examination. It is of special importance in cases of postnasal discharge, recurrent sore throats, cough, repeated earaches, recurrent colds, hoarseness, bronchitis, unexplained fever, bloody sputum, crusting, and occipital headaches. The author reports 150 cases observed over a 2 year period in which epipharyngeal pathology was the sole apparent cause of these symptoms, exhaustive study having eliminated all other possible pathological factors. In each case the symptoms were alleviated after therapy to the epipharynx. Therapy consists of surgical removal of hypertrophied lymphoid tissue or pharyngeal bursa, if present, followed by irradiation with the 50 mgm monel metal radium applicator (Crowe technique). Local treatment consisted of the application of 5 per cent silver nitrate through the Yankauer speculum and, in cases, electrocauterization when bleeding was the predominant symptom.

Examination of the epipharynx is carried out by anterior and posterior rhinoscopy with the use of the

nasopharyngoscope, and by direct nasopharyngoscopy with the Yankauer speculum. In a few of the cases the pathology consisted of pharyngeal bursa, lymphoid hypertrophy and the presence of purulent or jellylike secretions. The author states that one should always be on the alert for the presence of an epipharyngeal carcinoma.

NECK

The Significance of the Protein Bound Blood Iodine in Patients with Hyperthyroidism. GEORGE M. CURTIS and ROY E. SWENSON. *Ann. Surg.* 94:3, 1-8-44:3.

The authors point out that much of the confusion encountered in the making of a diagnosis of so-called borderline hyperthyroidism has arisen because there are but few direct methods of measuring thyroid function itself. The basal metabolic rate is a measure of oxygen consumption which is the end result of many oxidative processes. Thus it may be altered by hyperplastic neoplastic diseases such as carcinoma or leukemia, psychiatric diseases and the menopausal syndrome. This may be an especially difficult problem when nodular goiter also is found to be present.

As a test of the qualifications of the estimation of the protein bound iodine as a diagnostic procedure, the authors have studied the relationship between the basal metabolic rate and the protein-bound iodine in patients treated with a thyroid stimulating hormone and in patients treated with a thyroid blocking drug as propylthiouracil. A direct linear relationship was observed.

A series of 178 patients with nontoxic nodular goiter was then studied. It was concluded from this study that the iodoprotein level was a better index of thyroid activity than the basal metabolic rate. Hypertension, organic heart disease, neurocirculatory asthenia, psychoneurosis, neoplasms, and adrenocortical syndromes did not result in any elevation of the iodoprotein level.

A significant relationship between the basal metabolic rate and the protein-bound iodine was found in the cases of toxic nodular goiter studied. Furthermore, the protein-bound iodine seemed to suggest the subtle development of hyperthyroidism in the nontoxic nodular group. In cases of primary hyperthyroidism a similar relationship existed between the basal metabolic rate and the protein-bound iodine, but at higher levels. This presumably means that the patients had a higher grade of hyperthyroidism.

After iodine therapy the response of the protein-bound iodine in primary hyperthyroidism differs from that in toxic nodular goiter. In the former the response followed the usual lines, while in the latter the response seemed to follow that noted following the addition of iodine to whole blood *in vitro*. The authors were uncertain as to the significance of this finding.

WILLIAM C. BECK M.D.

Complications Following Irradiation of the Thyroid Gland. R. M. LUKENS. *Ann Otol Rhinol*, 1948 57 613.

Among roentgenologists irradiation of the thyroid gland is the method of treatment indicated for exophthalmic goiter and hyperthyroidism how ever the dose must be controlled, and filtration must be properly applied. Overdosage must be strictly guarded against.

The indiscriminate use of irradiation in the attempt to cure nonmalignant diseases of the thyroid gland can be damaging to the underlying larynx and trachea. The damage done to these structures is permanent and will require a lifetime of treatment. In addition the patient is constantly in danger of death due to asphyxia.

In the 5 cases recorded, obstruction to the airway was due not only to pathological narrowing of the larynx and trachea, but to the altered secretion accumulating at the point of stenosis.

Cartilages of the larynx and trachea are susceptible to intensive irradiation. Even slight overdoses will end in disastrous perichondritis, necrosis, stenosis, or sloughing.

Clerf reported 2 cases of exophthalmic goiter in patients who had had irradiation previously, and who required emergency tracheotomies on admission to his service. The wounds sloughed because of the devitalized pretracheal tissues.

Changes taking place in the neck and trachea are not at once apparent, and x ray films are of little or no help for generally they are negative. The condition may start as a tracheobronchitis which does not clear up but progresses to a definite localized lesion. The degenerative process is slow and may not give alarming symptoms until several years later when the damage is permanent and progressive.

Epithelium desquamates and the functions of the gland are either changed or destroyed, resulting in altered tracheal secretion which is not moved readily by ciliary action and which adheres to eroded and granulated surfaces. Crusts constantly form and are attached to the damaged areas. Proliferation of granulation tissue and in some cases definite hemangiomas lesions produce stenosis. The dyspnea occurring as a result of the stenosis is markedly increased by the thick secretions and crusts collecting about the stenosed area.

In all 5 of the patients the symptoms developed after an interval of from 1 to 7 years following irradiation of the thyroid gland.

The patients complained of hoarseness, sensation of a lump in the throat, inspiratory dyspnea, wheezing, dysphagia, expectoration loss of weight and pain in the chest.

The following physical findings were observed: congestion of the laryngeal mucosa, telangiectasis and inflammation of the laryngeal mucosa, telangiectasis of the vocal cords, stenosis of the trachea, granular lesions in the tracheal walls crowded inward of the tracheal wall, viscid adherent

tracheal secretions, and crusting. Cicatrices are not a common finding only a suggestion of cicatricial tissue was present in one case.

Tracheotomy was required in 3 cases. Treatment consisted of the removal of encrustations from the trachea and larynx, the cauterization of granulations and dilating stenotic areas. The author's patients required treatment for periods of from 1 to 11 years after development of their symptoms.

EDMUND R. DONOGHUE, M.D.

The Open Approach to Arytenoidectomy for Bilateral Abductor Paralysis, with a Report of 23 Cases. DE GRAAF, WOODMAN. *Ann Otol Rhinol*, 1948 57 695.

The author presents a report of 14 personal cases and 9 cases observed by fellow otolaryngologists throughout the country.

He describes his modification of the extralaryngeal approach to arytenoidectomy in which a more open approach and a wider field is advocated for the complete removal of the articular part of the arytenoid cartilage and the fixation of the vocal cord laterally to the thyroid cartilage.

The average estimated size of the postoperative glottic chink was 4.5 mm. Most of the patients had improved voices although some had only adequate voices. There was one death among the author's own cases.

All except 2 of the 23 patients discarded their tracheotomy tubes. These 2 had adequate epiglottic chinks but refused to go without their tubes because of an anxiety neurosis.

The results obtained with this operation by several surgeons throughout the United States indicates general success of the technique described.

EDMUND R. DONOGHUE, M.D.

Further Operative Results of Carcinoma of the Larynx. TH. D. DEMETRIADES and D. IOANNOWICH. *J Lar Otol Lond*, 1948 63 613.

In an earlier publication the authors reported the results obtained following operations for carcinoma of the larynx during a period of 6 years in the clinic of the Greek Red Cross Hospital in Athens. These early results are shown in Table I.

In the present study the authors review their work from 1931 to 1947 inclusive which consists of 88 cases however only 74 operations are considered here as the last 14 patients were operated upon too recently for inclusion in the series. In a large majority of cases the disease occurred in the fifth, sixth and seventh decades of life. Among 88 cases there was but 1 female, which differs from the commonly accepted ratio of 10 males to 1 female. The intrinsic type of carcinoma of the larynx (in 53 cases) was very frequently found to be limited to the vocal cords and the extrinsic type (in 21 cases) to the epiglottis. Most of the intrinsic carcinomas showed differentiation histologically (epithelial pearls) where as the majority of extrinsic carcinomas were undifferentiated.

tending posteriorly to erode the dura of the frontal lobe, with superficial necrosis of the brain, and a large intracranial and cerebral pneumatocephalus

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Follow Up Study of Men with Penetrating Injury to the Brain. JOHN A. AITA. *Arch. Neurol. Psychiat. Chic.* 1948, 59, 511

The author has made a follow up study of 100 patients who received penetrating brain injuries during World War II. He studied these patients more than 6 months after their discharge from an Army neurological center and for periods of 1 to 2 years after the injury. These 100 patients were surgically proved to have had dural penetration and injury to the brain by shell fragments or gunshot and were taken from a series of 320 men with cranio-cerebral injuries admitted to an Army neurologic neurosurgical center in the Zone of the Interior during World War II. Most of these men arrived at the center within 6 months after injury and were hospitalized from 3 to 9 months.

At this stage of the follow up, 28 men had required further medical attention for symptoms referable to craniocerebral injury. Their chief complaints were convulsive seizures, headaches, fainting, emotional instability, anxiety and fatigue. These symptoms were of more concern than paralysis, hemianopsia, aphasia or sensory loss. All patients were receiving disability pensions and those who were receiving less than 100 per cent compensation were dissatisfied. Sixty-two men showed significant improvement. Headaches were more common among those who had them while hospitalized and those with less severe damage to the brain.

At the time of the follow-up study, 34 men had had at least one convulsive seizure; the onset of which usually began from 4 to 9 months after the time of injury.

DANIEL RUGE, M.D.

Sturge-Weber Syndrome. ARCHIBALD D. MCCOY and HAROLD C. VORLIK. *Arch. Neurol. Psychiat. Chic.* 1948, 59, 504.

The Sturge-Weber syndrome has also been named the Kallischer Dimitri disease and the Brushfield Wyatt disease for the men who described the same condition in the eighteenth century. In this condition there is a facial nevus associated with hemolateral glaucoma and an angiomatous pathologic process involving the pia mater and the cerebral cortex. The brain shows a decreased quantity of white matter and areas of calcified blood vessels which have an "angeworm" appearance. The occipital lobe is the most commonly affected area.

Symptoms of the illness are convulsions, paralysis, mental retardation and visual disturbances, and since the pathology is usually in the occipital lobe there is a homonymous hemianopsia. Other ocular symptoms and signs which occur are optic nerve atrophy, papilledema, nystagmus, unequal pupils

and congenital glaucoma. The illness progresses slowly and the life expectancy is very good.

Treatment of the disease has varied and depends more upon the surgeons than upon the variations of the disease. Both radium and roentgen irradiation have been used. Surgery has varied considerably. The authors state that Pilcher obtained a good result from an occipital lobectomy for an angioma of the occipital lobe. Others have attempted to attack the vascularity either by ligating the internal carotid artery or ligating the surface vessels of the cortex.

The authors have observed a patient with the Sturge-Weber syndrome for 7 years. He appeared to be normal at birth except for an extensive nevus of the left side of the face, neck, and left upper extremity. However, when he was 7 months of age he had his first convulsive seizure limited to the right side of the body. He did not progress as a normal child; he became weak and inco-ordinated and a glaucoma of the left eye was noted in early childhood. Examination revealed increased deep tendon reflexes on the right, pathological reflexes on the right, and a right homonymous hemianopsia. Roentgenograms of the skull revealed an angworm area of calcification in the left occipital lobe and in the left posterior fossa. The patient has had little relief from anticonvulsant drugs and there has been neither regression nor progression of the disease during the 7 years that he has been under observation.

DANIEL RUGE, M.D.

A Pneumographic Study of the Temporal Horn with Special Reference to Tumors in the Temporal Region. ERIK LINDQREN. *Acta radiol. Stockh.* 1948, Supp. 69.

It is fitting that a monograph of this kind should be written in memory of Professor Erik Lysholm of Stockholm by a former student. Part of the monograph formed the basis of a paper delivered before the Royal Society of Medicine in May 1947. The work described was carried out at the Seraphimer Hospital during the period between 1937 and 1947 through the co-operation of the department of neurological surgery under Professor Öllvecrona, the department of neurology under Professor Antoni and the department of roentgenology under Professor Lysholm.

The material consists of 137 cases studied roentgenologically at operation, and at autopsy. In general, the work consists of an anatomical description of the normal temporal horn and the roentgenological examination of the temporal horn. The work is further amplified to include a general discussion of the pathologic anatomy of expanding intracranial lesions and their effects on the temporal horn. A special and by far the largest section of the monograph portrays the effects of tumors situated in special regions, and the manner in which they cause

Laryngofissure chordectomy (1931-1937) (1931-1937)	27	10		11	7
Partial laryngectomy (1931-1937)			3	—	—
Malignant Hæjek (1931-1937)		—	—	—	100
Total	30		3	11	7
Percentage (%)		30	10	66	—

Death due to spontaneous pneumothorax after 5 years.

extrinsic and in 4 intrinsic with differentiation histologically. Ten patients, or 26 per cent, died following the operation as a result of respiratory complications. Recurrence was observed in 13 cases, or 37 per cent, in from 6 to 8 months after the operation, mostly in cases of extrinsic carcinoma which histologically did not show cell differentiation.

The percentage of 5 year cures following total laryngectomy was only 17 per cent, while the combined percentage of cures following laryngofissures and laryngectomies was 43 per cent. Complementary irradiation was administered in all cases except those in which laryngofissure was performed.

During the period when sulfonamides and penicillin were available, no postoperative deaths occurred.

Early diagnosis by biopsy is essential. The authors consider irradiation without surgical treatment, as a palliative measure only.

ERNEST D. BLOOMENTHAL, M.D.

cartilage so that its contraction would cause ascent of the larynx. During the postoperative period the patient was taught to so grimace with the lower face that the diaphragm contracted at the instant of swallowing. By this maneuver the larynx was elevated and the patient was trained to swallow. It has now been more than 2 years since the operation and there has been no occasion to have recourse to the stomach tube. Swallowing is sufficiently satisfactory that the patient has been able to work in construction camps and partake of the more or less rough food which is available.

This work is well illustrated with several drawings and diagrams, illustrating not only the surgical technique but also the various phases and mechanisms of normal and abnormal deglutition.

HOWARD H. LANDER, M.D.

SPINAL CORD AND ITS COVERINGS

Surgical Experiences with Extramedullary Tumors of the Spinal Cord. FRANCIS G. GRANT. *Ann Surg* 94:5, 8-679.

This communication deals with a group of tumors namely the intradural, extramedullary and fibroblastic tumors as well as with their diagnosis, localization and surgical removal.

Since 1924 108 tumors of this type have been recorded in the Neurosurgical Service of the University and Postgraduate Hospital of the University of Pennsylvania. Of these 108 tumors 78 were found in females and 30 in males an unexpectedly high incidence of this type of tumor in women. The average age was 45.5 years, the youngest 10, and the oldest 78. Twenty-four of these tumors were in the cervical area of the cord, 70 in the thoracic area, 6 in the lumbar cord and 8 involved the cauda equina. The author states that a lumbar puncture with the application of the Queckenstedt test is an essential part of the study of any spinal cord lesion. If a tumor is suspected and if the hydrodynamic reactions and

chemical studies of the spinal fluid are not entirely normal, oil should always be introduced into the subarachnoid space of the spinal canal. It appears that oil is the most active means of reaching a level diagnosis.

In the group of cervical cord tumors, 6 lesions were situated at the level of the foramen magnum. In 3 instances the tumors were so nearly intracranial that cerebrospinal fluid circulation was impaired and a choking of the discs was reported. Three fatalities occurred in this group.

The question of operating upon the completely paralyzed patient is pointed out by the author. Sixteen patients (7 in whom the tumor was located in the cervical area and 9 in whom the tumor was located in the thoracic area) had total spastic paraplegia of the legs, loss of sphincter control and a complete or almost complete sensory loss below the level of the tumor. In the cervical group of tumors (7) the period from the onset of symptoms to the operation averaged 22 months and the period of complete paralysis averaged 10 weeks. In the thoracic group of tumors (9) the average time of duration of the symptoms was 26 months, and of complete paralysis 6 weeks. Yet all these patients made complete recoveries, those with cervical lesions in an average time of 18 months after tumor removal and those with thoracic lesions after 14 months. All have resumed work. Thirteen other patients were completely paralyzed and showed no postoperative improvement. It seems evident, therefore, that a patient with a spinal cord tumor who has been completely paralyzed for 2 months has better than an even chance for recovery if the tumor can be removed without additional damage to the spinal cord.

As regards mortality and morbidity in this group of 108 patients, 6 had postoperative deaths, 44 were completely cured and 13 were completely paralyzed (5 of the latter are known to be dead).

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Primary Rib Tumors. RALPH A. DORFNER and DEAN E. S. MARCY *J. Thorac. Surg.* 1948, 17, 690.

Primary rib tumors present no clinical character but are not found in similar tumors occurring elsewhere in the skeletal system. Because of their location, they do present certain diagnostic problems and surgical considerations not found in tumors elsewhere. Pain and tumor are the most reliable and symptoms. Persistent pain is the more reliable and constant finding since tumor may not exist. Pain often develops before a mass is recognizable either clinically or roentgenographically. Wide excision including resection of the periosteum underlying pleura, and adjacent muscles is the treatment of choice for all primary rib tumors.

Seven cases of primary rib tumors in patients operated upon at the State University of Iowa Hospital from 1934 to 1946 are reported. These include a recurrent chondroma, a fibrosarcoma, a chondrosarcoma, an osteochondroma, a fibrous dysplasia, a hemangioma, and an osteoid osteoma.

Fifty five cases of primary rib tumors reported in the literature since Sommer and Major's analysis of 81 proved cases (1942) are tabulated.

FRANK B. QUEEN, M.D.

Breast Reduction and Lactation. A. RAGNELL. *Brit. J. Plast. Surg.* 1948, 1, 99.

The author stresses the advisability of employing to the greatest possible extent an operative method based on the transposition of the nipple attached to a gland pedicle in which the milk producing capacity has been preserved on the fullest possible scale. Free grafting in conjunction with amputation on the other hand should be confined to cases in which pregnancy is out of the question or in which earlier pregnancies have not produced lactation as well as those extremely rare cases of breasts of such gigantic proportions as to prevent an ordinary mammoplasty. Pictures of patients operated upon and diagrams of operative procedures are reproduced.

JOHN J. MALONEY, M.D.

Early Diagnosis and Treatment of Carcinoma of the Breast. VICTOR RIDDELL. *Brit. M. J.*, 1948, 2, 635.

Only by reducing the delay period both for diagnosis and treatment can the mortality from cancer of the breast be reduced. Among the 170 radical mastectomies performed by the author there were already axillary metastases in 67 per cent of the patients.

A swelling in the breast of any woman in the cancer age should be considered cancer until proved otherwise. Since clinical diagnosis is fallible and the only early sign of cancer is a lump immediate

surgical exploration must be the guiding principle. There is no justification for observation of any doubtful breast lesion. The urgency for investigation is greatest in those patients in whom diagnosis is uncertain because it is with these that the chance of cure is highest.

Delay in hospital admission of suspected cancer cases is wrong too. The names of all early cancer or suspected cancer patients should be placed on a special waiting list, and such patients should be admitted immediately. Exploration of a swelling in the breast should be an emergency operation.

Clinical examination of the breast is important, and should be made with the patient's hands clasped behind the neck so that the breast is tensed to the chest wall. Sometimes if the patient raises her arms straight up above the head a dimple will appear over the affected area, or it may appear upon manipulation of a lump which otherwise appears unattached. The supraclavicular fossae should be examined from behind the patient's shoulders raised and hunched forward so as to throw the fossae into hollows.

The importance of examining for glands behind the anterior axillary fold and well below the level of the axillary outlet (over the second and third intercostal spaces) is emphasized. The frequency of glandular involvement in tumors attached to the skin and the clinical error in the diagnosis of metastasis to glands in 170 radical mastectomies are shown below.

Clinically all cases fall into one of the following broad categories:

Stage 1 tumor only stage 2 tumor and mobile axillary nodes stage 3 disease advanced with local metastasis stage 4 disease advanced with distant metastasis.

Stage 1 and stage 2 carcinomas are operable and radical mastectomy should remain the treatment of choice until a better method has been demonstrated. In certain late stage 2 cases it is recommended that

TABLE I — FREQUENCY OF ATTACHMENT OF TUMOR TO SKIN IN 170 PATIENTS

	Glands invaded	Glands free
Tumor attached to skin (74%)	74 per cent	26 per cent
Tumor unattached to skin (26%)	5 per cent	40 per cent

TABLE II — THE IMPALPABLE GLAND AND THE CLINICAL ERROR IN 170 PATIENTS

	Glands invaded	Glands free
Clinically palpable (6%)	70 per cent	30 per cent
Clinically impalpable (94%)	30 per cent	70 per cent

simple mastectomy with axillary irradiation be seriously considered—particularly if there is present a combination of two or more adverse factors such as rapid growth, wide involvement of the skin by infiltration or ulceration, age of over 65, or peripherally situated tumors of the inner hemisphere.

Stage 3 and stage 4 carcinomas are inoperable, although in special circumstances simple mastectomy may be indicated. Stage 3 comprises the group with enlarged supraclavicular nodes on either side, fixed axillary nodes, immobile or fixed axillary nodes on both sides, deep fixation of the breast to the ribs, secondary nodules of the skin, or edema of the arm. In these, symptomatic roentgen therapy is of value. Patients with stage 4 carcinoma should receive hormone therapy or roentgen therapy for symptomatic relief.

The collected operative mortality of 22 British surgeons among 11,044 radical mastectomies is cited as 1.65 per cent. The persistence of malignant cells in the axillary glands of patients given roentgen therapy alone was found by Adair in 1943 to be 92 per cent, and by Richards, in 1948 to be 65 per cent.

It is emphasized that there is no outward visible change in the appearance of the breast in early malignant disease and that lump is the only early sign of breast malignancy.

FRANK B. QUINN, M.D.

Simultaneous Evolution and Involution of Breast Carcinoma and Warts of the Mammary Region (*Évolution et involution simultanées de carcinomes du sein et de verrues de la région mammaire*). ARMAND JOSEPHAK, MARCEL DARGENT and MARCEL MAYER. *Presse méd.* 948, No. 57, 674.

This is a case report from the Centre Anticancerieux at Lyons, France.

A patient, 38 years of age, had been suffering for a year from a tumor of the superior outer quadrant of the breast without adenopathy. The lesion was first considered as Reclus' disease and treated with androgenic hormones. As the condition became much worse under the treatment, hormonal therapy was discontinued. About the same time, the patient became pregnant, the tumor grew considerably, axillary lymph nodes became palpable, and, beginning at the sixth month of pregnancy, numerous warts developed on the skin of the affected breast.

At this time the diagnosis of carcinoma of the breast was made, apparently without biopsy, and the prognosis was considered as very grave although the general condition of the patient remained good. No treatment was attempted during the pregnancy.

After delivery the tumor which at term had changed the breast into one hard solid mass, showed surprisingly fast spontaneous involution, the axillary lymph nodes decreased in size, and the warts disappeared. Lactation was maintained by the breast pump for 3 months to further the involution of the tumor. Then hemiterletochemotherapy was started. Only 3 months later, i.e., 1 year after the carcinoma

had been diagnosed, was the breast amputated. Histologic examination of the lesion revealed an atypical acanthoma.

The authors discuss the danger of hormonal treatment, especially with insufficient doses. In this case, the hormonal treatment obviously precipitated the growth of the tumor.

Furthermore, the authors emphasize the danger of any active treatment of breast carcinoma during pregnancy. A survey made at the Centre Anticancerieux proved that no treatment at all during pregnancy gives a better prognosis as to survival than any kind of treatment. After delivery lactation should be maintained by the breast pump as lactation has a beneficial effect on the involution of the tumor. Nursing, however, is contraindicated because of the carcinogenic milk factor. After cessation of the lactation, the patient should be sterilized with x-rays and only after the sterilization should the breast be amputated. Although, in this case, the time interval is too short for final judgment, the patient appeared clinically cured 1 year after the beginning of the treatment, whereas in cases actively treated during pregnancy recurrences and metastases occur in an explosive way within 6 months after delivery.

WALTER M. SOMMER, M.D.

Carcinoma of the Breast and Its Treatment. See CECIL WAXLEY. *Br. M. J.* 948, 2, 632.

In this general discussion it is emphasized that (1) the single early sign of cancer of the breast is the presence of a lump (2) the commonest cause of a lump in the breast is cancer (3) a lump must be removed in its entirety for histologic examination, (4) there is no lymphatic connection between the breast and the supraclavicular glands except via the upper intercostal spaces, and none between the axillary and supraclavicular glands. Involvement of supraclavicular glands, therefore, means that intrathoracic extension has taken place and the lesion is inoperable.

The treatment recommended depends upon the clinical stage of the disease. In stage 1 cases (tumor in the breast only) radical excision is recommended, however, if the woman is slight and the tumor is in the inner quadrant of a small breast, local excision followed by radiotherapy is advocated.

In stage 2 (tumor of the breast with skin changes, and/or involvement of the axillary glands) preoperative irradiation followed by radical mastectomy is recommended. Postoperative irradiation is reserved for patients in whom the condition has recurred.

In stage 3 (tumor of the breast and supraclavicular glands, or with fixation of the breast) palliation with roentgen therapy is the treatment of choice. In stage 4 (skeletal and visceral metastases) appropriate symptomatic therapy only is recommended.

An 81 per cent 5 year cure and a 65 per cent 10 year cure is obtained in stage 1 cases, while only a 15 per cent 5 year survival is obtained in stage 4 cases.

SURGERY OF THE THORAX

Nine cases of cancer of the male breast are reported. All patients died of mediastinal metastases. The average duration of life after operation was 30 months
FRANK B. QUEEN M.D.

Cancer of the Breast and Gestation (Cancer du sein et grossesse) JEAN PERROTIN *Presse med* 1948, 56 659.

Thirteen unpublished reports of cancer in the course of gestation and 29 collected from the literature are reviewed by the author

In 23 of the cases the condition was noticed during the pregnancy and in 10 during the lactation period and in 9 there was a recurrence of cancer with pregnancy. In 19 instances cancer was discovered in the early stages of gestation in 7 at about the fifth month and in 4 toward the end of the gestation period. Recurrences were recorded only in pregnant women before delivery and not during the lactation period. The youngest patient was aged 20 and the oldest 50 years. No correlation could be discovered between the occurrence of cancer and the number of preceding pregnancies. Approximately 50 per cent of all the women had been nursing before the development of cancer. In 20, some other lesion in the breast preceded the development of cancer viz. a benign tumor in 14 an inflammatory lesion in 4, a traumatic lesion in 1 and persisting galactorrhea in 1. Apparently pregnancy creates conditions favorable to a malignant degeneration.

Multiple nodules were found in 8 per cent of the entire group and bilateral involvement in 25 per cent.

Three aspects of cancer observed in the course of gestation may be distinguished: acute carcinomatous gestation may be distinguished as inflammatory form and mastitis, a subacute pseudoinflammatory form and a nodular form. No special pathologic-anatomic features characterize the cancer found in the course of gestation.

Radical breast amputation was employed in 15 cases. A 5 year survival period was recorded in 2. Of 7 patients treated with x rays only 6 developed recurrences within 1 year.

Radical surgery followed by x ray therapy was employed in 7 patients. The average survival period was 21 months. In 4 patients this mode of therapy was supplemented by castration. The author considers a radical mastectomy followed by x ray therapy as the method of choice. Castration which suppresses the ovarian activity and especially the secretion of folliculin deserves attention. If the malignant condition is discovered within the first 4 months of gestation and is in an early stage, a therapeutic abortion should be taken into consideration. The abortion should follow and not precede the amputation of the breast. A cesarean section should be considered if the malignant condition is discovered toward the end of the gestation period and the mother's condition is such as to create danger of the death of the fetus in utero. The section should be followed by bilateral castration.

A careful ex-

TRACHEA LUNGS, AND PLEURA

Congenital Tracheoesophageal Fistula without Esophageal Atresia CAMERON HAIGHT *J Thorac. Surg* 1948, 17 600.

Congenital tracheoesophageal fistula without other esophageal lesions is of very rare occurrence, and only some 6 to 10 cases have been reported. Atresia of the esophagus is much more common and some 500 cases of congenital atresia have been reported. During the past 12 years atresia has been observed in 63 infants at the University of Michigan Hospital, Ann Arbor, but tracheoesophageal fistula with no other lesion of the esophagus was observed in only 2. An incidence of about 3 per cent of all congenital esophageal lesions.

Diagnosis of fistula unaccompanied by atresia is difficult to establish. Esophagoscopy and bronchoscopy are useful and if the fistula cannot be seen, such as methylene blue is suggested as an aid. Roentgenography should be done in the prone position so that iodized oil will readily pass from the esophagus into the trachea. A suggestive, although not a diagnostic roentgenologic sign is the presence of an unusually large amount of air in the stomach or duodenum. Surgical closure of the fistula is recommended as soon as it is diagnosed.

A detailed case report of the closure of a congenital tracheoesophageal fistula in a 4 year old boy with no other lesion in the esophagus is given. There is but one other case reported in the literature.

FRANK B. QUEEN M.D.

The Management of the Pulmonary "Coin" Lesion E. J. O'BRIEN, WILLIAM M. TUTTLE, and JOSEPH FERRAKNY *Surg Clin N America* 1948, 28 1313.

Because of the high incidence of malignancy and inadequacy of diagnostic methods in rounded tumors or "coin" lesions appearing in the lung parenchyma, a radical attitude toward their treatment appears justified. Such tumors may be (1) malignant or benign tumors, (2) tuberculosis (3) chronic indolent abscesses, or (4) metastatic tumors. In 21 cases no definite diagnosis could be made prior to operation. One patient had inoperable carcinoma while 20 patients were subjected to resection. The diagnosis was bronchogenic carcinoma in 8 patients, sarcoma in 1 patient, tuberculoma in 8 patients, cyst in 1 patient, abscess in 2 patients and chondroma in 1 patient. No patient died as a result of the surgical procedure.

The symptoms of such coin lesions are minimal and the lesions are usually discovered during a routine or incidental roentgen examination of the chest. Of the 21 patients in this series, only 10 had symptoms related to the tumor mass: cough and hemoptysis were the most common ones.

Roentgenography, bronchoscopy and bacteriologic and cytological examination of the sputum may be entirely inadequate in establishing a diagnosis. To temporize is to waste time and perhaps life. Most

simple mastectomy with axillary irradiation be seriously considered—particularly if there is present a combination of two or more adverse factors such as rapid growth, wide involvement of the skin by infiltration or ulceration, age of over 65 or peripheral situated tumors of the inner hemisphere.

Stage 3 and stage 4 carcinomas are inoperable, although in special circumstances simple mastectomy may be indicated. Stage 3 comprises the group with enlarged supraclavicular nodes on either side, fixed axillary nodes, immobile or fixed axillary nodes on both sides, deep fixation of the breast to the ribs, secondary nodules of the skin or edema of the arm. In these symptomatic roentgen therapy is of value. Patients with stage 4 carcinoma should receive hormone therapy or roentgen therapy for symptomatic relief.

The collected operative mortality of 22 British surgeons among 11,014 radical mastectomies is cited as 1.05 per cent. The persistence of malignant cells in the axillary glands of patients given roentgen therapy alone was found by Adair in 1943 to be 92 per cent, and by Richards, in 1948, to be 65 per cent.

It is emphasized that there is no outward visible change in the appearance of the breast in early malignant disease and that lump is the only early sign of breast malignancy.

The prenatal care should include a careful examination of the breasts. JOSEPH K. NARAT, M.D.

TRACHEA, LUNGS, AND PLEURA

Congenital Tracheoesophageal Fistula without Esophageal Atresia CAMERON HIGHT, J. Thorac. Surg. 1948, 17 600.

Congenital tracheoesophageal fistula without other esophageal lesions is of very rare occurrence, and only some 6 to 10 cases have been reported. Atresia of the esophagus is much more common and some 500 cases of congenital atresia have been reported. During the past 12 years atresia has been observed in 63 infants at the University of Michigan Hospital, Ann Arbor, but tracheoesophageal fistula with no other lesion of the esophagus was observed in only 2, an incidence of about 3 per cent of all congenital esophageal lesions.

Diagnosis of fistula unaccompanied by atresia is difficult to establish. Esophagoscopy and bronchoscopy are useful and if the fistula cannot be seen bronchoscopy following a swallow of colored fluid such as methylene blue is suggested as an aid. Roentgenography should be done in the prone position so that iodized oil will readily pass from the esophagus into the trachea. A suggestive, although not a diagnostic roentgenologic sign is the presence of an unusually large amount of air in the stomach or duodenum. Surgical closure of the fistula is recommended as soon as it is diagnosed.

A detailed case report of the closure of a congenital tracheoesophageal fistula in a 4 year old boy with no other lesion in the esophagus is given. There is but one other such case reported in the literature.

FRANK B. QUEEN, M.D.

The Management of the Pulmonary Coin Lesion E. J. O'BRIEN, WILLIAM M. TUTTLE, and JOSEPH FERRANZ *Surg. Clin. N. America* 1948 28 1313

Because of the high incidence of malignancy and inadequacy of diagnostic methods in rounded tumors, or 'coin lesions' appearing in the lung parenchyma, a radical attitude toward their treatment appears justified. Such tumors may be (1) malignant or benign tumors, (2) tuberculosis, (3) chronic indolent abscesses, or (4) metastatic tumors. In 21 cases no definite diagnosis could be made prior to operation. One patient had inoperable carcinoma while 20 patients were subjected to resection. The diagnosis was bronchogenic carcinoma in 8 patients, sarcoma in 1 patient, tuberculosis in 8 patients, cyst in 1 patient, abscess in 3 patients, and chondroma in 1 patient. No patient died as a result of the surgical procedure.

The symptoms of such coin lesions are minimal and the lesions are usually discovered during a routine or incidental roentgen examination of the chest. Of the 21 patients in this series only 10 had symptoms related to the tumor mass: cough and hemoptysis were the most common ones.

Roentgenography, bronchoscopy, and bacteriologic and cytologic examination of the sputum may be entirely inadequate in establishing a diagnosis. To temporize is to waste time and perhaps life. Most

ably oiled or waxed. Small-eyed or atraumatic needles are advised. Free muscle grafts and pericardial reinforcements are suggested.

Ligature the use of metal clips, or both on branches of bleeding coronary arteries is discussed. The sternum when transected should be replaced with firm wiring. W. FORSTER MONTGOMERY, M.D.

Revascularization of the Heart. CLAUDE S. BICK. *Ann. Surg.* 94:3, 28-34.

A third method for revascularization of the heart is presented. This method consists of arterialization of the sinus. Arterialization of the coronary sinus was accomplished by grafting a systemic artery into the sinus and also by making a new branch from the aorta to the sinus with a free graft of artery or vein.

Arterialization of the coronary sinus is effective physiologically. After anastomosis has been made it is possible to ligate a major coronary artery with little or no mortality and with little or no infarction.

Various problems concerning circulation in the heart in the further study. One patient with severe coronary artery disease was operated upon. A free graft of brachial artery was placed between the aorta and coronary sinus. A fresh infarct developed in the interventricular septum probably at the time of operation. The anastomosis was patent at the time of death 1 day later. JOHN J. MALONE, M.D.

Neoplastic Metastasis to the Heart. AARO M. LEV KOWITZ. *Am. Heart J.* 94:3, 36-60.

Metastatic involvement of the heart by tumor growth is not too infrequent. The purpose of this article was to record an unusual case and to describe 5 other cases.

The first case reported was that of a 48-year-old white male who had had a history of acid gastritis of a black mole of the chest. He was first seen with numerous subcutaneous nodules. At this time the heart was enlarged, the rhythm was regular, the rate was 6 per minute, the sounds were of good quality, the blood pressure was 103/64, and there was a faint systolic murmur over the base. There was x-ray evidence of slight cardiac enlargement. Biopsy of a nodule confirmed the diagnosis of malignant melanoma. The patient died 3 days after admission. A autopsy revealed nodular infiltration over the surface of the heart and over the endocardium. Section of the heart muscle revealed extensive infiltration.

The author reports 5 additional cases, 3 of malignant melanoma, 1 case of bronchogenic carcinoma, and 1 of embryonal carcinoma of the left testicle.

The author points out that the failure to diagnose metastatic disease of the heart is the absence of any characteristic symptoms or signs. In the cases presented tachycardia, otherwise unexplained, was the only constant finding. The electrocardiogram was of no help. The author states that cardiac metastasis should be considered in any patient with malignant disease who has an unexplained tachycardia, even if their heart findings are negative.

ROBERT E. FLORENZ, M.D.

Chronic Constrictive Pericarditis Over the Left Heart Chambers and Its Surgical Relief. PART II. WHITE, FRED ALEXANDER, EDWARD D. CATHCART, and RICHARD H. SWETT. *Am. J. M. Sc.*, 94:3, 378.

Three case histories are presented of young adult males who suffered from chronic constrictive pericarditis involving preponderantly the left heart chambers and who required decortication (partial pericardiectomy) for relief. One patient died from a peripheral arterial embolism after two unsuccessful pericardial resections and an omentopexy. The 2 other patients have been greatly benefited by the removal of the pericardium from the left auricle and left ventricle.

In the 3 patients clinical evidence suggested the diagnosis of chronic constrictive pericarditis. An accentuated pulmonary second sound was present. There was cardiac enlargement involving the right ventricle, a shift of the electrocardiographic axis deviation to the right and a persistence of chronic congestion. A measurement of the pulmonary blood pressure by cardiac catheterization was an important test of the left heart chambers in 2 of the patients, and the marked elevation confirmed the constriction of the left heart chambers, which produced syndrome like that of mitral stenosis in its effect on the pulmonary circulation and the right heart.

ORVILLE F. GIBNEY, M.D.

The Surgical Treatment of the Infantile Type of Coarctation of the Aorta. JULIAN JOHNSON and CHARLES K. KIRBY. *Ann. Surg.* 94:3, 7-9.

Coarctation of the aorta may be divided into two types: (1) the infantile type in which there is an elongated narrowing at the isthmus, and (2) the adult type in which there is an abrupt constriction at or near the ductus arteriosus. Because statistics show that 66 per cent of the patients with the adult type of coarctation will die as the result of associated hypertension there seems to be sufficient indication for attempts at surgical correction.

The first operation for coarctation was done by Crafoord of Stockholm in 1944.

The authors report operations on 3 patients with coarctation of the aorta of the infantile type. In all 3 the constricted area extended over a distance of several centimeters. In each it was impossible to perform the type of operation used by Crafoord or Gross, so attempts were made (successful in 2 of the 3) to turn the left subclavian artery down to bridge the defect.

The cases are reported in detail. The first patient obtained a good result with return to normal of the blood pressure in the upper extremities. The second patient's systolic blood pressure did not fall although the diastolic pressure returned to normal.

It was necessary to abandon the operation on the third patient because of the friability of the vessels due to atheromatous changes.

In the infantile type of coarctation, excision of the area and end-to-end anastomosis will probably never

be feasible. If the subclavian artery is to be used the question will always arise as to whether the blood flow is materially increased by the procedure.

The problem of age and the decision to operate present several problems. If done too early there is some question as to whether the site of anastomosis will grow with the patient. If it is done too late the vessel wall may be so friable as to make suture hazardous. The period between the ages of 12 and 14 years would seem to be the most satisfactory one for operation.

W. FOSTER MONTGOMERY, M.D.

ESOPHAGUS AND MEDIASTINUM

The Treatment of Congenital Atresia of the Esophagus from a Technical Point of View. PH. SANDBLOM. *1st chir scand.*, 1948 97 35

Congenital esophageal stenosis is less common than congenital atresia. Although most instances of esophageal atresia are associated with tracheoesophageal fistula and are quite similar, esophageal stenoses take various forms and occur at all levels of the esophagus. The two conditions are probably caused by different developmental defects, atresias arising at an early stage when the fetal lung buds are separating from the fore gut and stenoses occurring at a later period when the digestive canal has become a solid epithelial structure. Stenoses are believed to develop much in a manner comparable to intestinal atresias.

Findlay in a collected series of 80 cases classified four types of esophageal stenoses:

1. Narrowing of the lumen or constriction of the esophagus for a short distance. This is attributed to failure of opening of the esophageal wall in development.

2. A membranous diaphragm believed due to a failure of proper channelization of the solid epithelial cord so that a portion of it persists as a diaphragm with a large or small opening located either centrally or eccentrically.

3. Localized fibrous or fibromuscular thickening of the wall of the esophagus of unknown etiology.

4. Spasm, a lack of proper co-ordination of the esophageal muscular activity. Cardiospasm is the most common example of this. Although some investigators have claimed a structural change in Auerbach's plexus with this disorder, the etiology in general is regarded as unknown.

Usually the proximal portion of the esophagus becomes dilated and hypertrophied, and in some instances a diverticulum may form.

Dysphagia and regurgitation are the manifestations of esophageal stenosis; the latter usually occurring in direct association with food ingestion. If food remains within the esophagus inflammatory changes often occur with exacerbations of symptoms. Acute aggravation of the symptoms is also found in catarrhal conditions which cause swelling of the mucous membranes.

In the very pronounced stenoses, symptoms may be present from birth, but in less severe cases they

do not arise until the child commences to take solid food. In those cases in which symptoms begin at a later date, it is probable that a less severe stenosis exists which is increased by some inflammatory process in later life. In these instances it is difficult to establish definitely whether the stenosis is of congenital origin.

When esophageal stenosis is suspected a barium swallow and endoscopy should be done. Differential diagnosis includes traumatic and chemical stricture, a congenitally short esophagus (which may be distinguished by the presence of gastric mucosa within the chest below the point of narrowing), and cardiospasm with hypertrophy of the musculature proximal to the site of the lesion.

Early treatment involves a dietary regimen with avoidance of solid foods and dilatation by bougies sometimes complemented by division of an obstructing membrane at endoscopy. Such treatment as this is effective only in those cases with a membranous diaphragm, and usually does not appreciably help a fibromuscular stricture or long area of narrowing. In these cases surgical intervention is indicated. This is easiest when the stricture is located very high or low. As early as 1892 Brenner described a case of high esophageal stenosis in which he effected a widening of the stenosis and closure of a tracheoesophageal fistula by esophagotomy. Others have successfully operated on stenoses above the cardia by the transabdominal approach. There have been a few patients with stenoses located in the middle third who were cured by operation.

The report of a 10 month old girl who had vomited frequently since birth is given. Following an attack of pharyngitis at the age of 9 months her dysphagia increased markedly so that she was unable to swallow any food or fluids. Roentgen examination after the ingestion of barium paste showed a stenosis at the junction of the lower and middle thirds of the esophagus. The esophagus was distended both below and above this point. Because of the rigidity and firmness of this stricture, no attempt at dilatation was made, but surgical intervention was advised.

Under endotracheal anesthesia a right posterior retropleural approach was used with a vertical incision between the spine and scapula. The pleura was reflected medially and the azygos vein and vagus nerve were divided to facilitate approach to the region. At the junction of the middle and lower thirds of the esophagus there was a fibrous induration of the esophagus about 1.5 cm. in length. This was corrected by a Heineke-Mikulicz plastic procedure which consisted of making a vertical incision and closing it transversely. Before the incision was closed a sound was passed through the esophagus to ascertain that no other strictures were present. After suturing was completed saline solution was injected to determine the adequacy of the repair. The operative field was drained and the wound cavity filled with penicillin solution. On the following day a Wittel gastrostomy was done. The postoperative course was uneventful. Oral ingestion was begun on

the fourteenth day and the gastrostomy was closed 5 days later. One month after the operation semi-liquid food could be swallowed without difficulty. Roentgen-ray examination 6 months later showed a dilated wide passage at the site of the old stenosis but a marked narrowing just above the cardia. Endoscopy revealed a membranous fold at this location. This was dilated and there was complete relief of the dysphagia. Ten months after the first operation, x-ray examination showed no obstruction in the esophagus.

The author considers the retropleural approach better than the transpleural route since the dangers of an opened cavity are avoided. He advises the use of a Heinecke-Mikulicz procedure when feasible rather than an anastomosis. The testing of esophageal suture by the injection of saline solution into the esophagus under pressure is advocated. A stenosis of greater length than in the patient presented here should be resected with an end-to-end esophageal anastomosis or an esophagogastrostomy.

C. FREDERICK KITTLE, M.D.

Spontaneous Rupture of the Esophagus. JULIAN A. MOORE and JAMES D. MURPHY. *J. Thorac. Surg.* 1945, 17, 632.

The difficulties in diagnosis and surgical management of spontaneous rupture of the esophagus are illustrated in the case presented, in which the authors report a recovery. The first impression was that of a ruptured peptic ulcer and the laparotomy performed revealed no pathology. Attention was centered on the left thorax during the postoperative period and a perforated ulcer in the stomach (which was found herniated through the diaphragm) was suspected. The rupture of the esophagus was discovered at the time of the transthoracic operation for correction of the hernia and drainage of an empyema. A rent 4 cm. long was present in the anterolateral esophagus just above the diaphragm and an esophagogastroplasty was performed by means of silk sutures. A jejunostomy was used for feeding. Penicillin was given intramuscularly. The postoperative convalescence was uneventful, and roentgenograms taken 3 and 4 months following surgery showed the stomach

in the abdomen, the lung re-expanded, and a normal appearing esophagus. The patient was discharged completely recovered 5 months after the rupture of the esophagus had occurred.

The diagnosis of rupture of the esophagus is to be suspected when there is severe upper abdominal pain associated with vomiting, particularly of blood, and especially when this is accompanied with cervical emphysema and pneumothorax. Roentgen findings of a pocket of gas behind the heart are considered a diagnostic aid by the authors.

Treatment should include drainage of the thoracic cavity, jejunostomy for feedings, intravenous fluids to supplement jejunostomy feedings and adequate antibiotics. The esophagus should be repaired only when the patient's condition permits.

W. HARRISON MEEK, M.D.

Benign Pedunculated Tumors of the Esophagus. RAYMOND C. BREKLER, JAMES V. COLLINS, and MARTIN F. HALL. *Am. J. Roentg.* 1948, 60, 466.

Benign pedunculated tumors of the esophagus are rare and may be encountered unexpectedly on routine examination since symptoms may be mild or absent. Those in the upper third of the esophagus are single and arise in the region where esophageal diverticula commonly have their origin; those in the middle and distal thirds may be multiple. The single tumors which arise in the uppermost portion of the esophagus occur as a result of the greater elasticity of the esophageal mucous membrane in this region. The tumors are smooth, variable in size, and may have multiple projections. Histologically they are usually fibrolipomas. The diagnosis can be made roentgenologically if such a tumor is suspected. Occasionally the tumors present in the mouth and the diagnosis is then obvious.

A case is reported of a 70 year old male with upper esophageal symptoms of 12 years duration. The bifid pedunculated tumor could be regurgitated into the mouth and then swallowed. It was successfully removed under direct vision through the oropharynx and the patient was asymptomatic when seen 4 years later.

JEROME E. THOMPSON, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

The Treatment of Primary and Recurrent Inguinal Hernia by Skin Graft (El tratamiento de las hernias inguinales primarias y recidivadas con injerto de piel) VICENTE F. PATARO and DIEGO E. ZAVALLETA. *Dis. Med.*, B Air 1943, 20: 2350.

Irrespective of the surgical method employed hernial recurrence is high and the results for the most part are poor. The excellent results obtained even in large hernias by the cutaneous graft technique recommend its use. Indications include repair of large hernias in which there is disintegration of the anatomic elements; repair of certain primary hernias in which radical surgical cure is likely to be disappointing; recurrent hernias; and postoperative eventration.

After careful preparation of the skin an elliptical incision of the skin is made over the hernia (roughly 5 by 2.5 cm). The upper apex is squared off and the skin cut longitudinally down the center sufficiently far enough to permit the passage and enclosure of the cord. The skin is then sutured as a collar about the cord and the margins are attached to the internal muscular border to Poupart's and Cooper's ligaments and to the symphysis pubis care being taken to keep the tension uniform. The cord is consequently displaced and the skin flap constitutes the floor of the inguinal canal. The principle is the same in recurrent hernias; however the source of the graft may be remote.

In the 59 cases in which the method was employed the results were most encouraging.

STEPHEN A. ZIEMAN, M.D.
Brit. M. J. 1943, 2: 743.

A Review of Femoral Hernias. ANDREW G. BUTTERS.

The author reviews the cases of 178 patients with femoral hernia who were operated upon in the period from 1942 to 1946 at the Royal Hospital in Sheffield.

Of 10 patients all were operated upon by the low method for femoral hernia repair. There were no recurrences among the 54 male patients but 4 recurrences among the 66 females. No increased likelihood of recurrence could be demonstrated in the aged as compared with the young in relation to heavy work or chronic cough or in relation to straining. However, 7 per cent of the patients subsequently developed inguinal hernia on the same side as the femoral repair.

The chief cause for recurrence was found to be failure to remove the sac adequately. There is a tendency to transfuse the sac too low down and to omit proper cleaning of its neck to permit complete retraction through the femoral canal.

The author concludes that the low operation is suitable for almost every case and gives the most satisfactory results.

EDWARD W. GIBBS, M.D.

Repair of Femoral Hernia with a "Postage Stamp" Fascial Graft. H. A. KINN. *Brit. M. J.* 1943, 2: 745.

A method is described for the repair of femoral hernia with a fascial flap. The principle of the operation is to cut a rectangular section of external oblique aponeurosis and let the attachment to Poupart's ligament remain intact and then swing this section down so that the free margin can be sutured to the peritoneum of the pubic ramus and thus close the femoral canal by a trap door of living fascia.

The author reports on 53 repairs by this method with 2 recurrences. Two patients subsequently developed direct inguinal hernia.

EDWARD W. GIBBS, M.D.

GASTROINTESTINAL TRACT

Polypoid Adenomatosis of the Entire Gastrointestinal Tract. MARK M. RAVITCH. *Ann. Surg.* 1943, 128: 283.

Two interesting cases demonstrating polypoid adenomatosis of the entire gastrointestinal tract are reported.

The first case was that of a white male infant who was seen initially at the age of 10 months. From birth he had suffered diarrhea with numerous large stools containing unchanged food. Duodenal enzyme studies did not support a diagnosis of cystic fibrosis of the pancreas but a rectal prolapse exposed many polypoid tumors of the rectal mucosa. Gastrointestinal roentgenograms finally showed numerous polyps in the colon but none in the small intestine. At the age of 18 months he was operated upon for intussusception which was resected. Many polyps were felt in the small bowel above the intussusception and many polyps were found in the resected ileum. Death occurred 24 hours after operation. The autopsy revealed that the entire gastrointestinal tract was involved by innumerable polyps with no uninvolved areas intervening.

The second case was that of a 16 year old white girl whose history revealed that at the age of 6 she presented complaints of bloody stools, anemia and abdominal pain and at operation two widely separated intussusceptions of the small bowel both associated with polyps were reduced and the polyps excised. Another laparotomy was performed at the age of 14 for the division of obstructing bands of adhesions. Sigmoidoscopic and repeated roentgen studies of the entire gastrointestinal tract were negative. At the last hospital admission she was found to have a severe secondary anemia blood in the stools and frequent abdominal cramps. Sigmoidoscopy revealed two small rectal polyps but gastro-intestinal roentgenograms failed to reveal any polyps. At operation two large polyps were removed from

the stomach by gastrotomy a 100 cm. long segment of jejunum containing eight large pedunculated polyps was excised, and end-to-end anastomosis was performed. Recovery from the operation was smooth and the patient was discharged. An interesting feature of this case was the observation of pigmentation of the buccal mucosa.

Polypoid adenomatosis of the colon. In true polypoid adenomatosis, the colon is the seat of innumerable polyps and the disease is familial and inevitably results in the development of cancer in one or several of the adenomas. This is in contradistinction to patients who have only a few six or eight, polyps of the colon. The latter disease is not familial and the development of cancer not so certain consequently treatment can be less radical in that excision of the polyps alone will be adequate. True polypoid adenomatosis should be treated by total colectomy with a permanent ileostomy.

Polypoid adenomatosis of the small intestine. Adenomatosis of the small intestine is familial only occasionally and malignant degeneration is uncommon. It is characterized clinically by abdominal discomfort which is frequently of an obstructive nature and leads to operation for the correction of intussusception. Some of the patients have a pigmentation of the buccal mucosa, which has been found to be associated with intestinal polyps. Treatment consists of resection of the intussusception segment containing polyps. At operation, if all the polyps are in one segment, it should be resected but if the entire small intestine is involved, only the offending areas are resected.

Polypoid adenomatosis of the stomach. Polyps of the stomach may be peculiarly silent, although they may cause indigestion, melena, hematemesis, or obstruction. Malignant degeneration may be as frequent as in polypoid adenomatosis of the colon, and the two are frequently associated. Roentgenograms are frequently negative. The treatment of choice is radical gastrectomy when polypoidosis does not exist elsewhere in the gastrointestinal tract.

Polypoid adenomatosis of the entire gastrointestinal tract. This condition is rare and only a substantiated cases have been found which are similar to the case first presented in this report, in that adenomatosis carpeted the intestinal tract from the caecum to the anus. There were 1 additional cases in which each segment of the intestinal tract, beginning with the stomach had at least a few polyps. All these cases are described.

Polypoid adenomatosis of the small and large intestine. There are a number of reports of adenomatosis with this distribution of lesions. The histories combine the pain and repeated intussusception of adenomatosis of the small intestine with the diarrhea and malignant degeneration of adenomatosis of the large intestine. The condition usually is not familial. In the absence of a familial history in patients with adenomatosis of the colon the small intestine must be explored before a colectomy is performed. If adenomas are widespread and numerous the condi-

tion is therapeutically hopeless. However resection may be feasible if the tumors involve only a few bowel segments of limited extent or if only a few large polyps are scattered about. A number of these cases are described. ERNEST D. BLOOMENTHAL, M.D.

Follow Up of Vagotomy Plus Gastroenterostomy or Pyloroplasty for Ulcer. E. N. COLLINS, GEORGE CRILE, JR. and J. B. DAVIS. *Gastroenterology* 94, 111-153.

During the past 28 months the authors have studied 140 patients who have been subjected to bilateral vagotomy at the Cleveland Clinic Hospital. Of these, 129 patients have undergone bilateral transabdominal vagotomy for either a duodenal or jejunal ulcer, in addition to which some ancillary procedure, such as gastroenterostomy or pyloroplasty was added to facilitate the emptying of the vagotomized stomach.

The percentage of follow-up studies was excellent and the shortest follow-up period was 5 months, the longest 28 months, and the average 11 months. Jejunal ulcers occurring after gastric resection were not considered in this study.

The authors conclude that an experience of many years is necessary before a final appraisal of this or any other form of treatment for peptic ulcer is conclusive. They state that approximately 85 per cent of their patients with duodenal ulcer are considered to be satisfactory candidates for medical management alone. The group of patients presented in this report were those who had not made satisfactory progress on a medical regimen and were therefore subjected to surgery.

One death occurred in the entire group of 84 cases. Of the remaining 83 patients, all had intractable pain and 29 had had gastric hemorrhage as well. Eight patients had had bowel perforation, multiple in 2 and 27 patients had symptoms of pyloric obstruction. The authors conclude that in their experience the patients having complicated duodenal or jejunal ulcers have shown better results following vagotomy than a comparable series of patients undergoing gastric resection or gastroenterostomy alone, the follow-ups being made over a similar period of time.

None of the patients subjected to operation has as yet developed any objective evidence of a recurrent ulcer. No patient has developed a jejunal or marginal ulcer at the site of the gastroenterostomy or pyloroplasty. It is the feeling of these surgeons that when surgery is indicated for complicated duodenal or jejunal ulcer bilateral vagotomy plus gastroenterostomy or pyloroplasty is the procedure of choice.

EDWARD F. LEWIS, M.D.

Management of Massively Bleeding Peptic Ulcer. JOHN D. STEWART, SIDNEY M. SCHWARTZ, WILLIAM H. POTTER, and ALFRED J. MANSOYER. *Ann. Surg.* 1948, 128, 79.

The authors report their experience in the treatment of massively bleeding peptic ulcer by unmo-

diate large blood transfusions and early gastric resection. Their series consisted of 54 patients 33 of whom were operated upon and 21 of whom were treated as control cases without operation.

By early operation the authors mean subtotal gastric resection within 24 hours of admission to the hospital by acute massive hemorrhage they mean the vomiting of blood or passage of blood by rectum within one week of admission the hemorrhage being severe enough to depress the red cell count to 2.5 million per cubic millimeter or less or to reduce the circulating red cell volume to 60 per cent of normal or less. The average interval between admission and operation in the operative series was 9.2 hours. At operation a subtotal gastric resection was performed, an antecolic Hoffmeister anastomosis was made and 80 per cent of the stomach was removed. The authors do not use x rays as a diagnostic aid in these cases.

The patients operated upon received an average of 3 600 c.c. of blood as compared with 2 040 c.c. for the control group. The author emphasizes that despite such large amounts of transfused blood the hemoglobin values remained at less than 75 per cent of normal. The authors found that at the end of 24 hours 22 per cent of the administered hemoglobin had left the circulation and at the end of 15 days 35 per cent of it was missing. There was no evidence of hemolysis in these cases to explain the figures and the author concludes that much larger amounts of blood are required in the replenishment therapy of hemorrhage than is usually realized. Elevation of the blood sugar was found to be the rule in the hemorrhagic state and this seems definitely related to the diminished amount of liver glycogen found by liver biopsies on these patients.

In these series the mortality rates were as follows for the 33 patients treated surgically 5 deaths or a 15 per cent mortality and for the 21 patients not operated on, 6 deaths or a 29 per cent mortality. The author states that while the series is hardly large enough to warrant statistical analysis all the men concerned in the work believe that more lives are saved by early adequate blood replacement and gastric resection than by the nonsurgical plan of treatment.

F J LERNMANN JR., M.D.

The Prognosis and Treatment of Massive Hemorrhage from Gastric and Duodenal Ulcers. ENRIK D. BARTILIS. *Acta med scand* 1948, 131 Supp 213 p. 65

For this report 31 cases of fatal hematemesis and melena from all causes and 34 cases of fatal bleeding from gastric or duodenal ulcer or gastritis were studied. The patients were chiefly elderly or old people. The differential diagnosis is not easy in these cases and may occasionally only be made by x ray examination.

It was concluded that life threatening hemorrhage from the gastrointestinal canal should be regarded as due to a benign disease and treated accordingly until malignancy is proved. The treatment of acute gas-

tric hemorrhage should in the first instance be one of rest, confinement to bed and from the very beginning a diet rich in protein and fluid the form of which is of minor importance. The first few days one should be on the lookout for shock symptoms and if such occur give large and frequent blood transfusions as well as morphine. The salt and electrolyte balances should be carefully watched.

It is essential that the exact cause of the hemorrhage and the severity of possible complications be ascertained as soon as possible. If the diagnosis is one of gastric or duodenal ulcer and profuse hemorrhage persists for more than from 36 to 48 hours in a patient without severe complications roentgen examination should be made and operation considered particularly if the patient is in the age group between 50 to 70. In younger patients the hemorrhage will nearly always stop spontaneously.

The author is of the opinion that about one third of the patients in the present series might perhaps have been saved if the principles discussed had been carried through. The remaining two-thirds were so ill from other diseases or complications that probably no treatment would have saved them.

JOHN L. LUNDQUIST M.D.

Considerations on 941 Interventions for Gastro-duodenal Perforations (Considerazioni su 941 interventi per perforazioni gastro-duodenali). LEONIDA MANZOCCHI. *Chirurgia* 1948, 3 105

All cases of gastroduodenal perforation occurring from 1934 to 1947, at the Polyclinic Hospital in Milan are analyzed by the author. During this time 941 patients were seen and operated upon by a group of 80 surgeons. There has been an increasing number of gastric resections performed in the later years for perforated peptic ulcer. In 1939 and 1944 there were no resections performed and the mortality was 9.9 per cent and 14.8 per cent respectively. In 1947 the over all mortality was 7.5 per cent. During this year 22 or 33.8 per cent of 65 cases of perforated ulcer were resected with a mortality of 4.5 per cent. In 1934 the mortality for gastric resection in perforated ulcer was 60 per cent. The improvement is the result of treatment for shock and the use of sulfonamides and penicillin. With proper treatment for shock plus the use of sulfonamides and penicillin the period within which resection can be carried out has been extended as far as from 16 to 18 hours after perforation has occurred.

The author believes that gastric resection for perforated ulcer should be used more and more. Simple suture is resorted to only in cases in which gastric resection would not be used were it an elective procedure as in cardiacs diabetics or in cases of grave and persistent shock. The author believes that gastric resection is indicated particularly in perforation of marginal ulcer in which the mortality is less than for simple closure.

The use of drainage has been eliminated with improvement of the results especially since the advent of sulfonamides and, better still penicillin. Fewer

postoperative complications are encountered since the general use of local anesthetics has been resorted to, in preference to general or spinal anesthesia.

LOUISE J. FRODUTT, M.D.

Gastric Resection: The Schoemaker Billroth I Operation. JOHN F. HICOCK and O. TIERON. *CLAGETT Surgery* 948, 24, 6-3.

The purpose of the authors' presentation was to consider (1) the Schoemaker modification of the Billroth I operation, (2) some of the reasons why when feasible, this operation seems better than the Hofmeister Polya operation (in which the treatment of the stomach is the same but reconstruction of continuity of the intestine is different), and (3) the immediate results in 95 cases in which the Schoemaker Billroth I technique has been used.

The Billroth I types of gastric operation are the most logical in so far as reconstruction of continuity of the alimentary tract is concerned and, of these, the Schoemaker modification is one of the easiest to perform, permits wide resection when desired and yields the most nearly natural gastroduodenal continuity and relationship.

The Billroth I type of gastric operation has been much neglected in favor of the Polya forms of the Billroth II type. This neglect is largely the result of operations for duodenal ulcer for which only a Billroth II type of anastomosis is possible in most instances. However it also has resulted from the general use of the full Polya anastomosis in cases of gastric carcinoma as well as duodenal ulcer. In this procedure the straight across transection and use of the full mouth for anastomosis make a gastro-junoostomy almost mandatory. Only occasionally can a von Haberer Billroth I operation be done with such a gastric stump, and then only if the duodenum is unusually large and mobile.

It is naturally true and obvious that a Schoemaker Billroth I operation cannot always be done, because of a fixed or immobile duodenum, a fixed stomach, a stenosed or inflamed duodenum, or because resection along the greater curvature of the stomach is of necessity high. However the various duodenal and gastric features must be evaluated and considered in each case. This is well illustrated in the extreme in those cases in which esophagoduodenostomy has been possible after total gastrectomy.

From a physiologic standpoint the narrow stoma of a Schoemaker Billroth I or a Hofmeister Polya anastomosis seems better than the wide stoma of a full Polya anastomosis. The Schoemaker Billroth I anastomosis seems better than the Hofmeister Polya. The small stoma and the reconstruction of normal continuity by gastroduodenostomy seem to return the duodenum and stomach as nearly as possible to normal physiologic activity.

It might be argued that the small stoma resulting from use of the Schoemaker Billroth I or the Hofmeister Polya technique predisposes to a greater incidence of postoperative gastric retention than does the larger stoma of the posterior Polya operation.

It is possible also that this is more marked after the Schoemaker Billroth I operation than after the Hofmeister Polya.

If, however, clinical impressions as to comfort, maintenance of body weight, and degree of post-prandial distress are confirmed by factual laboratory studies (as they seem to be so far) then the order of preference, when possible, would seem established for these methods of gastric resection.

Immediate results in 95 cases in which the Schoemaker Billroth I technique has been used are given in the complete article.

The Appraisal of Patients After Gastric Resection During the War (Die Bewertung Magenresezierter in Krisenzeiten). R. BOLLER and D. MÜNSTERHAUER. *Wien. med. Wochschr.*, 1943, 95, 455.

In 1943 the authors made an attempt to contact 931 patients operated on during the period from 1916 to 1940. This group consisted of patients with non-malignant lesions of the stomach, operated on according to the Billroth II method. The Hofmeister Flosterer modification was employed nearly exclusively.

The diagnosis was ulcer in 95 per cent and gastritis in 5 per cent of the cases.

Ninety-seven patients, or 10.5 per cent, of the entire group were dead in 1943, while 633 appeared for a check-up. Sixty-eight per cent of them had had a duodenal ulcer, 23 per cent a gastric ulcer, 5 per cent gastritis, 3 per cent both a gastric and a duodenal ulcer and 3 per cent a jejunal ulcer.

The indications for operation were as follows: hemorrhages, 3 per cent perforation, 8 per cent stenosis with vomiting and loss of weight, 8 per cent. Intractable pain, a penetrating ulcer, neurotic conditions, or simply the advice of the family physician accounted for the remaining 73 per cent. In other words an absolute indication was present in only 28 per cent of the entire material.

The onset of the disease was most frequent in the third decade of life. The average period between the onset and the operation was 11 years in men and 10 years in women.

Of the 633 patients who appeared for a re-examination, 274 had no complaints. Sixty-six per cent of those who registered some complaints had disturbances of the function of the small intestine, 32 per cent had gastritis of the remaining stump of the stomach, 32 per cent had symptoms of the "little stomach," 26 per cent had hypersensitiveness to milk, and 20 per cent had biliary belching. Disturbances of fat digestion and anemia accounted for only 8 per cent. It is possible that a diet rich in carbohydrate and poor in fat and proteins was responsible for the great frequency of jejunitis.

Approximately 20 per cent of the entire material showed improvement 3 years after the operation, 37 per cent of the patients were cured and 43 per cent were not benefited. The percentage of cures was higher in the group with gastric ulcer than in that with duodenal ulcer.

SURGERY OF THE ABDOMEN

After the operation the majority of patients drifted toward professions not requiring physical effort. Only very few regained the weight that they had lost before the operation.

JOSEPH K. NARAT M D

Pyloric Stenosis Caused by the Ingestion of Corrosive Substances: Report of a Case. HOWARD K. GRAY and CHESTER L. HOLMES. *Surg. Clin. N. America* 1948, 28 1041

The authors article is based on the report of a case in which pyloric stenosis developed about a month after the ingestion of 1 5 ounces (45 c.c.) of sulfuric acid. A review of the literature has disclosed reports of 139 other cases in which pyloric stenosis has followed the ingestion of a corrosive substance.

The ingestion of caustic alkalies injures the esophagus and frequently causes stricture stenosis of this organ. Although corrosive alkalies are usually quickly neutralized after they enter the stomach gastric or pyloric stenosis occurs in about 20 per cent of the cases in which these corrosives are ingested.

The effect of ingested acids is noted generally as a pyloric or antral stenosis. This usually causes symptoms in about 4 to 6 weeks, although the literature contains reports of several cases in which there was no evidence of pyloric obstruction until 5 or 6 years after the ingestion of an acid. Approximately 20 per cent of patients with pyloric stenosis due to ingestion of a corrosive acid also will have an esophageal stricture.

In most cases the diagnosis will be simple if the physician is aware of this propensity of acids to inflict the major damage on the pylorus. It may be impossible for the roentgenologist to distinguish the stenosis of corrosive origin from carcinoma of the stomach if the request for roentgenologic examination is not accompanied by the case history.

In the early surgical treatment a jejunostomy may be indicated to assist in the restoration of fluid and electrolyte balance, and to maintain nutrition until inflammation in the stomach and esophagus subsides. In this manner time will be gained and the patient can be observed in order to determine if severe stenosis is going to develop. The general condition of the patient and the local operative procedure may permit more extensive operation. The early stages of the disease. Of the three procedures most frequently used partial gastrectomy would seem to offer the most satisfactory results.

Acute Pseudomembranous Enteritis or Enterocolitis. A Complication Following Intestinal Surgery. CLAUDE F. DIXON and ROGER E. WEISSMAN. *Surg. Clin. N. America*, 1948, 28, 999.

Acute pseudomembranous inflammation involving the mucosa and submucosa of the gastrointestinal tract has been studied by pathologists in connection with severe infectious diseases, serious poisoning and severe constitutional disorders. Except in the acute severe diarrheal maladies or in dysentery the clinical manifestations of the condition have not

been thoroughly understood. Pathologists also often have been unable to ascribe clinical importance to pseudomembranous lesions of the digestive tract found at autopsy.

Such lesions apparently follow surgical procedures sufficiently often to be of importance. Surgeons have become increasingly aware of this disorder in the study of postoperative mortality. There is however insufficient information available regarding incidence etiology pathogenesis clinical manifestations and treatment. This lack of information has prompted the authors to carry out this study.

At the Mayo Clinic acute pseudomembranous ileocolitis has been encountered at autopsy in cases in which a wide variety of both medical and surgical conditions have existed. In many cases these inflammatory intestinal lesions were an important, or the sole cause of death. The lesions have been observed at postmortem examination in cases in which death had followed operations on the brain spinal column breast gall bladder uterus stomach or other organs. They also have occurred from a variety of causes in nonsurgical cases.

The authors interest was stimulated by the recovery, under treatment of 2 patients who following radical resection of the colon presumably had mild or moderate acute postoperative pseudomembranous ileocolitis. These cases are included in their series of 23. Twenty more cases of the 23 were secured when they reviewed clinical records of a period of 7 5 years. Their survey included records of all cases in which the patients died following operation on the small or large intestine or the rectum and in which the pathologists discovered significant pseudomembranous lesions of the mucous membrane of the stomach or of the small or large intestine. Finally in 1 case of the 23 permission for autopsy was not obtained but the clinical manifestations strongly suggested that the patient died of acute pseudomembranous enterocolitis. Several of the patients including the 2 mentioned who did not die were observed by one or both of the authors.

The frequency with which the lesions occur cannot be determined in this study but it appears that pseudomembranous lesions were more frequently encountered in the last 18 months than earlier in the period of study. The reason is not apparent and the increase occurred in spite of use of sulfonamides in preoperative preparation for intestinal surgery.

There were 13 males and 10 females in the series. The oldest patient was 76 years old and the youngest 2 days old. Seventeen of the 23 patients were more than 40 years of age. This incidence may be expected however because of the greater number of older persons who require major intestinal surgery.

The lesions often involved the duodenum only, jejunum only or most of the small bowel terminating sharply at the ileocecal junction. Intrinsic factors of mechanical or circulatory nature seem to be important. In more typical varieties of the series

lesions were present largely in the ileum and superior portion of the colon.

Acute, subacute and chronic infarctions usually result in degeneration and necrosis of the entire bowel wall the extent depending on the degree of ischemia. Congestion of the intestine as a result of congestive heart failure chronic pulmonary disease or portal hypertension was noted by Bockus as an important predisposing factor of many inflammatory changes.

Successful management demands that the condition be recognized at once. From the foregoing experience certain manifestations strongly suggest the presence of pseudomembranous enterocolitis. Acute cramping diffuse abdominal pain with or without diarrhea or frequent or constant discharge from a colonic tooma may be the earliest signs. In many cases, however, severe circulatory collapse usually unexplained may precede the onset of external intestinal involvement; this is particularly important if as unlikely the state of shock is resistant to antishock measures. The abdomen is usually mildly to moderately distended tenderness is diffuse nonlocalizing and mild. Vomiting may be present. Although of little value from the standpoint of early diagnosis later in the course the fecal contents become extremely foul serous or seropurulent and may contain identifiable pseud membrane.

Differential diagnosis of this condition from the more common postoperative complications in the abdominal is extremely difficult.

In spite of the fatal outcome in most cases of their series, in which ten cases of pseudomembranous enterocolitis existed either alone or in combination with serious intra-abdominal disturbances, the authors believe that the prognosis is not uniformly hopeless. Heroic effect are needed though, if many of the patients are to survive.

Definitive treatment of pseudomembranous enterocolitis must be largely on empiric grounds until basic etiologic and pathogenic factors are understood. Of primary importance are realization of the possibility of presence of the entity prompt recognition of related symptoms and during the ensuing hours of antishock treatment an attempt to make tentative or a working diagnosis.

Aggressive and prompt replacement of fluids preferably in the form of whole blood and plasma must follow recognition of the downhill course.

In the presence of marked circulatory collapse or rapidly developing tissue ischemia administration of oxygen by inhalation would be an important adjunct to other supportive treatment.

Antibiotics preferably penicillin in doses up to 100,000 Oxford units every 3 hours should be instituted to assist the intestinal wall in combating secondary invasion by certain pathogenic microorganisms which appears inevitable when suffice it damage to the mucosa and submucosa has taken place. Streptomycin has not to the authors knowledge been used with success in the treatment of this condition.

If fecal discharges are excessive some good effect may be obtained from codeine, pantopon, dilaudid or morphine in combating peristalsis.

The question of the value of poorly absorbed or nonabsorbable sulfonamides, orally or by gastrointestinal tube could not be ascertained.

Laparotomy in the presence of acute pseudomembranous enteritis, is contraindicated unless other intra-abdominal lesions necessitate such surgical treatment. In some instances the presence of a severe process such as perforation of a viscus, leakage at an anastomosis or strangulating obstruction may be so strongly suggested that no other course is open. Operation on the bowel itself may be hazardous because the pseudomembranous lesions of the mucosa are of any great extent.

Of the 20 cases in which autopsy revealed the presence of severe gastric or intestinal pseudomembranous lesions of the mucosa, reports of 4 are given in some detail. These cases are considered typical of those in which the pathologist considered the pseudomembranous inflammatory lesions to be one of the most important contributing causes of death. The entire series is summarized within the article.

Duodenitis (Le duodenitis). A. TAVERNIER, *Arch. Mal. Mal. pp. dig. 943, 4: 287*

An extensive study of the anatomy and histology of the duodenum led the author to the conclusion that pure isolated, circumscribed duodenitis is a rare condition because usually the inflammatory process involves also the adjoining portions of the stomach. Therefore, the term "gastroduodenitis" or "duodenopyloroenteritis" is a more appropriate term.

Heterotopia, such as the presence of islands of gastric mucosa in the duodenum, and vice versa, is of great importance for the pathologic anatomy of this region and must be considered in the pathogenesis of ulcerative processes. In the strict sense of the word the nosologic or pathologic entity of duodenitis is not acceptable. Numerous lymphatic communications exist between the duodenum and the stomach. Close connections can be demonstrated also between the lymphatic system of the appendix on the one hand and the duodenopancreatic region on the other. From the purely anatomical point of view no clear border can be established between the stomach and the duodenum. It follows that the duodenum alone cannot be made responsible for the pathogenesis of inflammatory processes originating in that region. As a rule, alterations may be found in the adjoining organs such as the liver or pancreas.

Duodenitis may follow cholangitis, cholecystitis, pancreatitis, or appendicitis.

Acute and chronic varieties of duodenitis may be distinguished.

JOSEPH K. VABAT, M.D.

J. Junctional Insufficiency: Its Relation to the Sprue Syndrome. E. LEONARD FORNEY JR. and J. ARNOLD BAXTER, *Surg. Clin. N. America*, 943, 28: 903.

The pathologic condition which has been recognized as a deficiency state akin to or representative

of the sprue syndrome is due to various causes. In some of the reported cases of the sprue syndrome in which the patients have had symptoms of a deficiency state exploratory laparotomy or autopsy has disclosed an unsuspected disease of the small intestine or has revealed that a variable portion of the small intestine had been isolated previously by a short-circuiting procedure.

The authors wish to re-emphasize that sprue is a syndrome which may have a diverse origin.

It becomes obvious that (1) an intact wall of the small intestine (2) a normally functioning mucosa, (3) normal peristalsis and normal transportation of the chyme (4) the presence of adequate digestive enzymes and bile and (5) intact lymphatics are essential for adequate digestion and absorption. A break in any of these may eventuate in a deficiency state. Impairment of the absorptive ability of the small intestine is almost universally incriminated as the underlying cause of jejunoileac insufficiency.

Experiments on animals have demonstrated that the immediate effects of massive resection of the intestine are hunger, thirst, loss of weight, and diarrhea. As much as 66 per cent of ingested foodstuffs may be lost in the feces. Compensation occurs gradually. If the animals are fed a rich, easily assimilable diet digestion becomes normal. The animals are able to absorb all foodstuffs and there is a considerable increase in the absorption of carbohydrates. The animals appear normal but they are very sensitive to unfavorable dietary and environmental conditions.

The compensatory process is characterized by hypertrophy and hyperplasia of the remaining portion of the intestine proximal to the site of the resection. Neither the stomach nor the portion of the intestine distal to the site of the resection undergoes any change. The diameter of the portion of the intestine involved in the compensatory process increases and may become twice as large as normal. There also is an increase of as much as 400 per cent in the absorptive surface of the involved portion of the intestine. It appears likely that this increase in the absorptive surface approaches the epithelial area of the excised portion of the intestine. This compensatory process also has been observed in human beings who have undergone massive resection of the intestine.

The amount of human intestine that can be resected without causing serious sequelae or death varies greatly in different cases. Resection of the small intestine of human beings is followed by many sequelae. Diarrhea is the most frequent one. It is associated with an excessive loss of fat, protein and electrolytes in the feces. This abnormality may be so severe and intractable as to interfere greatly with bodily nutrition and it even may cause death. The diarrhea is aggravated by the inclusion of an excessive amount of fat in the diet. Anemia of various types, loss of weight, edema, tetany and pernicious vomiting are other sequelae that may occur. There also may be a decrease in the concentration of calcium and protein in the serum.

After resection of the small intestine the physical condition of the patient appears to depend on the following factors: (1) the pathologic conditions which necessitated the resection, (2) the length and physical condition of the remaining portion of the intestine and the extent to which it is able to compensate for the resection, (3) the resistance of the patient, and (4) the type of dietary regimen that is instituted after the operation.

This article is based on a study of a large number of patients with jejunoileac insufficiency and includes a report of 6 illustrative cases.

The Surgical Treatment of Congenital Megacolon.

CLAUDE F. DIXON and DAVID B. JUDD. *Surg. Clin. N. America* 1948, 23: 889.

Congenital megacolon or Hirschsprung's disease ensues from an imbalance in the nervous mechanism which controls the function of the bowel. As a result the bowel tends to dilate more readily than to contract. This imbalance in turn, may be due to a deficiency of ganglia and fibers in Auerbach's plexus. As a result of prolonged and marked dilatation the bowel becomes elongated and its walls hypertrophied. Attempts to overcome the imbalance by drug therapy and other medical measures have met with variable and incomplete success.

Resection of the lumbar sympathetic ganglia and nerves is a surgical means of attacking the problem from the same angle, and it too has achieved uncertain results. Many authors have expressed satisfaction with this method of treatment but the experience of the authors has not been encouraging. Of 26 patients in whom sympathectomy was performed only 1 appeared to have a satisfactory result. Aside from this there remains the fact that sympathectomy does not remove the pathologic condition present, and it appears that the danger of disaster such as from obstruction, volvulus or perforation of the diseased segment of bowel is not lessened by sympathectomy.

On the other hand the authors' experience with resection of the diseased bowel has been most encouraging. Of all the patients in whom resection was performed 78 per cent were benefited and 67 per cent were completely relieved of their symptoms. If only the traced patients are considered, 93 per cent were benefited and 84 per cent were completely relieved. The two main reasons that resection has not been in greater favor as the treatment of choice for congenital megacolon are (1) a high primary mortality rate and (2) fear of recurrence in the portion of colon not removed. It is the authors' belief that the mortality rate during hospitalization need not be high following this procedure. With proper co-operation between pediatrician, internist, and surgeon all facilities for preoperative preparation of the patient can be utilized to the fullest extent and the risk of the operation can be reduced accordingly. In their most recent series of cases the mortality rate during hospitalization was 4 per cent, and they believe that the rate will be even lower in the future.

Resection should not be performed in children under 5 years of age unless it is absolutely necessary since they do not tolerate resection of the bowel well. The postoperative mortality rate in this age group was nearly 45 per cent. In the majority of such cases the symptoms can be controlled reasonably well for a time by medical measures, including diet, laxatives, enemas, and drugs such as mecholyl; therefore, these young children should be carried along on the regimen until they are 5 years of age or older. However it is not advisable to prolong the regimen in the presence of persistent and severe symptoms such as constipation, abdominal distention, nausea, and vomiting.

Frequently by the time the child is of school age it becomes apparent that he is not like normal youngsters and the parent as well as the patients want something done to achieve more early complete relief from the symptoms, particularly the symptom of abdominal distention which when marked often cause the distal margins to flare out. Also it appears that if the symptoms are not well controlled by medical measures the danger of ultimate disaster is great. Fewer more effective measures are employed.

The fear that the disease will recur in the remaining portion of bowel after partial colectomy is not substantiated by the authors' experience with this procedure. In the group of 54 cases in which resection was performed, there were 4 in which half or less than half of the colon was removed and in case was there evidence of recurrence of the disease in the remaining portion of the colon. In 5 of these 41 cases there was complete relief from symptoms.

For these reasons the authors believe that cases of congenital megacolon the treatment of choice is resection of the diseased segment of bowel. If the patient is 3 years of age or younger surgical treatment should be delayed and the symptoms should be controlled as much as possible by medical measures until the child becomes older. It is the authors' belief however that in the majority of cases resection of the diseased bowel will be necessary before complete relief from symptoms is obtained.

Hemorrhoids and Cancer NIEL CARSTAM. *Lids och Mand.*, 948, 97 ?

Hemorrhoids are enlarged and varicose condition of the hemorrhoidal veins, and may be external when they arise from the inferior hemorrhoidal veins and drain into the anal system and internal when they arise from the superior hemorrhoidal veins and drain into the portal system. They may be coexistent and merge into one another. External hemorrhoids are relatively less serious and less important, although they may in rare complications such as infections and anal hematomas, which are frequently painful. Bleeding is not so frequent in this type of hemorrhoids.

Internal hemorrhoids are more serious because of pain and discomfort, and are more important because their recognition is valuable in the differential diagnosis of other rectal lesions.

TABLE I.—HEMORRHOIDS AND CANCER INDICATIONS FOR ROENTGENOLOGIC EXAMINATION IN 164 CASES OF CANCER OF THE COLON

	PO	SM	SP	SP	SP	SP	Total
I Hemorrhoids without other symptoms (Routine examinations)							
II Suspicion of internal general symptoms, relation to age with bleeding as a partial symptom	4		5		6		
III Suspicion of tumor, obstruction, palpable abdominal tumor etc. with not bleeding	8	9	16		8	5	77
IV No symptoms of colon, intestinal obstruction	3	14			3		37
V Palpable tumor per rectum							6
VI Known untraceable							64

The not infrequent association of cancer with internal hemorrhoids is emphasized by the author. The fact that from 10 to 20 per cent of the patients admitted at a large clinic for rectal cancer had undergone previous hemorrhoidectomy is mentioned. Since 1910 not only a thorough palpation of the rectum but also a roentgenologic examination of all cases of hemorrhoids in patients over 40 years of age has been the rule at the Surgical Clinic of Lund. This report considers the patients so examined from 1913 to 1946 inclusive, and the author endeavored to determine the frequency and correlation between hemorrhoids and cancer of the colon and rectum. Patients with cancer of the colon and rectum were examined both by palpation and proctoscopy to ascertain the presence or absence of hemorrhoids and similar examination was made on control material.

Table I demonstrates that, at the Lund Clinic, the routine roentgenologic examination of patients with hemorrhoids but without other symptoms has not led to the discovery of cancer of the colon.

Table II tends to show that hemorrhoids are probably not more common in patients with colonic or rectal cancer than in otherwise healthy people.

The author concludes that if anoscopy of a patient free of symptoms of a tumor permits a clear diagnosis of hemorrhoids, and palpation and sigmoidoscopy permit one to establish the absence of cancer in the

rectum and rectosigmoid the necessity of a roentgenographic examination may be questioned
 ERNEST D. BLOOMENTHAL, M.D.

Anterior Resection for Malignant Lesions of the Upper Part of the Rectum and Lower Part of the Sigmoid. CLAUDE F. DIXON *Ann Surg* 1948, 128 475.

The operation of anterior resection for lesions of the terminal part of the large intestine with re-establishment of intestinal continuity has been criticized by many authors as not being sufficiently radical. The complete article is an evaluation of the operation. The efficacy of any surgical procedure for cancer is judged by the number of persons undergoing the procedure who are alive 5 years or more and not on an anatomic basis—the extent of the excision.

This study is limited to the most controversial segment of the large intestine namely the distal 20 cm. It is for this region that new procedures are constantly being advocated and interest in old ones is being rekindled. A matter of 3 or 4 cm. from the dentate line makes the difference between an operation involving a permanent colonic stoma and one in which intestinal continuity can be re-established. While the majority of patients become adjusted to a permanent colonic stoma there are some who have difficulty in its management. Those cured by an anterior resection can live normally in every respect.

Anterior resection for removal of carcinomas of the sigmoid was performed in 426 cases at the Mayo Clinic from 1930 through 1947. While there is a slight predominance of males in the series the female patients tend to be younger and their lesions tend to be of a higher grade and closer to the dentate line. There were 25 deaths among the 426 cases a mortality rate of 5.9 per cent. Following 270 resections since the present method of preoperative and postoperative management has been used there were 7 deaths (2.6 per cent). Of 272 patients the 5 year survival rate was 67.7 per cent.

Comparisons of the mortality and survival rates according to the location of the lesions in various segments of the bowel revealed that the operation is sufficiently safe and radical for lesions of the upper half of the rectum. In cases of adenocarcinoma of the mucous (colloid) and papillary types the prognostic mortality rate in colonic surgery in the past 10 years has not been as marked for lesions in the rectum as for those immediately above that region. Whereas 10 years ago operations for rectal lesions were safest this is no longer true. The survival rate after resection of low rectal lesions is poorer than that following resection of lesions higher in the bowel and greater difficulty in resecting the region of spread. The lesions covered by this study are considered in terms of their distance from the dentate line because of this consideration and because this distance determines preservation of the sphincter.

Experiences with Operation for Rectal Carcinoma with Preservation of the Sphincter (Unsere Erfahrungen bei der Operation des Rectumcarcinoms mit Sphinktererhaltung). A. BRUNNER *Helvet chirurgica* 1948 15 375

The author reports on 9 cases of operation for carcinoma of the rectum with preservation of the sphincter in which he followed the pull through procedures of Karschner and Bacon. If the tumor is not too large and is freely movable the procedure may be carried out provided the lower limit of the tumor is from 5 to 6 cm. above the anus. In the 9 reported cases the lower limit of the tumor was from 6 to 7 cm. (5 cases) and from 9 to 14 cm. (4 cases) above the anus. Therefore up to 30 cm. of intestine could be extirpated. The preservation of the sphincter muscle carries with it the danger of strangulation of the pulled through intestine because of postoperative swelling of the tissues.

One of the author's coworkers had 1 case of necrosis of the lower intestinal segment followed by a fatal ascending infection of the pelvic connective tissue. A second patient was lost as a result of massive pulmonary embolism 3 weeks after operation. In the other cases the blood supply of the pulled through intestine remained good.

A certain degree of stretching of the sphincter muscle cannot be avoided but this is never so severe that recovery of muscle function does not occur within the course of a few weeks. Sphincter closure begins in a short time but under some circumstances satisfactory continence is not achieved for a few months. In the early period thin stools cannot be retained and the patients are annoyed by an increase in bowel movements. In 1 patient a definite stricture developed which required dilatation for months. In the 6 other patients the local condition of the anus was very satisfactory. Since no mucosal prolapse developed these patients had no complaint of moisture. The sphincter admitted the passage of one finger easily. Active closure was very good. Several months after operation gas could be retained.

JOHN L. LINQUIST, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Hepatic Coma. T. LYNCH MURPHY, THOMAS C. CHALMERS, RICHARD D. ECKHART, and CHARLES S. DAVIDSON *J. M. England* 1948 239 605

Hepatic coma is a distinct clinical syndrome occurring in patients suffering with acute or chronic, severe liver disease, and characterized by lethargy, progressing to noisy confusion, coma and usually to death. The state has inapely been termed cholemic acidosis in the blood as being the etiologic factor is now generally discredited. The syndrome may occur without evident cause in patients suffering severe liver disease, or may be precipitated in such cases by (1) infection such as pneumonia or peritonitis (2) acute hemorrhage as from esophageal varices or by

(3) the injudicious use of sedatives such as morphine, the barbiturates, or paraldehyde.

In an attempt to elucidate the underlying pathologic physiology of the condition the authors studied 40 patients who died in coma and who clinically and pathologically had severe primary liver disease. Twenty cases of uncomplicated coma in which no other cause for death than liver disease was found and 20 complicated cases in which the patient had some major complication such as hemorrhage, peritonitis, tuberculosis, or pneumonia in addition to marked liver disease were selected for consideration. In all cases the neurologic findings were inconstant. Laboratory estimates were made of the blood non protein nitrogen, carbon dioxide combining power, blood sugar, serum bilirubin, blood prothrombin content, thymol turbidity, and cephalin flocculation; none of these were distinct other than of severe liver damage and did not significantly differ in the comatose state from the precoma findings.

Treatment is directed at the maintenance of nutrition, control of hemorrhage or infection, and avoidance of sedatives, but is in general unsatisfactory. Analeptics such as glucose, sodium succinate, caffeine or benzedrine are without effect on the comatose state. W. A. F. FELD CAMPBELL, M.D.

The Operative Treatment of Gallstone Disease in the Light of Ultimate Results (Die operative Behandlung des Gallensteinleidens im Dauererfolg)
VICTOR HOFFMANN, *Chirurg* 948, 9 337

In the year 1943 the author sent questionnaires to 74 patients whom he had operated upon for gallstones from 5 to 20 years previously. The material comprised 79 cases of which only 3 could not be located. From the replies returned by the operative patients he was able to deduce statistically with considerable exactness (they were all operated on by himself either as chief surgeon or as assistant) the results obtained.

From the data received it is concluded that the operation for gallstones (cholecystectomy and in some cases choledochotomy with drainage) resulted in complete relief from the bile passage symptoms in 64 per cent of the cases. However, when the cases with a single or with a few attacks following the operation, and those relieved by a second operation are included as well as those with dyspeptic symptoms but without true gallstone colic, the percentage of success rises to 90. In 8 per cent of the patients the pains were either not relieved or they recurred later but they were not so severe as in the original attacks and were unattended by jaundice. Not all of these attacks of pain were colicky in character. Only in 3.1 per cent were the attacks of pain at all characteristic and accompanied by jaundice. Of these patients, 5 were reoperated upon and in 3 a stone was found in the choledochus. In 1 of these the stone had been overlooked at the first operation and in 2 another stone had apparently formed. In the remaining 2 a stone was not found at reoperation, but the choledochus was dilated with infection in 1

patient. A choledochoduodenostomy at reoperation brought complete and enduring relief.

In this material during this period, there were 20 deaths however none of these deaths could be imputed to the operation or to the continuance of the gallstone disease after operation.

The author emphasizes the fact that these patients could by no means be considered as having been operated upon early. He thus believes that the operation of cholecystectomy is effective in gallstone disease, that the mortality of the operation and the importance of recurrences attributable to the disease following the operation have been grossly exaggerated, and that the efforts of the surgeon should be expended in bringing these patients to operation as early as possible if possible before the stone invades the choledochus. The author recommends cholecystectomy as soon as the roentgenologic examination discloses the presence of stones in the gall bladder no matter how small they are, and considers the operation a pressing one as soon as any indication arises of the presence of an accompanying pancreatitis. The presence of pancreatitis must in these cases be sought with greater diligence than has heretofore been customary. JOHN W. BRYNAR, M.D.

The Pancreatic Fistulas and Their Treatment.
MICHAEL P. KASKEVAS, *Helleniki Iatriki* 1947 6 909.

The author described in detail the case of a pancreatic fistula after marsupialization of a pancreatic cyst. He succeeded in curing the fistula by implanting it into the posterior wall of the stomach. The patient was completely cured 15 years after the operation.

This case the first of this condition in which surgery was used in Greece led the author to study the international references to all similar cases reported up to this time amounting to 42. He describes the details of the operative technique and recommends that the implantation be made preferably in the stomach in the cases of fistulas occurring above the anterior curvature of the stomach, while the implantation should be made in the posterior wall of the stomach when the fistulas are in the gastrocolic ligament.

If a resection of the stomach was done previously the implantation may be made on the excluded jejunum, the duodenal stump or the gall bladder. The immediate results of the operation are exceptionally satisfactory. The only failures among these 42 operations were 2 deaths and 1 relapse. The remote results are not known except in only a few cases. However in 10 cases reported in the literature the patients were well from 1 to 10 years after operation.

In contrast to the excellent results of the operative treatment, the results of the various conservative treatments proposed up to now are of doubtful efficiency and for this reason the author recommends that when 5 months of conservative treatment fails or proves unsatisfactory operation should be done.

GYNECOLOGY

UTERUS

Age, Incidence and Distribution of 4 652 Cases of Carcinoma of the Cervix. MARVIN G. SADDORF and JAMES P. PALMER. *Am J Obst* 1948, 56 680.

An age study was made of 4 652 patients with carcinoma of the cervix who were admitted to the Roswell Park Memorial Institute Buffalo New York, during the period from 1914 to 1946 inclusive. The age of the youngest patient was 18 years and that of the oldest 84 years. Three cases of proved carcinoma of the cervix were found in women under 30 years of age. A detailed study is presented of these 3 cases. It is important that the physician realize that malignancy of the cervix may occur at any age period after the first decade of life and the possibility of the presence of carcinoma of the cervix should not be eliminated solely because of the age of the patient.

Although the majority of carcinomas were found in patients in the 40's 15 per cent were noted in those under 40. A similar percentage also was found in those over 70 years of age.

JOHN R. WOLFF M.D.

The Ovary in Endometrial Carcinoma. EPHRAIM WOLF, ARTHUR T. HEATING, GEORGE VAN S. SMITH, and LEMT C. JOHNSON. *Am J Obst* 1948, 56 617.

Previous studies of the ovary in cases of endometrial carcinoma made by the authors showed that there was a stromal hyperplasia of the ovaries. To confirm the significance of this stromal hyperplasia a study of the stroma of the normal ovary was undertaken. These findings were then compared with the stromal changes in 331 cases of carcinoma of the endometrium.

The ovarian stroma differentiates into the cells of the granulosa theca interna corpus luteum and corpus albicans. This process normally follows an orderly sequence which possibly is regulated by the ovum.

In senility this differentiation recapitulates the normal sequences but in disorderly manner leading to stromal hyperplasia thecomatous cortical granuloma formation and granulosa and theca cell tumors.

Stromal hyperplasia makes its appearance in the fourth and fifth decades reaches its height in the sixth decade and thereafter tends to subside with old age. This stromal hyperplasia is significantly more frequent in cases of endometrial carcinoma (from 56% to 92%) than in a controlled group (from 36% to 43%) and persists into advanced old age. The thecoma is significantly more common in endometrial cancer than in the control series (9 to 1). Sebaceous corpora lutea and theca lutein cysts are also more common in the cancer cases.

The existence of hormonal factors in endometrial carcinoma is discussed. JOHN R. WOLFF M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Torsion of the Hydatid of Morgagni. RALPH A. REIS and EDWIN J. DE COSTA. *Am J Obst* 1948, 56 770.

The hydatid of Morgagni is usually thought to be an innocent structure. Yet during the past 10 years at the Michael Reese Hospital Chicago Illinois Reis and DeCosta have operated on 5 patients whose symptoms were due to torsion of this structure. Although a review of the world literature reveals only 21 references to this clinical syndrome the authors believe that this condition probably occurs fairly frequently. At times it may be overlooked at others misdiagnosed.

Since torsion and even gangrene can occur with few if any complaints the pelvic organs should be examined at every laparotomy. This is important when serousanguinous fluid is encountered.

The clinical symptoms of torsion simulate those of appendicitis with colicky intermittent abdominal pain. Nausea and vomiting are frequently present. The temperature usually is less than 101 degrees and the pulse under 96. Examination gives the impression of appendicitis either on the right or left side. Bimanual findings are not helpful.

Torsion even when associated with gangrene does not always lead to serious intra abdominal disease. Aseptic necrosis with only slight peritoneal reaction and complete recovery may occur.

Pedunculated hydatids of Morgagni encountered during surgical procedures should be removed prophylactically. JOHN R. WOLFF M.D.

Hemoperitoneum of Ovarian Origin (Emoperitoneo de origine ovarica). RICCARDO MONTANELLI. *Riv ostet gin* 1947 2 338.

Two women one 37 years of age and the other 24 years of age were admitted to the hospital a few hours after coitus with symptoms of peritoneal hemorrhage. Both presented extreme anemia and puncture through the vaginal fornix brought to light fresh blood in the pouch of Douglas. Both were diagnosed as presenting tubal abortion and they were immediately laparotomized. In each case the source of the bleeding was found to be a ruptured corpus luteum cyst of the ovary. The older patient had 4 living children and there was also a corpus luteum cyst in the nonruptured ovary so that it was thought advisable to remove both ovaries. In the younger patient the other ovary was normal in appearance and was left in situ.

Histological examination disclosed in addition to the usual picture of a ruptured corpus luteum cyst, extensive extravasation of blood throughout the remainder of the ovary (ovarian apoplexy) a dilatation and an increase in the number of the blood vessels about the cyst especially in the area of its base and a great number of developing ovarian

follicles. This appearance of tumultuous follicular development is suggested to be the result of a hyperandrogenism, and to this hormonal disturbance is ascribed also the angiomatoid vascular development and the tendency toward ovarian apoplexy. The coitus was regarded in each instance as merely the exciting cause.

In these cases the diagnosis of tubal abortion was made solely on the sudden attack of anemia and the results of the vaginal puncture but, of course these findings do not tell anything about the point of origin of the bleeding. The author does not believe that the distinction between ruptured extrauterine pregnancy and ruptured corpus luteum cyst can always be made however in these cases of hemoperitoneum in nonpregnant women, an attentive search should have been made for other signs of pregnancy. Thus, he believes that a more nearly exact diagnosis could be achieved in many of these cases, and while it might not radically alter the therapeutic procedure, it would at least gain more insight into the manner of distinguishing the two conditions and would permit of a more enlightened planning of the therapy to be pursued.

JOHN W. BRENNER, M.D.

Brenner Tumors with a Predominance of Muciparous and Granulosa-like Elements (Tumore di Brenner con prevalenza di elementi mucipari e granulosa-like) L. GAGLIARDI. *Riv. Ital. Ginec.*, 1948, 3: 37.

The tumor studied by the author for histologic interpretation was one of bilateral growth removed by subtotal hysterectomy and bilateral salpingo-oophorectomy from a 39 year old woman who had borne one living child and who was menstruating normally without evidence of abnormality in other organs of masculinization, or of abnormal appearances in the endometrium. The two masses presented much the same macroscopic appearance, but the tumor making up the right ovary was smaller than that on the left side and was roughly reniform and mammillated. The tumor involving the left ovary on the other hand, was rounded and on cross section exhibited two rather large cystlike formations.

Sections from various areas of this large rounded tumor mass presented the usual histologic findings of a typical Brenner's tumor namely, a fibroepithelioma, the epithelial elements of which were composed of paramesonephric epithelium pseudomucinous and serous epithelium (in many places cystic and vacuolated) and a number of other findings which have not so far been described for the Brenner tumor and which make them worthy of publication at this time.

One of these odd findings was extensive areas of young connective tissue as a rule surrounding the more immature types of Brenner-cell formations, which strongly resembled the cells of the granulosa-cell tumors, but were evidently not of that origin and were ascribed by the author to have an origin in common with the ovarian teratoma. Another odd finding was that of muciparous cells in rosette arrange-

ments about small central vacuoles and the presence of muciparous elements with nuclei pushed to the periphery which were seen scattered about among the connective tissue elements and closely associated with them. These are the findings in the so-called solid pseudomuciparous adenoma of the ovary and their appearance in the Brenner tumor affords a new proof of the close relationship between Brenner's tumor and the pseudomucinous tumors.

On the whole, the author ascribes the origin of these tumors to a heterotopic implant in the ovary of the same nature as that from which teratoma of the ovary arises.

JOHN W. BRENNER, M.D.

EXTERNAL GENITALIA

Gynostreosis: Three Uncommon Clinical Types. R. G. MALPHEANT. *Brit. M. J.*, 1948, 2: 555.

Anomalies due to aplasia of the female genital tract are not infrequent and all varieties and degrees of gynostreosis may result. The more complex congenital abnormalities are usually associated with a nonfunctioning uterus and are rarely of much practical importance.

The author describes three unusual types of gynostreosis, with certain features in common. Failure of canalization was limited in extent and localized to the cervical or vaginal segments of the müllerian tract and the symptomatology was dependent upon the presence of a functioning uterus. In 2 cases, hematometra was observed as the result of atresia at the level of the cervix. In the third case a hydrocolpos was found—a condition in which an accumulation of watery or mucous fluid in the vagina may produce serious mechanical effects during infancy and childhood.

The first case was one of congenital atresia of the cervix with hematometra. Usually hematometra is caused by occlusion of the lower end of the vagina, and it then occurs as a secondary (though important) complication of hematocolpos. Stagnation of blood in the uterine cavity due to obstruction at the cervical level, is usually an acquired condition and develops as a result of scarring following operation or childbirth. Hematometra due to strictures of obstetric origin generally occurs after difficult confinements associated with infection and much coagulation. Postoperative hematometra has usually been reported after plastic operations on the cervix, but has also occurred following the use of radium for benign uterine hemorrhage. In many cases of acquired stricture the stenosis is incomplete and, while blood accumulates within the uterus, there is some leakage past the obstruction.

Congenital occlusion of the cervix is a condition of great rarity and few examples have been recorded in the literature. Cervical aplasia is usually associated with more complex developmental anomalies of the genital tract, and the uterus then is rarely developed enough to perform the function of menstruation.

A case of hematometra in an atresic horn of a bicornate uterus in a girl aged 13 is also reported.

She was admitted because of severe dysmenorrhea. Her menses had started 9 months previously and were regular and lasted 7 days every 28 days. The menstrual pain was localized mainly to the left iliac fossa.

Three types of gynaesthesia are described. Distinctive clinical features were observed in each type and all were amenable to conservative treatment. Developmental anomalies of this order though rare are of much practical interest, for unless recognized patients may be submitted to needlessly radical operative procedures.

Cleavage Planes in Reconstructive Vaginal Plastic Surgery. J. V. RICCI, C. H. THOM, and W. L. ARON. *Am. J. Surg.* 1948, 76: 354.

The vagina as a point of *d'appui* is directly involved in surgery for relaxations, lacerations, fistulous formations, and the descent of the urethrovesical and rectovaginal parts.

These basic relationships are clear. There is a complete fusion between the anterior vaginal wall and that of the urethra throughout its entire length. Because of this fusion, surgical separation of these two structures can be accomplished only by blunt dissection and this leads to an unavoidable oozing. There is a clear-cut line of separation, an areolar cleavage plane between the anterior vaginal wall and the juxtaposed bladder wall from the urethrovesical area to the point of fusion of the vagina and the cervix. This areolar cleavage plane extends beyond this point and separates the bladder wall from the cervicofundal surface up to the vesicouterine peritoneal reflection. These definite lines of separation or areolar cleavage planes lead to a bloodless separation of the bladder from the vaginal wall and from the cervicofundal surface. There is a complete fusion of the posterior vaginal wall with the short perineo-anal body. Separation of these structures, which can be accomplished only by blunt dissection, leads to an unavoidable oozing. There is a clear-cut line of separation, an areolar cleavage plane between the posterior wall of the vagina and the wall of the rectum extending from the anorectal area to the cul-de-sac peritoneal reflections. The presence of this areolar cleavage plane permits a bloodless separation of these two organs but in no instance does a surgically useful fascia line the vagina or encase it or any of the juxtaposed organs.

In the normal state the anterior vaginal wall meets and fuses with the cervix at an obtuse angle, the degree of angulation increasing proportionately to the amount of retrodisplacement of the normally placed uterus. In the presence of a prolapsed elongated cervix the vaginal wall meets and fuses with the cervix at an acute angle. At the apex of this angle, the bladder wall, instead of coming to a sharp point, curves away from this vaginocervical angulation thus creating a clear space or blind pocket thinly packed with scattered areolar fibers. A similar blind pocket in both the normal and prolapsed state exists between the cul-de-sac peritoneum as it swings cep-

halad to cover the rectosigmoid and the posterior vaginal wall as it swings caudad from its point of fusion with the posterior cervix. This pocket is packed with a loosely felted areolar mesh. A knowledge of these relationships and of the utilization of precise methods of approach to avascular spaces and cleavage planes shortens operating time, minimizes bleeding and in brief simplifies vaginal plastic surgery.

HARRY W. FINX, M.D.

MISCELLANEOUS

Prostigmine for the Cure of Amenorrhea (*La prostigmina nella cura delle amenorree*). T. M. CAYRA. *Rivista Ginecologica* Tor. 1948 14: 373.

Prostigmine injections were employed by the author in 67 women either for diagnostic purposes in cases of suspected pregnancy or for the treatment of amenorrhea.

In 6 of 10 patients with menopausal amenorrhea prostigmine failed to establish the menstrual flow.

Negative results were obtained also in a group of 7 women with amenorrhea of endocrine origin.

In 14 of 17 patients with amenorrhea without evidence of any disturbance of the endocrine system prostigmine produced menstruation. The injections were not followed by a menstrual flow in any of the 11 pregnant women but in another group of 4 patients a slight flow followed the administration of the drug, of the 2 abortions in this group only one was possibly attributable to prostigmine. The other was probably provoked by the ingestion of quinine.

The author concludes that prostigmine is an innocuous drug and is valuable for diagnostic and therapeutic purposes.

JOSEPH K. NARAT, M.D.

Investigation and Treatment of Infertility. JOHN ROCK. *Med. Clin. N. America* 1948 32: 1171.

The author has listed and discussed the commonest known causes of failure of fertility and suggestions are made as to how to use easily available methods of identifying these causes and relieving them. Normal health of both mates is assumed.

If anatomic obstruction cannot be overcome by dilatation with glass vaginal forms of gradually increasing size inserted two or three times daily by the patient herself or if instruction of the too considerate or inefficient husband is futile, recourse must be had to careful plastic surgery.

Bacterial vaginitis can be relieved by semidial 2 quart douches with 0.5 per cent boric acid or sodium perborate solution or by suppositories containing 200,000 units of penicillin inserted twice daily for about 1 week. The trichomonas is susceptible to Devedan tablets inserted morning and night following a douche of 0.5 per cent sodium perborate solution. Flonagin tablets may also be effective.

The normal morphology straining qualities and to a slight extent the behavior of spermatozoa may be observed and appraised by appropriate methods. So little is known of the essential biochemical and biophysical properties of the seminal fluid however

that the study of this medium has not yet entered the clinical field. Even the work on hyaluronidase, and on the metabolic functions of spermatozoa and their demands on and utilization of their substrate is still in the stage of research.

When cervical mucus at ovulation time contains pus, there is endocervicitis and possibly endometritis. If, of minor degree, the finding of pus may not be significant but it must not be underestimated. The presence of many leucocytes at times other than at the time of ovulation may be physiologic.

For endocervicitis, superficial cauterization and topical medication are valueless. The sulfonamides and penicillin may be of value if given at least during the first 10 days of several successive cycles, in doses adequate for other infections. If the cervicitis is marked, careful and conservative cauterization of the external one half of the cervical canal, supplemented by treatment with antibiotics, is in order.

In the presence of endometritis, other than that which is tuberculous, antibiotics, often without curettage, should be tried throughout several consecutive cycles. Formerly tuberculosis was treated by hysterectomy and bilateral salpingectomy. Streptomycin may make such radical treatment unnecessary.

Constitutional hypoplasia of the uterus reflects a disorder of puberty and early adolescence and is exceedingly resistant to available therapy. Treatment is still highly experimental. Theoretically effective doses of estrogens usually will inhibit ovulation. They may be tried for a few months in doses of 2 to 0.5 mgm. of ethinylestradiol or 5 mgm. of diethylstilbestrol with the justifiable expectation that ovulation if stopped will be resumed with the cessation of treatment.

Ignorance doubtless clouds our insight into the complete function of the fallopian tube. Perhaps its fluid normally offers more to the ovum and sperm than a protective medium. At the moment the most we expect of the tube is that it will collect the ovum, transport it to the uterus, and provide a fluid medium in an unobstructed channel through which, also, sperm may travel. For these purposes there must be patency and a lining that secretes fluid and (by means of cilia) cooperates with some peritoneal or follicular fluid into the uterus. Normally muscle fibers in the tubo-ovarian ligament, the mesosalpinx, and well developed fimbria bring about the application of this fan-shaped flaring end of the tube to the vary so as to form a "virtual ovum."

HARRY W. FINEK, M.D.

Experiences with a New Semisynthetic Alkaloid of Secale Cornutum in Obstetrics and Gynecology (Esperienze con un nuovo alcaloide semisintetico della segale cornuta in ostetricia e ginecologia)
ANTONIO GIAROLA. *Atti e. Med. g.* 1945, 70: 449.

Stoll and Hofmann (*Helvet. chimica acta* 1943, 24: 945) succeeded in a partial synthesis of tartaric acid (one of the fundamental alkaloids of secale cornutum) which resulted in the produc-

tion of methyl ergobasum. This alkaloid differs from the natural alkaloid ergobasum, developed by Stoll and Burckhardt in 1935 in that it possesses a hydroxy-butylamido radical in place of the hydroxy propylamido radical of the natural alkaloid. The tartaric acid salt of methyl ergobasum was introduced to the attention of the medical profession as methergine in 1943 and has since been employed extensively in the United States and Switzerland in an experimental capacity. This preparation was used at the Obstetrical and Gynecological Clinic at Milan, Italy in 470 cases. Of this number 330 represented obstetrical conditions and 80, gynecological conditions.

Of the obstetrical patients, 100 were in the second stage of labor and the injection was made immediately after the birth of the child, 215 patients were in the puerperal period, the drug being used in place of the usual preparation of secale cornutum. 5 patients presented uterine inertia, and 10, puerperal subinvolution. During the discharge of the placenta, methergine exerted exactly the same effects as the natural preparation except that it acted much more rapidly and in the author's material there was no instance of retention of the membranes or incarceration of the placenta. In the puerperium there was not an instance of postpartum hemorrhage or of uterine atony. In the cases of bleeding due to uterine inertia the preparation exhibited an action very similar to that of pituitrin but without the hypertensive effects of the hypophyseal extracts. When the cases of puerperal subinvolution showed evidence of inflammatory involvement, the treatment with methergine was combined with excellent results, with hot douches (45-50° C) and sulfonamides.

The 80 gynecological patients presented 15 cases of metrorrhagia, of probable hormonal etiology in women in the period of sexual maturity; 12 cases of metrorrhagia on a premenopausal dyshormonal basis; 5 cases of metrorrhagia due to a benign neoplasm in the premenopausal period; 34 cases of metrorrhagia accompanied by inflammatory affections of the female genital apparatus; 5 cases of metrorrhagia of the menopausal period but without neoplasm; and 9 cases in which the preparation was administered preoperatively as a prophylactic measure against hemorrhage.

In the metrorrhagias associated with hyperplastic endometritis the favorable effects resulted in permanent cure when the methergine was associated with active hormonal preparations (corpus luteum, tritular hormones) in appropriate dosage. In the neoplastic cases the results were not good and the methergine treatment had to be supplemented by irradiation therapy to overcome the metrorrhagia. When methergine was given preoperatively there was more or less marked diminution of the bleeding during the subsequent operation, however the results depended more or less on the type of operation (retroversion operation, fibroidectomy) as well as on the manner in which the individual patients reacted to the drug.

On the whole the preparation was tolerated perfectly whether given by mouth or parenterally

JOHN W BRENNAN M D

Present Position of Neurosurgery in Gynecology
ALBERT DAVIS. *Brit M J*, 1948 2 585.

The rationale, technique, and results of a variety of operations mainly designed to interrupt sympathetic pathways from the uterus but all concerned with the relief of pelvic pain are described

Resection of the presacral nerve is curative in cases of severe spasmodic dysmenorrhea. Of 86 cases extending over a period of 16 years the results in later cases show a considerable advance over results in earlier cases. The patients operated on before 1934 showed a cure rate of 54 per cent and those operated on up to 1945 a cure rate of 71 per cent. Of 8 patients operated on since that time however only one is not cured and she admits to considerable improvement. This progression is due to a variety of causes: more extensive denervation; more careful peritoneal stripping; and more extensive coincident surgery but the main factor has been increased care in the selection of cases. It has now been established that the only dysmenorrhea for which presacral neurectomy is basically indicated is the primary spasmodic type; congestive secondary cases may be improved but the result is always problematical. Accordingly it is the author's practice to limit the operation to those patients suffering from intolerable colicky pain centered over the hypogastrium and in whom all minor and operative measures—exercises, antispasmodics, cervical dilatation and alcohol injection—have failed. Under these circumstances he found that 4.8 per cent of patients complaining of dysmenorrhea were suitable for presacral neurectomy. The results of this operation for the relief of pain of incurable pelvic carcinoma in 8 patients has not been encouraging.

Ovarian sympathectomy is effected by the division of the infundibulopelvic ligament near the pelvic brim after mass ligation of the structure. The operation is useful as an adjunct to conservative operations on the adnexae as in endometriosis and in selected cases of mittelschmerz. It is questionable whether the advantages of this operation outweigh the possible dangers of interference with the hormonal function of the ovary.

Alcohol injection of the pelvic plexus is primarily of value in cases of severe spasmodic dysmenorrhea which have failed to react to medical treatment. It should be combined with dilatation of the cervix. Of 61 cases of primary spasmodic dysmenorrhea, 43 (nearly 70%) were permanently and adequately relieved.

Intrathecal alcohol injection is indicated in all cases of visceral pain arising from incurable pelvic carcinoma. When combined with simultaneous alco-

hol injection of the pelvic plexus the results seem to be considerably better. A solution of ammonium sulfate may be substituted for the intrathecal alcohol to circumvent some of the difficulties inherent in alcohol injections. However in a personal case the injection was painful and in neither was there a reasonable degree of subsequent relief.

Section of the uterosacral ligaments chiefly through the vaginal approach is of value in intractable dysmenorrhea but is mainly indicated for the relief of what might be called the posterior parametritis syndrome. The basic pathology of this condition is a uterosacral lymphangitis secondary to cervicitis. The prime symptom is chronic low back ache aggravated by walking, menstruation and coitus and examination reveals the tender contracted cordlike ligaments. The efficacy of this operation is controversial probably due to variations in the depth and extent of the uterosacral division. In 4 cases the results have been disappointing. Uterosacral alcohol injection, epidural block, paravertebral block and chordotomy are briefly presented.

GEORGE BLINICK, M D

Study of the Uterine Cavity and of Tubal Permeability in the Fetus by the Method of Hysterosalpingography (Lo studio della cavità uterina e della permeabilità delle tube con il metodo della isterosalpingografia) P. SPOTO and I. ORLANDINI. *Qued clin* 1948 3 400.

Twenty-two female fetuses which were born dead or died soon after birth and were without evidence of maceration and apparently without genital or extra-genital malformations were examined by the same technique as that of hysterosalpingography in the adult living female for sterility. This material comprised 3 fetuses in the third month of intrauterine life, 3 in the sixth month, 4 in the seventh month, 6 in the eighth month, and 6 in the ninth month.

In all these cadavers the tubes were permeable, either *in situ* or when the examination was repeated on the excised genital organs. In the work on the isolated organs the technique used was that of Markoff (*Gyn obst* Par 1931 23 323). In all cases the tubes were tortuous in the isthmus portion and undulatory or even spirally coiled in the ampullar portion. In no instance were there evidences of inflammation or of inflammatory sequelae in the tubal walls.

The images of the tubes and the uterus were always uniform for the age of the fetus examined and frequently bore a striking resemblance to those described by other authors for the uteri of women suffering from the congenital form of primary sterility. The cervical cavity tended to be cylindrical without evidence of constriction at the cervicoisthmus junction and the cervical shadow was at least twice as long as that of the corpus uteri.

JOHN W BRENNAN M D

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Concerning the Biologic Reaction of G III Malignant in the Diagnosis of Pregnancy. Preliminary Studies. (Sulla reazione biologica di Galli Mainini per la diagnosi di gravidanza. Prime osservazioni) LECTIVO NORDI. *Riv. Ital. ginec.*, 948, 31 352.

In repeating the experimental work on the diagnosis of pregnancy by the Argentine physician Galli Mainini in 1947 the author has been using instead of the frog *Bufo arenarum* of Hensel the common field frog of Italy the *Bufo vulgaris*. The reaction depends, as in the Mainini test, on the finding of mobile spermatozoa in the urine of the male frog following the injection of the serum, or urine of the pregnant woman into the dorsal lymph sac of the frog.

In 36 pregnancies from the first to the third month the test was negative in only 2 (these later showed positive) in 30 advanced pregnancies (from the fourth month on) the test was invariably positive. In a few women during the puerperium the test was positive as late as the sixth postpartum day.

In 3 cases of adenitis, 20 of benign and 9 of malignant tumor 6 of secondary amenorrhea, 6 of the menopause 3 of disturbed endocrine function, and in 10 men the test was always negative. In 3 ectopic pregnancies there were negative reactions, and in 6 incomplete abortions there were 5 in 10 nonpregnant women there was only 1 positive result.

These figures, together with the constantly positive result following the injection of 0.01 U of the gonadotropic chorionic hormone and the constantly negative results following the use of the other hormones (ovular, luteal, and testicular) confirm the specificity and exactitude of the test. The test has practical value because of the speed of the reaction, the simplicity of the technique, the ease of microscopic demonstration of the spermatozoa, and the economy in procuring and rearing the test animal.

The author will report in future communications a larger material and more extensively on the physiologic basis of the reaction. Further studies will also be concerned with the exact dosages involved and the significance of the clinical factors present.

JOHN W. BRIDGMAN, M.D.

Pregnancy and Subacute Bacterial Endocarditis. CURTIS L. MENDENHALL. *Am. J. Obst.* 948, 36 645.

Prior to the introduction of antibiotics, subacute bacterial endocarditis was a fatal disease. Pregnancy was rarely complicated by this condition. From 1932 through 1947 there have been 10 such cases complicating pregnancy among some 50,000 patients at the New York Living In Hospital. Three cases occurred before the use of penicillin and all of the patients died during pregnancy or the puerperium.

Seven patients treated with penicillin survived pregnancy and delivered normal living children. In 5 of these cases the blood cultures proved that subacute bacterial endocarditis existed beyond doubt, while in 2 cases the blood cultures were negative.

A past history of subacute bacterial endocarditis is not a contraindication to subsequent pregnancy. The advisability of childbearing should be determined by the current cardiac status, and treatment should be given accordingly. Pregnancy does not alter the treatment of this disease. The prophylactic use of antibiotics during labor and the early puerperium is suggested to prevent the development or the recurrence of this condition.

JOHN R. WOLFE, M.D.

The Ureoretic Imperfection Coefficient of Maillard in the Nephropathies of Pregnancy. (Il coefficiente di imperfezione ureoretica di Maillard nelle nefropatie gravidiche) A. FAVINI. *Riv. Ital. ginec.*, 948, 3 293.

Thirty-six cases of nephropathy of pregnancy were studied by means of the coefficient of Maillard. Twelve of these were simple cases of albuminuria, 10 were instances of acute nephritis and 5 were cases of eclampsia in pregnancy. The coefficient is expressed by the formula
$$\frac{\text{Formol N}}{\text{hypobromide N}} \times 100$$
, in

which the Formol N represents the ammonium N plus the N of the amino acids, and the hypobromide N represents the ammonium N plus the urea N plus the N of the amino acids. The method was chosen because it was believed to give a fairly comprehensive picture of the functioning of the liver. The results here obtained were then run parallel with those of the Ambard constant in order to determine if these two values respond in the same manner to the vicissitudes, normal and pathological of the functioning of the kidney and liver. The normal average value for Maillard's coefficient is found to be about 6.5.

In the group of simple albuminurias the findings were either within the normal or slightly above, but they were always comparable to the physiologic figures for that period of pregnancy. In these patients the figures in 50 per cent of the cases returned to the normal nonpregnant level within 4 or 5 days postpartum. In the others the period of return to normal was as long as 10 days. In 2 instances in which the original figures had been quite high the coefficient was still elevated at the end of the tenth day in the puerperium. In the frankly nephritic cases the coefficient could again be forced into the limits of normality; however, the cases when viewed individually frequently gave figures too high to be explained otherwise than as an involvement of the liver. In this group the return to normal did not occur until from 10 to 15 days postpartum. In the

eclampsia group the figures both for the period of pregnancy and that of the puerperium were quite similar to those given previously.

On the whole the author concludes that the protein metabolism as indicated by the coefficient of Maillard has not been sufficiently consistent or definite in his material (which is admittedly meager and was studied in part during the war years when protein food stuffs were scarce) and therefore cannot serve as the sole indication as to the condition of the protein metabolism in the kidney involvements of pregnancy.

JOHN W. BRENNAN, M.D.

LABOR AND ITS COMPLICATIONS

Labor in Brow Presentation (Sul parto nella presenta-
zione di fronte) COSIMO PUTIGNANO. *Riv. ostet.*
ginec., 1948 3 197

Fifty nine cases of delivery in brow presentation were found among 13,234 births in the obstetrical and gynecological department of the University of Bari in the 20 year period from 1926 to 1945. This represents an incidence of 1.4 per cent. This high incidence is explained on the basis of the reluctance of the women of this region to present themselves at the clinic except for dystocia. In fact, the other common complications of childbirth also make up a high percentage in this material.

The mechanism of development of this complication is discussed in the light of the various theories propounded from time to time (La Chapelle, Mangiagalli, Pollockson, Marchionneschi and Alfieri). Special stress is placed on the "open mouth" theory of Alfieri and the clinical and cephalometric study of this theory by Moracci (*Arch. ostet. ginec.* 1946 51 17). —*Internal Abstr. Surg.* 1947 84 76). In the author's material the determining factor could be established in 66 per cent of the cases. The factor in 32.2 per cent was precocious rupture of the membranes in 23.72 per cent pelvic deformity and in 6.77 per cent maceration of the fetus. There was one example each of twins and of placenta previa. Most numerous were the women over 27 years of age, multiparity and fetuses of more than 3,750 gm. of body weight.

When the patient entered the hospital the membranes were intact in 35.42 per cent of the cases and the cervical dilatation was 3 cm. in 18.64 per cent, 5 cm. in 11.86 per cent, 7 cm. in 23.72 per cent and more than 7 cm. in 45.76 per cent. The fetus was alive in 59.32 per cent of the cases, in distress in 23.72 per cent, and dead in 16.95 per cent. The presentation was occipitobasiposterior in 55.93 per cent of these labors, occipitolaeva-anterior in 25.42 per cent, occipitolaevaposterior in 11.86 per cent and occipitodextra-anterior in 6.77 per cent.

In this clinic an expectant attitude predominated as a rule. The labor terminated spontaneously in 27.11 per cent of the patients, with forceps in 54.23 per cent and with version in 11.86 per cent. Cesarean section was resorted to in 5.08 per cent of the mothers (always because of a deformed pelvis) and embryot-

omy in 16.94 per cent. Hysterectomy with bilateral salpingo-oophorectomy was done in a case of ruptured uterus.

The fetal mortality was 35.59 per cent, this included the fetuses which were dead on admission (16.94 per cent) and those dying after admission. Those dying during the surgical intervention comprised 13.55 per cent and those dying in the course of labor 5.08 per cent. There was a percentage of 27.77 of fetal deaths among the primiparas and of 30.03 among the pluriparas. Among the women with intact membranes on admission the fetal mortality was 20 per cent and among those with ruptured membranes the mortality rose to 43.53 per cent. Spontaneous deliveries resulted in a fetal mortality of only 6.25 per cent, the mortality following the application of forceps was 46.87 per cent and that following the classical version 57.14 per cent. Among the small fetuses the mortality was 30.76 per cent, among those of normal weight it was 37.93 per cent and among the large fetuses it was 41.76 per cent.

The maternal morbidity was 18.64 per cent, however only 1.72 per cent (1) of the mothers died, this mother had a ruptured uterus.

JOHN W. BRENNAN, M.D.

Spondylolisthesis as a Complication of Childbirth
(Ueber die Spondylolisthesis als Geburtskomplika-
tion) KEIJO SORVA. *Acta obst. gynec. scand.* 1948 28
137

The author adds 1 more case of pregnancy in a young woman with spondylolisthesis to the approximately 30 cases of this type already reported. His patient had participated in the work about a farm house had never noted any discomfort and had not noted that she had become shorter in stature. She did not recall that any special stress had been placed on her spine and had had no accidental injury of any kind to her back.

External observation evidenced immediately the peculiar characteristics of the spondylolisthetic individual: her back was short and broad, she had no waist, the chest sitting immediately on the top of the pelvis and she had a deep depression over the area of the lower lumbar spine, this depression terminating abruptly by the sharp offset of the rather prominent upper angle of the sacrum. Roentgenologic examination both before and after the removal of the child by cesarean section showed that the fifth lumbar vertebra had slipped entirely off the articular surface of the upper end of the sacrum and was resting horizontally with its lower articular surface applied flatly to the anterior surface of the sacrum. This vertebra had of course dragged the fourth lumbar vertebra down with it into an almost horizontal position.

Since the pelvis was not greatly deformed it was concluded that the spondylolisthetic process began rather late after the pelvic bones had consolidated and had perhaps become accelerated to produce the condition found only after the beginning of the pregnancy.

JOHN W. BRENNAN, M.D.

Pethidine and Scopolamine in Labor HILDA ROSENTHAL *Brit. M. J.* 948, 590.

A series of 500 patients receiving pethidine (demerol) and scopolamine in labor has been observed. The first dose consists of pethidine, 100 mgm. and scopolamine $\frac{1}{150}$ gr (0.43 mgm.) intramuscularly. A second similar dose is given 1 hour after the first, but its administration must be judged according to the merits of each case. Subsequent doses can be given at intervals of 4 to 6 hours, however if possible scopolamine is not given within 2 hours (at least) of delivery as it may promote some neonatal operation of the mother and some respiratory depression of the infant. The maximum dosage of scopolamine in this series was three doses each of $\frac{1}{50}$ gr and it was given over a period of 18 hours, together with 400 mgm. of pethidine. The maximum amount of pethidine used in a single case in this series was 500 mgm. and this was given over a period of 30 hours together with two doses of scopolamine each of $\frac{1}{50}$ gr. The drugs were generally given intramuscularly but if the patient was suffering unduly and immediate relief was required the first dose was given intravenously.

The degree of relief obtained was good in 83 per cent satisfactory in 38 per cent and fair in only 36 per cent of the patients. In 2 patients the degree of relief was difficult to assess. The results do not show any increase in either maternal or fetal mortality rates and the incidence of postpartum hemorrhage is not raised.

There is a suggestion that pethidine and scopolamine may have the effect of shortening the duration of labor. Uterine contractions, as recorded with the aid of an abdominal tambour, did not seem to be altered in rhythm or amplitude. The blood pressure and respiration are not significantly affected. In no case could the application of forceps be said to be due to the analgesia. GEORGE BUNICK, M.D.

PUERPERIUM AND ITS COMPLICATIONS

Epulis and the Puerperal State (Epulis nato puerperale) GIOVANNI L. CO *Riv. ostet.* 948, 36.

Three cases of epulis, developing during pregnancy in young women from 22 to 28 years of age and disappearing completely 2 or 3 months after childbirth, are reported. In all of these patients the dark red violaceous excrescences in the gingival border on the left side of the upper jaw in the region of the canine tooth. In 1 of these the growth returned with a second pregnancy but in this instance it, as located on the right side, involving the area of the lateral incisor tooth. In this patient a biopsy specimen disclosed the typical confused arrangement of sarcomatoid fusiform cells interspersed with huge cells with many centrally located nuclei (myeloplax).

In the third patient the gingival growth started in the lower jaw more or less on the midline and spread somewhat toward the right side. Here a small biopsy specimen near the edge of the growth exhibited the

same sarcomatoid stroma without atypical karyokinesis as in the previous biopsy and without evidence of myeloplax. This growth was quite vascular. After delivery there was the same diminution in size of the growth and the same paling to a normal pinkish color. In this case another biopsy specimen was procured a month after delivery and histologically it exhibited a more mature connective tissue type of stroma cell forming a sort of meshwork around extensive areas of hyaline degeneration of sarcomatoid cells. The blood vessels had also apparently undergone the same hyaline regressive change. The basal layer of the overlying epithelial layer appeared to be undergoing the same type of hyaline degeneration. The epithelial layer was thinner than normal and the epithelial pegs had largely disappeared.

The author suggests that the regression of these growths after childbirth might be the result of the protective action of lactation against the allegedly carcinogenic action of the estrogenic hormone of the ovary and he believes that extracts of the active mammary gland should be tried in cases of epulis developing under nonpregnant conditions.

One thing is certain, and that is that the treatment is not surgical. JOHN W. BRECKMAN, M.D.

Puerperal Perigenital and Perineal Hematomas. FRANK J. WALSH and HOWARD I. GARDNER. *Am. J. Obst.* 948, 56-60p.

Puerperal perigenital and perineal hematomas are accumulations of blood in the perigenital soft connective tissue resulting from the rupture of a blood vessel usually a vein, incumbent on the trauma of labor. Such a complication usually occurs during the descent of the fetus or shortly after delivery. The blood escaping into the connective tissue follows the planes of cleavage of the fascia. When this occurs high in the genital tract, the blood tumor forms within the broad ligaments, fills the pelvis, and may extend retroperitoneally to the region of the kidney or the diaphragm. When low in the genital tract, the hematoma will fill the vagina, distend the perineum and vulva, or displace the rectum or urethra.

Three cases observed at the St. Elizabeth Hospital, Chicago, are presented—1 perineal, 1 vaginal, and 1 supravaginal.

Early incision of the hematoma with ligature or suture ligation of the large vessels and packing of the hematoma cavity is the treatment of choice for perineal or vaginal hematomas. In the supravaginal variety laparotomy is indicated, and hemostasis must be secured even if a hysterectomy is necessary.

NEWBORN

Some Aspects of the Problem of Hemorrhages in the Newly Born (Algunos aspectos do problema das hemorragias no recém-nascido) OTTO CERNY. *Riv. ostet.* 5 *Paide.* 947, 8.

Hemorrhage in the newly born may be due to vascular lesions incurred during labor to so-called

hemorrhagic disease of the newly born and to hereditary conditions. Systematic autopsies have shown that natal and neonatal mortality from hemorrhage caused by traumatism of labor is much greater than was hitherto accepted. The most important and the most frequent of these hemorrhages are the intracranial and the suprarenal. Intracranial lesions especially of the septa of the dura mater are nearly always accompanied by hemorrhage. In addition the suction acting on the head of the fetus after rupture of the membranes may produce blood suffusions in the brain. The varying sites of the hematomas and the degree of compression which they exert on the brain cause the variability in symptoms when the child survives labor.

Massive hemorrhage of the suprarenals is nearly always bilateral may reach the capsule, and may result in effusion of blood between the layers of the peritoneum and into the peritoneal cavity itself. In most cases the diagnosis has been made at autopsy but it is possible to make the diagnosis during life. The condition presents the appearance of pneumonia and for this reason has been given the name of pseudopneumonia of the newly born however the true condition can be recognized by means of a careful clinical examination and study of the blood. It should also be noted that cases of hemorrhage due to traumatism of labor tend toward aggravation during the first days of life.

Clifford's concept that hemorrhagic disease of the newly born is a syndrome of spontaneous internal or external hemorrhage associated with hypoprothrombinemia is now generally accepted. In this connection should be remembered the fact that there is a physiologic hypoprothrombinemia in the newly born during the first days after birth under normal conditions the child is born with a relatively high concentration of prothrombin which from the first day after birth decreases gradually and then increases gradually to reach normal values about the sixth day. Thus all newly born are exposed to the potential danger of hemorrhage during the period of physiologic fall in the rate of prothrombin. In addition this prothrombinopenia may turn into a pathologic condition if the natural processes do not promptly help to re-establish a sufficient concentration of prothrombin. Some authors claim that, if the prothrombin rate falls below 25 per cent of normal, hemorrhagic disease ensues. Other conditions may also contribute to the hemorrhagic tendency the liver may be in sufficient or incapable of producing prothrombin although the necessary materials are present in the organism, or the bile ducts may be obstructed and, despite normal liver function and the presence of vitamin K in the intestine, this vitamin cannot be emulsified for absorption. And recently some investigators have shown that in some cases of hemorrhagic disease prothrombinopenia cannot be accepted as the direct cause of the disorder.

In rather rare instances the newly born may be a carrier of hereditary abnormalities such as hemo-

philia, hereditary pseudohemophilia (hereditary hemorrhagic thrombasthenia of Glaxmann thrombopenic hemorrhagic purpura, or hereditary thrombopenic purpura) hereditary hemorrhagic telangiectasia, better known as Osler's disease (disease of Lendu-Osler of Weber or hereditary familial angiomatous disease of Goldstein)

The rate of prothrombin in the newly born can be increased by means of vitamin K administered to the mother or to the child and it would seem that the best effect can be obtained by giving an adequate oral dose (50 mgm.) to the mother from 12 to 4 hours before labor. This method is indicated in all cases in which the occurrence of hemorrhage in the fetus is thought to be likely. Some authors have advised the systematic use of vitamin K in all pregnant women during the last weeks of pregnancy as a prophylactic measure against hemorrhage of traumatic or spontaneous origin or to prevent the usual prothrombinopenia of the newly born. The advantage of this measure is open to discussion. It would be justified in vitamin K deficiency in the mother with repercussion on the fetus. Evidently it could not change the incidence of intracranial and other hemorrhages due to traumatism of labor but it could prevent aggravation of these hemorrhages. It could also be used to advantage in cases in which breast feeding is impossible. However vitamin K should not be the only recourse in cases which do not respond promptly to treatment. For instance in hemophilia the transfusion of whole blood is the only available measure although its results are rather uncertain while vitamin K may help to correct the physiologic prothrombinopenia and thus improve the possibility of blood coagulation.

As the transfusion of whole blood plays a very important part in the solution of the problem of hemorrhage in the newly born, rigorous classification of the blood to be used is imperative. Parents should never be taken as donors however when no Rh negative donor is available, maternal blood may be used for the transfusion of washed red cells.

RICHARD KEMEL, M.D.

MISCELLANEOUS

The Permeability of the Human Placenta to Water and the Supply of Water to the Human Fetus as Determined with Deuterium Oxide. L. M. HILLMAN, L. B. FLEXNER, W. S. WHEAT, G. J. VOSSYAN, and N. K. PROCTOR. *Am. J. Obst.* 1948, 56: 861.

Changes in the permeability of the human placenta to water have been measured from the fourteenth week of pregnancy to term. Deuterium oxide was the tracer material used.

The human fetus receives across the placenta at the fourteenth week of gestation 700 times and at the thirty first week, 3,800 times as much water as is incorporated in the growing tissues.

JOHN R. WOLFF, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Paraganglioma. CARLETON A. SMITH. *J Urol* Balt., 94, 60: 697

A case of an extra adrenal medullary tumor (paraganglioma) is presented. The symptoms consisted of paroxysmal hypertension and blanching of the finger tips. Roentgenologic studies showed a soft tissue mass 6.5 by 5 cm. containing flecks of calcium located between the left transverse processes of the second and third lumbar vertebrae. An excretory urogram showed the left ureter to be deflected around this mass. An accurate preoperative diagnosis was made.

Surgical removal was immediately followed by shock which was successfully treated by the subcutaneous and intra-venous injection of epinephrine, the intramuscular injection of epinephrine in oil, the intravenous infusion of isotonic solution of sodium chloride, the transfusion of blood, and the use of adrenal cortical extract. JOHN L. ENCKETT, M.D.

Anatomy of Pararenal V. Ins. BARRY J. ARBON, EARL W. CAULDWELL, JAMES W. PICK, and LINDSAY E. BEATON. *J Urol* Balt., 94, 60: 74.

Four hundred and fifty adult cadavers were examined with reference to the pararenal system of veins. This precise and painstaking work by the authors makes it quite clear that the traditionally simple form of renal pedicle commonly portrayed in standard anatomical texts cannot be accepted in the light of critical study of the kidney area. The kidneys receive numerous arteries from varied sources, and venous tributaries converge upon them from both adjacent and remote visceral and parietal structures. The pattern of renal and pararenal vascularity varies within definable ontogenetic limits and the authors describe the more common plans, together with the more usual variations. JOSEPH E. MAUREN, M.D.

Treatment of Bilateral Renal Calculi. M. S. S. EARLAM. *Austral. N. Zealand J Surg* 94, 8: 6.

The determination of the suitability for operation of patients who have bilateral staghorn calculi is difficult. In general three principal criteria are used: (1) the renal function, (2) the degree of urinary infection, and (3) the age and general condition of the patient. The patient should be reasonably young, with good renal function and minimal infection. Other factors to consider are the size and complexity of the branching calculus and the thickness of the remaining renal parenchyma. Occasionally bilateral operation is feasible. In some cases in which the disease is advanced on one side and moderate on the other, conservative surgery on one side and nephrectomy on the other is the procedure of choice.

The most important point in operative technique is adequate exposure, with resection of the twelfth

rib if necessary. Usually the greater portion of the stone can be removed through a pyelotomy incision, the remaining pieces being extracted through nephrostomy incisions. Complete removal of all stony material is most important to avoid recurrence, and should be checked roentgenologically during operation. Postoperative drainage is maintained by means of a nephrostomy tube. In some cases a ureteral splint is left in place for a period of 3 weeks.

Postoperative treatment consists of a copious intake of fluids and chemotherapy. Continuous lavage with Suby G solution through the nephrostomy tube should be done in all cases in which it is suspected that fragments of stones remain, or in cases in which severe alkaline infections complicate the situation.

Long term treatment to prevent recurrence of stone consists of chemotherapy, a permanently increased intake of fluids, and acidification of the urine by means of the acid-ash diet. Adequate amounts of vitamins should be taken. Attempts may be made to reduce the excretion of calcium and calcium solubility without alteration of the pH of the urine by the administration of stilbestrol, or reduction of the excretion of phosphates by the injection of "amphojel."

"Decubitus" calculi (calculi which form during long periods of immobilization) are caused by decalcification of the skeleton and stasis in the renal pelvis and calices during prolonged periods of confinement to bed. The best method of prevention is the liberal administration of fluids and frequent turning of the patient. When this condition is refractory acidification of the urine may be necessary.

Parenchymal calculus is the result of occlusion of the renal tubule by proliferation of the tubular epithelium. The mass of cells degenerates until a homogeneous mass is formed on which calcium salts are deposited. These calcium "masses" or "calculi" usually maintain their position in relation to the pelvocaliceal system, without change for years. Occasionally however they may work their way into the pelvis and be passed.

Partial Nephrectomy in Renal Hydatidosis (La nefrectomia parcial en la hidatidosis renal). ENRIQUE A. BORDABERRIE and RUBEN ARDAS. *Rev. Soc. Cir. Uruguay*, 94, 9: 75.

Hydatid cysts of the kidney are always intrarenal and subcapsular and when found in the renal cavity always arise from a small base in one calix.

The pathologic and clinical picture consequently will be that which results from mechanical obstruction because of the size of the cyst and atrophy from pressure upon the glomeruli and tubules.

Since a hydatid cyst is considered an encapsulated parasite arising from a small base, modern surgical

procedure calls for the simple removal of the cyst as along with the base and its adjacent tissues. The kidney is no exception in this regard.

Two cases are reported in which partial nephrectomy with complete removal of the cyst was done. Rapid uneventful recovery and permanent cure followed.

STEPHEN J. ZIEMAN M.D.

Cysts of the Mesonephric Tract. E. R. REAY *Am J Surg* 1948 18 26

The author presents 2 cases of cysts which he regarded as vestigial remains that arose presumably from the wolffian tract. The first patient was a newborn female infant. The cyst presented in the anterior vaginal wall which caused retention of the urine and filling with an opaque medium showed a large pelvic cyst which deformed the bladder and pushed it forward. A lower sausage-shaped portion of the cyst extended into the vagina. The contents of the vaginal portion of the cyst were drained and this part of the cyst had not refilled after 6 months.

In the second case that of a man 56 years old there was a large cystic abdominal tumor which displaced the left kidney upward, the ureter medially and the colon laterally. Surgical exploration showed the cyst to be too extensive for removal so the contents of the cyst were aspirated. The lining of the cyst was peeled out and the bleeding was controlled. Microscopic section of the wall of the cyst showed it to consist mainly of primitive renal tissue. The glomeruli were scanty and primitive and showed all stages of atrophy and degeneration.

The author gives the embryologic explanation for the occurrence of these cysts.

JOHN L. EMMETT M.D.

Spontaneous Subcapsular Perirenal Hematoma (Sull'ematoma perirenale sottocapsulare spontaneo) DOMENICO SALERNO *Polidinica sez prat* 1948 55 1137

The etiopathogenesis of nontraumatic perirenal hematomas has been and still is the subject of discussion. They are divided into three groups according to their location (1) the subcapsular which are rare in comparison with the others (2) the extracapsular which occur in the perirenal fatty tissue and may spread to the iliac fossa and even the root of the thigh and (3) the mixed which begin as subcapsular break through the capsule and become also extracapsular.

The acute forms start suddenly and present nearly always the symptomatic triad of Wuenderlich: sudden violent pain in the lumbar region, irradiating to the entire abdomen but always more intense on the side of the lesion; signs of acute anemia due to increases rapidly and retroperitoneal swelling which of an enlarged kidney which may extend upward to the costal margin and downward to the pelvis. Sometimes there are premonitory signs consisting of small colics caused by small perirenal hemorrhages

preceding the large one. The symptomatic triad may be associated with less constant symptoms: hematuria, fever shock, peritonitic signs, subicteric anuria, ecchymosis, scoliosis and roentgen signs of paranephritis.

In the chronic forms, which are much rarer than onset and course are silent and the hematoma is discovered at autopsy or the silent onset is followed by slight, occasional colics due to small hemorrhages which tend to become encysted or there may be only a sensation of weight and painful pulling in the lumbar region.

When Wuenderlich's triad is present, the diagnosis can be safely established but it is impossible before operation in the chronic forms. The prognosis in the acute forms must be very reserved since the mortality in operative cases amounts to about 50 per cent. The prognosis is better in the chronic forms. The treatment can be only surgical and must be instituted promptly.

The author reports a case of acute, spontaneous subcapsular perirenal hematoma in which preoperative diagnosis was nearly impossible because the pain was not as sudden and as violent as in the classical cases and the signs of acute hemorrhagic anemia were sketchy and were not accompanied by a rapidly increasing lumbar swelling. It seems that an exclusively renal origin of the disorder must be rejected since the kidney did not present any tumoral suppurative, tuberculous or hydronephrotic lesions, but showed a picture of paranephritis with acute inflammatory changes in the capsule and moderate inflammation of the cortex. The patient had received a contusion of the dorsolumbar region 8 years previously and another 3 years previously and had been submitted to diathermocoagulation for bladder papilloma 1 year and 3 months respectively before admission and these interventions had been followed by cystitis and pyelitis. Consequently the occurrence of the paralytic phenomenon of Sanarelli-Schwartzmann could be invoked as explanation of the disorder. According to this interpretation there would have been the following succession of events: (1) contusion of the lumbar region with probable production of a local hematoma, a site of minor resistance into which bacteria gained a foothold by the hematoma route with resulting paranephritis. (2) new introduction of toxins into the circulation during the cystitis-pyelitis, and the formation of special angio-hemorrhage. From this point of view the case may be regarded as a typical and rare example of subcapsular perirenal hemorrhage probably due to allergic changes in the perirenal vascular system.

RICHARD KEMEL, M.D.

Mesoblastic Nephroma in Adults. ORMOND S. CULP and FRANK W. HARTMAN *J Urol* Balt. 1948, 60 552

Embryonal tumors of the renal cortex have been reported with more than 50 different pathologic diagnoses. The resulting confusion in nomenclature

Sarcoma. The sarcoma group was the most confused and the most difficult to review satisfactorily. In the early literature sarcomas were diagnosed on gross examination alone by bits of tissue removed through ureteral catheters and even on the assumption that any bilateral renal tumor must be sarcoma. Today the sarcomas are confused with undifferentiated carcinomas. The only tumors that might fully belong in this group are neoplasms composed only of embryonic connective tissue elements. The authors found one such tumor in their series and after careful examination of 114 reported cases in adults, they selected 30 which may belong in this embryonal group. The others were omitted because of their incomplete morphologic data or because of obvious origin in the renal capsule.

Renal sarcomas have varying microscopic pictures and have been grouped as fibrosarcoma (including spindle cell type) myosarcoma (including leiomyosarcoma and rhabdomyosarcoma) liposarcoma, lymphosarcoma, osteoblastic, and undifferentiated. These subdivisions illustrate the extreme multipotentiality of the parent cells and represent increasing degrees of malignancy.

The clinical analysis of this group closely paralleled the mixed cell tumors. No significant differences were found in sex or site of the primary growth. Symptomatology was similar to that of the mixed cells with no diagnostic signs or symptoms indicative of sarcoma per se.

Most of the patients were nephrectomized and died soon thereafter despite postoperative irradiation in many cases. Local recurrences of the sarcomas were common and metastases were found most frequently in the lymph nodes, lungs and liver. No correlation was found between survival and the type of sarcoma.

Undifferentiated. Most of the highly malignant cortical tumors composed of very primitive cells can be identified as either undifferentiated carcinomas or undifferentiated sarcomas. Smith mentioned an embryoma in which he thought it was impossible to recognize either epithelial or connective tissue elements and designated it as a completely undifferentiated tumor of embryonal origin. This 63 year old patient died.

The authors summarized that after reviewing the literature and studying 8 of their own embryonal cortical tumors, they are convinced that all these embryonal neoplasms are closely related rather than distinct morphologic entities. They suggest that they be called mesoblastic nephromas and that more complicated pathologic terms as well as the name Wilms tumor be avoided.

These tumors occur at any age in both sexes in either kidney, usually are very malignant and tend to recur after either lumbar or transperitoneal nephrectomy, they metastasize to lymph nodes, lungs, and liver most frequently cannot be distinguished from other renal neoplasms clinically and appear to be influenced very little by irradiation. The clinical course usually is rapid and most

deaths occur within 12 months of diagnosis and treatment regardless of the specific tumor type.

Like other malignant tumors operative cures will depend on very early recognition and even then survival will probably be confined to the few mesoblastic nephromas with relatively low malignancy.

ROBERT O. BEADLES, M.D.

Adenocarcinomas of Kidney. JAMES D. FRYFOOLE, MALCOLM B. DOCKERTY, O. THORON CLAGGETT and JOHN L. EMMETT. *J. Urol.*, Balt., 1948 60: 321.

The authors of this article wish to present a specific group of tumors that show a constant microscopic cellular differentiation, the dark-celled adenocarcinomas and to correlate the clinical, surgical and post-operative records with the pathologic study which they made.

Seven hundred and sixty-eight malignant neoplasms of the renal cortex were examined grossly and microscopically. The fresh frozen section technique with Terry's polychrome methylene blue stain was used to rule out those tumors presenting the typical hypernephroma picture of the clear vacuolated cell types. Because of the necrotic condition of some of the tumors and the difficulty of using the fresh tissue stain on formalin fixed material all doubtful lesions were recut and stained with hematoxylin and eosin.

An effort was made in this study to compare the cytologic characteristics of the dark-celled carcinomas with normal renal histologic structure. Specimens of normal kidneys were taken from a 7 month stillborn infant and from subjects in each decade through 70 years of age in an effort to find a microscopic picture compatible with the renal strain of the varied age groups. None of these subjects had died from renal disease yet evidence of epithelial regeneration especially about the glomeruli in the older kidneys was seen. In 2 of the subjects more than 40 years of age glomerular capsular proliferation with compression of the tufts was noted. These proliferating cells were small and darkly stained and had faint basophilic granulations. The epithelial cells forming the crescents presented varying stages of fibrosis. The intracapillary cytologic pattern showed no significant changes except in 1 case in which hyalinization marked previous glomerulonephritis.

Careful study of the component parts of the tubule showed cells of clear cytoplasm lining the proximal and distal convoluted tubules. Horizontal sections through the medullary rays provided sections of Henle's loop.

Two factors contribute to the continued use of the term "hypernephroma" even though the origin of cortical carcinomas is now established as being the renal parenchyma. (1) the historic use of the term and the extreme controversy when it was introduced and (2) the confusion of names applied to cortical malignant lesions by two main groups, the radiologists and the pathologists. The fallacy of classification of any group of tumors on the basis of clinical

benefit derived from roentgen rays without pathological support is evident.

Likewise, the abundance of patterns seen microscopically in cortical malignant lesions should be proof in itself of the inadequacy of classification on this basis.

Cytology as a basis for classification has been dismissed because both dark-celled and clear-celled strands are usually seen in the same tumors.

For these reasons teachers have been reluctant to discard the term "hypernephroma," which although genetically false is understood by all to mean a malignant renal tumor.

For the sake of clarity the authors too have used the term "hypernephroma." In the microscopic reports but after being confronted with a lesion that in no way gross or microscopic, resembled Grawitz original description, examining all the other "hypernephromas" removed at the clinic, and writing this article they are convinced that the dark-celled adenocarcinoma is a tumor entity in itself and deserves recognition as such.

In the authors' series, 12 of the patients had extrarenal extension. Of these only 4 survived for long periods: 1 whose lesion was graded 3; 1 with aortic nodal involvement and 2 with a venous thrombus. All 4 patients were women.

With an average of symptoms measured in months prior to diagnosis, it does not seem logical to assume that in clinic patients the diagnosis is made earlier than elsewhere. Those patients who at operation had widely disseminated or high grade lesions died from their tumors in the same manner and time intervals that are recorded for all types of cortical malignant lesions be they clear-celled dark-celled or mixed.

The survival of patients with large tumors (from 1,000 to 3,400 gm. in weight) is of interest. These patients were all women.

The close microscopic resemblance of embryonal dark-celled tubules and the exactness of the microscopic picture of dark-celled adenomas to the tumors under discussion point to the possible site of origin.

In the present series there were 29 cases of pure dark-celled adenocarcinomas (3.8 per cent of cortical malignant lesions). Their diagnosis cannot be made as such preoperatively but it is suspected by alteration of the gross color and ill-defined encapsulation and is proved by multiple microscopic sections showing only the dark granula cells. The tumors differ from mixed and from clear-celled adenocarcinomas in that they contain little or no intracellular fat, they appear to occur more frequently in women than in men, and that the most frequent symptom complaint is that of a mass. They frequently calcify and regardless of size, if the tumor is removed before extrarenal extension occurs the patients especially the women have long-term survivals. The prognosis in this small series was somewhat better than for hypernephromas.

Of 29 patients 8 underwent operation within the last 5 years, 1 patient was followed up for only 3

years which left 20 patients eligible for the calculation of a 5 year survival rate. Ten patients (50 per cent) lived 5 or more years after operation. Although the series is small it is interesting to note the difference between the survival rate among men and women. The 5 year survival rate for men was 25 per cent (2 of 8) as compared to a 67 per cent (8 of 12) 5 year survival rate for women. Also, all of the long term survivals occurred in women. These were 21, 22 and 31 years postoperatively.

Late Results of Surgical and Nonsurgical Treatment of Ureteral Calculi Studied with Excretion Urography (I risultati lontani della cura chirurgica ed inchiostro della calcolosi ureterale studiati con l'urografia di eliminazione) L. GORGIAN, *Ann. Ital. Chir.* 94B 25: 353.

In an attempt to verify the condition of 30 patients with ureteral calculi treated at the Surgical Clinic of Pisa from 1927 to 1947 Gurgian found that 10 could not be traced and 4 had died (3 from general diseases and 1 following operation for lithiasis of the contralateral kidney). 5 wrote that they were well but refused to come to the clinic for examination, and the remaining 11 of whom 8 had been treated surgically and 3 nonsurgically from 9 to 20 years previously agreed to submit to excretion urography and the usual urine examinations. Three roentgenograms were taken of each of the 11 patients one before injection of opaque substance to determine the eventual presence of calculi another during the first minutes after the injection, and the third from 20 to 25 minutes after the injection. Chromocystoscopy was performed in 2 patients in whom excretion urography was completely negative.

From the clinical point of view the late results of both surgical and nonsurgical treatments may be said to be good if not optimal, since all patients after removal or elimination of the calculus have been in excellent health and have not experienced any significant disturbances of the urinary system. From the functional point of view the excretion urography showed normal results in 8 patients a slight alteration in 2 and complete absence of function in 1 patient.

From the morphologic point of view there were ectatic changes in the renal pelvis and the ureters of 6 patients (4 cases were septic). In 1 patient the change could not be demonstrated because of complete absence of elimination of the opaque substance but there was no doubt about its presence since lumination of indigo failed. In addition, ureteral catheterization revealed stagnation of fluid which was clear like water. In another patient no picture was obtained by excretion urography. In the remaining 3 patients there were no morphologic changes worthy of note.

In conclusion it may be stated that in the absence of serious infectious complications the treatment of ureteral calculus should always be conservative with regard to the kidney because the late results are good even in kidneys that are partly altered in their

morphology and function. Besides there is always time to remove a kidney which functions only partially and which after all constitutes a functional reserve for the organism. RICHARD KEMEL, M.D.

BLADDER, URETHRA, AND PENIS

Spontaneous Rupture of the Urinary Bladder h
A. RUSSELL TAYLOR *Brit J Urol* 1948 20 117

The author reports a case of spontaneous rupture of the bladder in a patient with compression fracture and complete paraplegia with loss of sensation up to the inguinal region. He modifies the classification of spontaneous rupture of the bladder by stone as follows:

1. Inflammatory lesions of the bladder wall (a) intramural in origin including tuberculosis of the urogenital tract particularly of the bladder wall itself (b) extramural in origin
2. Malignant disease of the bladder wall (a) vesical (b) intravesical (c) extravascular
3. Obstructive changes at the bladder neck (a) prostatic enlargement—benign malignant, and inflammatory (including seminal vesiculitis); (b) calculi (c) paralytic, due to interference with the nerve supply of the bladder wall (d) uterine and adnexal disease (e) occurring during labor
4. Obstructive lesions in the urethra (a) stricture—organic or spasmodic (b) valves diverticula—usually congenital (c) tumor (d) calculi (e) penile urethral inflammation (f) penile urethral tumors
5. Overdistention of the bladder due to alcoholism.
6. Ulceration of the diverticulum due to a retained phosphatic concretion.
7. Degeneration of the musculature of the bladder wall appearing as areas of fibrosis or necrosis from any cause. *Example* fatty degeneration or syphilis
8. Pressure from a drainage tube
9. Internal violence due to lavage of the bladder with overdistention of the diseased wall

JOHN A. LOFF M.D.

A Contribution to the Treatment of Diverticula of the Bladder (Contribution au traitement des diverticules de la vessie) GUY VIOLET *J urol med* Par 1948, 54 451

Observations on 33 patients with diverticula of the bladder led the author to the following conclusions:

Whenever an obstacle can be demonstrated in the bladder it should be removed and unless there are some contraindications a diverticulectomy should supplement the removal of the obstacle. If no obstacle can be detected a diverticulectomy alone may be expected to produce cure and therefore resection is superfluous. The extravascular approach is the method of choice.

The preoperative treatment includes the introduction of a retention catheter and repeated irrigations of the bladder until the urine becomes clear. Urographic examinations are indicated. Penicillin is given for prophylactic purposes.

If the diverticulum can be easily exposed and isolated through the extraperitoneal extravascular route it may be necessary to incise the formation and to dissect it after the introduction of a finger into it in a manner similar to the isolation and removal of a hernial sac. A drain is inserted into the paravesical space at the termination of the operation and penicillin is given until the temperature remains normal for at least 48 hours. Unless an infection is present, a retention catheter may be employed in place of a cystotomy for the drainage of the bladder.

The author's remarks do not pertain to patients with congenital malformations or those in whom local or general conditions contraindicate surgical intervention.

JOSEPH K. NARAT M.D.

A Pathologically Displaced Upper Femoral Epiphysis as a Foreign Body in the Urinary Bladder
E. SAEK, *Brit J Urol* 1948 20 114

The author reports the case of a pathologically displaced upper femoral epiphysis as a foreign body in the urinary bladder in a young male 14 years of age who was hospitalized for a swelling in his left knee with limited motion of the left knee and hip and a sinus over the sacroiliac joint. He also complained of painful and frequent urination. He gave a history of having been injured in a basketball game about 2½ years previously. This injury which consisted of laceration of the left thigh subsequently became infected and drained for about 7 weeks. Shortly after this several metastatic abscesses developed which were incised and drained. About 6 months later a plaster spica was applied to the left hip after forceful extension. Fifteen days later the patient noticed that his urine became turbid and that it contained shreds. There was also a hematuria in increased frequency and nocturia.

Since the patient's illness in February 1945 there had been a slight swelling of the left buttock accompanied by pain. In January, 1947 this swelling opened spontaneously and drained a thick odorless pus which gradually became thinner and then subsided completely.

Examination of the urinary tract revealed these essential findings: the urine was turbid and contained shreds of mucus and pus; culture of a catheter specimen of the urine showed the presence of *Staphylococcus aureus* on passing a sound into the bladder a click was heard denoting a hard foreign body.

Roentgenograms of the pelvis showed an inflammatory process involving the left sacroiliac joint with an almost complete destruction and flattening of the acetabulum, and an upward displacement of the neck of the femur without any evidence of the head. Over the left ischial spine at the brim of the pelvis there was a big rounded shadow about 1½ inches in diameter. A lateral film showed this to be the head of the femur displaced anteriorly.

After a study of intravenous pyelograms it was decided the head of the femur was free in the bladder and a cystotomy was performed for its removal.

JOHN A. LOFF M.D.

On Tumors of the Bladder with Particular Attention to Their Clinical Classification and Prognosis. P. I. TROVATZKY. *Ann chir gyn-fenn.*, 918, 37: Suppl. 5

This comprehensive monograph is based on a study of 260 patients with tumors of the bladder who were treated at the First Surgical Clinic of the University of Helsinki during the years from 1925 to 1946. The author delineates the finer points in determining the transition from a benign to a malignant state and by successive repetitions emphasizes significant signs. Thus the suspicion of malignancy exists when tenesmus is associated with hematuria. A congested mucous membrane frequently indicates malignant infiltration as does rigidity and roughness or raggedness of bladder contour (noted in the cystogram). In a similar manner by repetitious statistical studies the author seeks to justify his clinical classification of bladder tumors and the modalities of treatment which are recommended.

The classification is based on cystoscopic and cystographic findings and on the clinical course. Histological diagnoses are not reliable although verification of clinical diagnosis by such means is of value. There are then, three groups: benign papillomas comprise 55 cases; a second group is comprised of 78 cases of malignant papillomas and papillary carcinomas which are often difficult to distinguish from each other; the third and largest group is comprised of solid carcinomas. There are 5 undefined tumors. It is evident, however, that complete accuracy in classification is lacking since several of the patients with benign tumors (as noted in late follow-up reports) have died of malignancy. Further the unpredictability of tumor behavior is borne out by a benign classification in the early stages of almost one half of the cases which ultimately were designated as belonging to group 3.

There are two main forms of treatment: conservative (electrocoagulation) and operative. Under the latter modality the author lists "sectio alta," (suprapubic cystotomy) with diathermization of the tumor resection of the bladder and cystectomy (used in only 3 cases).

In the case of benign papillomas particularly the best results were obtained by conservative measures (used in 38 patients). After 5 years 74.7 per cent of the patients were living and after 10 years 65.2 per cent were living.

Results of open operative procedures were less satisfactory even allowing for the greater severity of involvement which made this modality preferable. After 5 years 50 per cent of patients were living and after 1 year 30.8 per cent were living. The author is particularly disappointed with "sectio alta" and diathermization. This procedure does not prevent recurrences; does not remove all the tumors in multiple growths and may amount only to a somewhat radical method of obtaining a biopsy. In this tumor group, open operation should be performed in cases of malignant degeneration, in cases which hemorrhage has occurred or in the presence of other com-

plications in which conservative treatment is inadequate.

Among the cases of malignant papillomas and papillary carcinomas of a more serious nature in a higher age group (60.4 years as compared to 55.7 years in the group with benign lesions) the mortality was higher. Here too conservative treatment was more satisfactory and 34.8 per cent of patients were alive after 10 years as against a corresponding figure of 28.6 per cent for the operative cases.

In patients with solid tumors the prognosis is poor. At the end of one year 32.1 per cent of patients were alive following electrocoagulation or x-ray therapy as compared to 22.6 per cent following operation. In this collection of 122 solid carcinomas, 33 were untreated and the end results were no worse than for those operated upon openly.

By way of complementary observation the author noted a marked tendency of all bladder tumors to recur. However it is believed that these recurrences may often be affected mucosal areas which have been insufficiently treated. Most tumors are localized to the trigonal area or to regions about the ureteral orifices. Less than 10 per cent of the tumors involved the vertex. Metastases are not a common finding on clinical examination, and at autopsy metastatic involvement was found in only one-fourth of the cases. Death usually was due to stasis and infection of the upper urinary tract.

The author concludes that the treatment of choice will gradually come to lie between radiology combined with endovesical coagulation and cystectomy. Abstractors note. This opinion will not find ready acceptance in the United States where there is a tendency to drift away from roentgenological therapy which most of us believe has only temporizing qualities and frequently induces a cystitis that is worse than tumor disease. We are however doing earlier and more numerous cystectomies although segmental bladder resection, with removal of adequate (3 cm.) cuffs of normal tissue is still a good operation in suitable instances.

ALLAN K. SWERDLE, M.D.

Carcinoma of Urinary Bladder. JOHN R. M. DONALD and GERARD J. THOMPSON. *J Urol*, Balt., 918, 60: 435.

It was believed that a study of a sizable group of surgically removed carcinomas of the urinary bladder might be worth while if the accompanying bladder were available also. Many investigations have been made on vesical neoplasms by utilization of tissue removed transurethrally but in such studies only a portion of the underlying bladder at most, can be studied. Information which the surgeon obtains from the pathologist is oftentimes woefully inadequate as applied to the method of treatment which should be employed in such a case. Furthermore, when surgical therapy is given such a patient suffering from a carcinoma, the factors entering into prognosis have been vague, much more vague than in cases of carcinoma elsewhere in the body.

From a histologic and anatomic study of 274 vesical tumors in which all or a portion of the urinary bladder along with the tumor had been removed surgically certain features were determined to be of great importance in the matter of prognosis and treatment (1) whether invasion had or had not occurred (2) when the invasion had occurred whether the fat was or was not involved (3) whether evidence of invasion of the veins or lymphatics was present or absent and (4) the cytologic and anatomic type of tumor whether it was transitional-celled squamous-celled or adenocarcinoma or a mixture and whether it was papillary or nonpapillary

Management of Injuries of the Urethra. ANGEL I REYES. *Philippine J Surg* 1948 3 143

Twenty male patients whose ages varied from 12 to 65 years were treated for injury to some segment of the urethra. Eleven were treated within 24 hours after the injury the remaining 9 patients had sustained their injuries from 3 months to 4 years before the author saw them. In 3 cases the injuries were caused by shrapnel. All others occurred as a result of straddle falls or truck accidents.

The author claims that the bulbous urethra is injured most frequently during straddle falls and that the membranous urethra escapes during this type of trauma because of protection by the triangular ligament. The majority of patients with injury to the membranous portion of the urethra had suffered fracture of the pelvis.

Unsuccessful catheterization, inability to urinate, arterial bleeding or perineal hematoma prompted operation. The author urges early re-establishment of urethral continuity diversion of urinary flow by suprapubic cystostomy exploration of questionable cases the use of an indwelling urethral catheter for 3 to 4 weeks if the injury is acute (or for 5 to 6 weeks in an old case) and postoperative dilatation until the urethra can accommodate a 26 French sound. Most of the author's operations included perineal exposure and repair of the damaged urethra.

No deaths occurred among these 20 patients. Among the cases of acute injury complications—a stricture which was treated promptly—occurred in only 1 case. Strictures with or without fistula incontinence or calculi, were present in all cases of long standing when first seen. Some patients were followed for as long as 2 years after operation while others had not been seen by the author for a period of 6 months.

ORMOND S CULP M.D.

Should We Operate on Urethral Stricture? (Sollen wir die Urethralstriktur operieren?) A. LEHNER. *Helv. chir. acta*, 1948, 15 385.

The author discusses the expediency of resection of the entire stricture site followed by exact suture for cases of urethral stricture in which the passage of bougies becomes increasingly difficult and is followed by reaction, in which the stricture is a chronic ulcer gives rise to constant pain and causes a high grade of incapacity for work, and for cases in which the firm

pressure sensitive stricture must be considered as a granuloma which discharges pus constantly and undelies a stimulus urethritis. The indications for operation are more urgent when a stricture that can be tensioned only with difficulty leads to obstructive retention and the elevation of urinary nitrogen values in the blood.

Improvement of the results of suture either for primary urethral injury or following resection of immobile stricture can be achieved only when complete cicatrization of the mucosa can be guaranteed with greater certainty. A method which assures rapid cicatrization of the mucosa is yet to be discovered. Since the danger of new stricture formation is just as great following resection and suture as following primary suture the regular passage of bougies is indicated following operation.

JOHN L. LIMQUIST M.D.

Congenital Absence of the Penis. SIX HAROLD GILLIES and R. J. HARRISON. *Brit J Plast Surg* 1948 1 8.

The authors report 2 cases of true congenital absence of the penis together with a third borderline case. They discuss the embryological factors and a method of phalloplasty.

Stage 1 of the operation designated the three in one incorporates (1) the urethra inside (2) the tubed pedicle together with (3) the cartilage. The cartilage is embedded in the fat of the tubed pedicle in similar fashion to that described by Frumkin but the tubed pedicle is cut on a marked curve. On the skin of the abdomen medially to the tubed pedicle a rectangular piece of skin is marked out of a width of 4 cm. by whatever length of urethra it is necessary or desired to fashion in the particular case. This rectangle is incised skin deep on both its long sides (that on the outer being of course part of the inner incision for the tubed pedicle). On both sides of the rectangle the skin is now undermined superficially to one third of its width. Each edge can thus be lifted toward the center so that they can be sutured together to form a skin tunnel. The long narrow flaps receive their blood supply from the undisturbed central third. To facilitate this maneuver a No. 10 catheter is attached by adhesive down the center of the rectangle and as the flaps are undermined they can be made to adhere to the sides of the catheter so as to facilitate suture. The raw edges of the two long turned flaps are now sutured with fine catgut. One layer of sutures is adequate care being taken to invert and appose the edges accurately.

There is now a skin lined tube surrounding the catheter and a raw surface on either side and over it. The medial cut edge of the abdominal skin is now widely undermined so that it can be pushed toward the middle to make room for the superimposition of the tubed pedicle flap. The tubed pedicle flap is now cut and raised.

In 3 weeks (stage 2) the pedicled flap is again raised but on this occasion the urethra is dissected with the pedicle and its remaining skin connection

at each end is divided. The two long edges of the tubed pedicle flap are now united round the urethra with interrupted or continuous end-on mattress black silk stitches. At this same operation the lower end of the pedicle may be increased in length downward toward the pubis. It should be noted that the thoracopigastrie vein should be included in the main line of the pedicle. The raw area caused by this operation is similarly grafted with a dermatome skin graft.

At 5 weeks (stage 3) the pedicle may be freed at its upper end and brought down to make a direct union with the existing urethral opening.

GENITAL ORGANS

Physiologic Pathology and Conservative Treatment of Hypertrophy of the Prostate (Die physiopathologie und nichtoperative Behandlung der Prostatahypertrophie) KORN WILDMOELL. *Archiv. klin. Med.*, 1945, 5, 51.

Hypertrophy of the prostate is found in 73 per cent of men over 60 years of age and in 100 per cent of those over 70. As to the etiology, the author attacks the widely accepted theory of Gelsenordorfer—that the involution of the senescent testicle leads to decreased production of the male hormone, and that the prevalence of follicle hormone causes proliferation of the originally rudimentary perurethral glands of the prostate and simultaneous atrophy of the true prostatic parenchyma. Based on this theory treatment of prostatic hypertrophy with male sex hormone has been performed to a great extent.

Two facts speak against this theory: (1) the sometimes dramatic effect of castration (in 87 per cent of the cases the symptoms improve, and the volume of the prostate decreases) and (2) the failure of treatment with testosterone to affect the symptoms and signs of benign hypertrophy. Prostates removed after long continued hormonal treatment do not show any histological difference from prostates of untreated patients.

On the other hand treatment with follicle hormone gives excellent results if the doses are high enough and it obviates prostatectomy in many cases. The author suggests a dose of 3 mgm. of stilbestrol daily until 125 mgm. are given. This series is repeated once or twice yearly. The side effects (gynecomasty, loss of libido) disappear soon after the stilbestrol has been discontinued. The danger of mobilizing a quiescent carcinoma by this high dosage of follicle hormone appears negligible and is outweighed by the advantages of the treatment.

The author criticizes the tendency of American urologists to operate on all diagnosed prostatic hypertrophies and gives more conservative indications for surgery. Only if the residuary urine is more than 200 c.c. or if the sleep and general condition of the patient are disturbed considerably should surgery be done. With conservative treatment, the condition was progressive in only one-third of his pa-

tients and led to operation. In another third the prostate condition remained stationary and in the last third it showed spontaneous involution.

No theory of his own as to the pathogenesis of prostatic hypertrophy is presented by the author.

WERNER M. SOHNKE, M.D.

Surgical Treatment of Prostatic Hypertrophy (Traitement opératoire de l'hypertrophie prostatique) CH. PERRIER. *Revue. chir. Acta*, 1945, 15, 666.

The author presents a brief review of the different technical procedures used in surgery of the prostate. Four routes of approach are possible: the transurethral, perineal, suprapubic transvesical, and retropubic prevesical.

Transurethral resection is a difficult operation that requires great practice and experience. The mortality is not negligible if resection is performed only in cases in which prostatectomy is contraindicated. However the reported percentage of mortality varies so much according to different statistics that it is hardly possible to form a correct judgment. The resection should not go beyond the frenum of the verumontanum.

In perineal prostatectomy it is important to spare the external and, if possible, the internal sphincter. Also the colliculus seminalis should and can be spared as the adenomas always develop superiorly to it. The advantage of this method is that it causes fewer general complications and less surgical shock than the transvesical prostatectomy. The patient gets out of bed on the fourth postoperative day. Its disadvantage is the danger of urethroperineal or urethrorectal fistulas, and of impotence.

The suprapubic transvesical method is easier technically and permits more exact hemostasis, especially with the improvement devised by Harris. It avoids the danger of fistulas and of impotence. However it is a more formidable operation and should be risked only if the general condition, and the circulatory and renal functions are satisfactory. In cases of marked renal insufficiency the operation should be performed in two stages. Bed rest for 20 days is required after this operation.

The most recent method of prostatic surgery is by means of the retropubic prevesical approach, devised by Jacobs and Casper in 1933 and modified by Millin in 1945. This operation does not involve the danger of fistulas or impotence. The convalescent period is practically painless and much shorter than after the transvesical operation. However the operation is technically more difficult, especially in obese patients. In cases in which the transvesical method is too hazardous because of renal or circulatory insufficiency the Millin operation is the procedure of choice.

WERNER M. SOHNKE, M.D.

Diphtheritic Cystitis and Urethritis Following Prostatectomy GEORGE WOLSKOW. *Brit. J. Urol.*, 1945, 20, 18.

The author describes a case of diphtheritic wound infection which occurred after prostatectomy and

affected the suprapubic wound, the bladder and the anterior urethra

Severe complications appeared as a direct or indirect consequence of the infection i.e. congestive cardiac failure due to toxic myocarditis and peripheral neuritis affecting the peroneal nerve. The occurrence of a urethral stricture must also be the result of the infection

The source of the organisms was undoubtedly the patient himself as he was found to be a faecal carrier of diphtheria bacilli. It seems likely that the organisms were transmitted through the patient's fingers to the urethra and from there to the bladder and suprapubic wound. Alternatively it is possible that the postoperative state of the bladder wall acted as a place of least resistance where blood borne pathogenic organisms could readily settle.

Serum therapy was tried in this case but did not meet with obvious success. This disappointing result agrees with the experience of others who used it in instances of wound diphtheria

JOHN A. LOFF, M.D.

Observations on Hypospadias. A. M. LOUGHRAN
Brit. J. Plast. Surg., 1948, 1, 147

Loughran reports late results of Ombredanne's hypospadias operation in 29 patients who could be followed up completely. He believes that the basic cause of hypospadias is likely to be some discord in the endocrine symphony of mother and child; it is both familial and hereditary. In his series the condition was encountered in father and child and in several sets of siblings. The degree of hypospadias also seems to be hereditary and familial. In the differential diagnosis adrenal virilism in the female and a congenitally short anterior urethra must be excluded. The former can be diagnosed if a vagina is present, but when the labia are fused and the clitoris is hypertrophied, an error can be made. Since no biological assay is available laparotomy and biopsy of the genital glands must be performed in doubtful cases. In a congenitally short anterior urethra in spite of the penis bowing and the redundant foreskin the prepuce is complete and the urinary meatus is at the tip of the glans.

In some hypospadias patients there is considerable bowing in some there is none, and in the third variety the penis appears to be foreshortened because of the ventral penoscrotal webbing, if the web is not corrected the penis will become bowed as growth proceeds. Loughran believes that early operation should be performed before psychical trauma has occurred. Operation should accomplish correction of the penile curvature, a satisfactory stream in the standing posture, the absence of stricture, absence of urethral hairs and a satisfactory cosmetic appearance.

Of Loughran's 59 patients only 43 could be traced and in only 29 was follow-up complete. A good cosmetic result was recorded in 24. The meatus was at the tip in 25 and somewhere on the glans in 3. A good stream in the standing position was claimed by 24.

Fistula on the glans was present in 3. No hairs were observed in any cases. Enuresis was present to a later age in 34 per cent. Therefore a good result could be claimed in 24 and a fair result in 4; failure occurred in 1 case (among 75 operations performed on the 29 patients).

Ombredanne's operation is the operation of choice because the late results are good, the operation is simple to perform, no special instruments are required, deflection of the urinary stream is unnecessary and the penoscrotal web if present is incidentally destroyed in the raising of the pouch.

DAVID ROSSERLOOM, M.D.

MISCELLANEOUS

Urea Clearance by Perfusion of the Intact Small Intestine. N. S. R. MALIN. *J. Urol.*, Balt., 1948, 60: 307

A method is described for perfusing practically the entire small intestine in man by means of a 3 way modified Miller Abbott tube. Most of the perfusion fluid is sucked back through one of the conduits into a container.

The perfusing liquid is a per cent anhydrous diacid sulfate which is only slightly hypertonic to plasma.

When the rate of inflow is between 25 and 30 c.c. per minute the concentration of urea in the outflow fluid is approximately equal to that in the plasma. (It is advisable to put a little xylene in the recipient bottle to inhibit bacterial splitting of the urea.) The urea clearance is thus roughly equal to the number of cubic centimeters per minute.

The amount of urea removed in unit time varies with the rate of perfusion and with the concentration of urea in the plasma. The amount of urea that can be extracted in unit time is equal to or greater than that extracted by other methods of diffusion peritoneal irrigation and external dialysis ('artificial kidney').

The merits of this procedure as compared with those of peritoneal irrigation and external dialysis are discussed.

JOHN A. LOFF, M.D.

The Significance of Calcareous Tuberculous Glands in the Abdomen in Relation to the Urinary Tract. JAMES A. ROSS. *Brit. J. Urol.*, 1948, 20: 100

The author reviews a total of 5,000 case reports to ascertain the frequency and symptomatology of calcified glands in relation to the urinary tract.

Calcified glands were found in 608 patients; i.e. in from 12 to 16 per cent of cases. In only 25 (0.5 per cent), or 1 in 200, could the glands be considered as a possible cause of symptoms and in only 10 (0.2 per cent), or 1 in 500, could the calcified glands be considered to have effects on the urinary system.

These effects consisted of a deviation of the ureter a bend or kink in the neighborhood of the glands with or without slight dilatation of the ureter or pelvis above it, and with or without symptoms. The symptoms consisted of slight pain in the respective side or

slight renal colic. No stenosis of the ureter was found and a case reviewed 8 years after localized deviation and dilatation of the ureter in the neighborhood of calcareous glands had been reported showed the ureter to be practically normal.

Unless a definite kink or deviation of the ureter can be shown the discovery of calcareous glands in the course of an investigation can be dismissed as being of very little significance.

JOHN A. LOAF, M.D.

True Abacterial Pyuria. GUSTA J. SEOK. *Ida. J. Med.* 943, 97: 33.

Jonsson reports 3 cases of true abacterial pyuria which were exhaustively studied. A diagnosis of urinary tract tuberculosis was ruled out through the absolute failure to demonstrate tubercle bacilli and the spontaneous regression of pyelographic changes.

The author states that the diagnosis of bacterial pyuria is possible only after the exclusion of tuberculosis. The majority of cases described have occurred in men. Possible biological factors are (1) toxins from a focus (2) coccal infections and (3) virus infections. Histologically the lesions in true abacterial pyuria are very superficial and are classified as pyelitis and urethritis follicularis. The lesions do not penetrate lower than into the submucosa. Clinically a cystitis is present with frequency urgency pain in the region of the bladder and occasional hematuria there is no fever nor is there any general disturbance of health. Some cases subside spontaneously. The urine contains numerous leucocytes but no bacteria are demonstrable on smear, culture or guinea pig inoculation. No anatomical changes of the external or internal genitalia are present. Renal function is unimpaired. The cystoscopic picture of abacterial pyuria shows hemorrhagic cystitis edema, and fibrin deposits. This is

contrary to the picture of tuberculosis in which specific lesions lie next to areas of normal mucous membrane. Kidney urines contain leucocytes and the capacity of the bladder is reduced. In the author's cases, pyelographic changes suggestive of tuberculosis were present.

Cases of dilatation of the pelvis and ureter in abacterial pyuria are reported in the literature. In the author's patients, striking improvement as observed following the administration of neomycin, the pyuria subsided and the urographic abnormalities disappeared.

DAVID ROSENBLUM, M.D.

Cancer of the Urachus (Cáncer del uraco). RICARDO BROOKS. *Bol. Soc. Cir. Rosario*, 943: 5, 7.

The world literature reveals only 154 cases of urachus affections. Because of the relationship of this organ to the bladder, the presenting symptoms are those of vesical complaints and early treatment is usually directed toward the bladder.

Two cases are presented in this article. The first was that of a 64 year old man who complained of pain in the hypogastrium ardor and polyuria. Palpation revealed a discrete tumor below the umbilicus giving the impression of probable metastatic growth. Cystoscopy disclosed nothing worthy of note and endoscopic biopsy of the tumor showed cancer of the urachus, the histopathologic diagnosis being cylindrical papillary epithelioma with origin in the epithelial rests of the urachus.

The second case was discovered incidentally during the course of an operation for removal of an enlarged prostate. The tumor was of the nature of a small partially calcified cyst adhering to the bladder. The histopathologic diagnosis revealed a cyst of the urachus, the epithelium covering being of immature bladder cells.

STEPHEN A. ZIERMAN, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS ETC

Hyperplastic Callus Formation With or Without Evidence of a Fracture, in Osteogenesis Imperfecta Sir H. A. THOMAS FAIRBANK, *Brit. J. Surg.* 1943 36 1

The author presents 8 interesting cases of hyperplastic callus formation 7 of which are definitely osteogenesis imperfecta. Each case shows abnormal calcification of local callus sometimes without recognizable recent fracture. Some of the cases show markedly excessive formation of ossified callus enveloping the shaft to an unusual extent, with result of permanent enlargement of the affected bone. Some cases showed the formation of bony excrescences on the shafts of the long bones particularly on the interosseous borders and without the faintest sign of antecedent fractures.

In 2 of these cases the mass of bone resembled neoplasm, and biopsy and microscopic examination were necessary to make the diagnosis. The tissue in these cases was of a fibromucoid cartilagelike structure (chondroid).

The trabeculation of the larger bony masses was very coarse and there was no tendency to reabsorption or remodeling of the bone such as would be seen in cases of scurvy or other types of subperiosteal hemorrhage with ossification.

No attempt is made to show the cause of this abnormal bone but the author believes that the only exciting cause that can be assigned to these cases is trauma.

NEWTON C. MEAD M.D.

Bone Lesions in Eosinophilic Granuloma, Hand-Schueller-Christian Disease, and Letterer-Siwe Disease. IGNACIO POMERET, *J. Bone Surg.*, 1948 30-A: 811

Eosinophilic granuloma Hand-Schueller-Christian disease and Letterer-Siwe disease have a number of clinical, roentgenological and histological characteristics in common eosinophilic granuloma being a more localized lesion in bone while the granuloma lesions of Hand-Schueller-Christian disease and Letterer-Siwe disease are more widely spread and may affect many organs.

Eight cases are presented. The first case was that of a 2 1/2 year old white girl with eosinophilic granuloma of the skull. Excision of the tumor resulted in a very cellular tissue containing large cells with granular protoplasm and a number of eosinophils.

The second case was that of a 42 year old male with injury to his left leg. On examination a slight, nontender tumor was found on the lateral aspect of the left mid thigh. The knee appeared normal. Biopsy revealed relatively avascular and granulomatous tissue with large mononuclear cells eosino-

philic large giant cells and fibroblasts. Roentgen therapy was given without any success. A mid thigh amputation was then performed. The histological section did not show any convincing evidence of malignancy. There was no evidence of metastases 5 years after surgery. The remaining cases suggested from their course and clinical findings resemblance to osteomyelitis, tuberculosis and endocrine disturbances.

The pathological findings however suggest that all 3 conditions are manifestations of the same process. A large liver and spleen, moderate enlargement of all palpable lymph nodes, anemia, leucocytosis and extensive infiltration of both lungs suggest Letterer-Siwe disease. Diabetes insipidus, increased blood cholesterol and blood lipids are more characteristic of Hand-Schueller-Christian disease. The histological picture however is practically the same. It is often difficult to classify properly the symptoms presented by a patient affected with lipogranuloma in any one of these conditions.

GEORGE I. REIMS, M.D.

Solitary Plasmacytoma of Bone with Renal Changes GEORGE LUMB, *Brit. J. Surg.* 1943 36 16.

A case of solitary plasmacytoma of the sacrum is reported along with a brief review of the literature. The principal interest of the case is the association of fatal renal tubular blockage of the type found in multiple myelomatosis. Solitary plasmacytomas have not usually been associated with either the finding of Bence Jones proteins in the urine or renal disease process as multiple myeloma, but the findings in this case and in one other case (reported elsewhere and cited by this author) suggest that this is a single focus of a disease usually presenting multifocal form.

The author suggests that the appearance of Bence Jones protein in the urine is a result of actual tumor volume and is due to the amount of bone marrow involved. In this case the tumor was large replacing the entire sacrum.

A complete report of biopsy findings is presented. NEWTON C. MEAD M.D.

Ruptured Quadriceps. ERIC I. LLOYD, *Brit. J. Surg.* 1943, 36 94.

Rupture of the quadriceps femoris almost always occurs in heavy elderly men following indirect violence. It is often wrongly diagnosed and there is rather a high risk of pulmonary embolism.

The diagnosis would be easy if the condition were always remembered as a possibility. Inability to extend the knee associated with a palpable depression on the surface of the extensor tendon, can only be due to a ruptured quadriceps but the diagnosis is often missed owing to lack of familiarity with the condition. Three cases are cited as examples. An

anteroposterior radiograph of both knees on one film will demonstrate that the patella on the ruptured side is quite obviously lower than the patella on the normal side caused by loss of postural tone.

Operative treatment offers the only chance of regaining normal power. Twenty-four hours before the operation a 3/4 inch zinc-pelatin bandage is fixed to the foot, from the web of the toes to a point 2 inches above the ankle joint, and the upper inch of this is then covered by a cuff of felt 4 inches wide which is stitched or stuck around the limb. Five hundred thousand units of penicillin are given intramuscularly in one dose on the day before operation and repeated the next day.

A generous curved incision, concave proximally, exposes the frayed torn ends of the tendon and surrounding blood clot. The synovial membrane may be sutured at this stage if bruising and edema of the tissues do not make it too difficult. Sufficient tendon occasionally remains attached to the patella to make direct suture possible but it is much more common to have to drill the bone and to proceed as follows. A suture of No. 1 kangaroo tendon is inserted through the tendon and is then passed through a single transverse drill hole in the upper third of the patella. This suture re-establishes continuity of the rectus femoris with the patella, but it must be supplemented by a series of interrupted chromic catgut sutures both centrally and on either side before the wound is closed without drainage.

A strong plaster slab is now placed along the back of the limb so that it rests on the felt strip just above the ankle and upon a second which encircles the upper one third of the thigh. The plaster slab is held to the limb by a few turns of plaster bandage above and below the field of operation, and an ample dressing is firmly bandaged over the wound so that it can later be removed without disturbing the plaster which is used to hold the knee joint in full extension.

The patient is returned to bed with the injured limb on a pillow beneath a cradle. As soon as he has regained consciousness he sits up and is provided with a back-rest and overhead hand-hold. He is asked to move his ankle and toes through a full range of movement for a few minutes every hour. These patients are frequently over 70 and there is a real risk of pulmonary embolism if they are allowed immobility.

In 4 or 5 days the patient may begin static exercises to the quadriceps and he is gradually coaxed into moving his plastered leg and even lifting it off the bed. The stitches are removed in 10 days and the plaster completed in such a way that static contractions of the patella remain possible. The patient should be out of bed and walking with a stick next day and soon afterwards be walking with full weight bearing. The plaster is removed 6 weeks after the operation and active and passive movements with radiant heat are given to the knee joint.

In recent examples the results of operative treatment are concluded to be excellent and in patients

operated upon within 3 months of the injury the results have been fairly satisfactory.

RUDOLPH S. RUTHER, M.D.

An Unusual Localization of a Brodie's Abscess in Bone; the Distal Diaphyseal Epiphyseal of the Radius (Localizzazione rare dell' ascesso osseo di Brodie: la diáfiso-epifisale distale del radio). V. DIAMONDO LAURICELLA. *Riforma med.*, 948, 6 464.

The author reports a case of Brodie's abscess in a man 24 years of age who was first seen January 15, 1948. The author believes the abscess to be unusual in view of the fact that it occurred at the diaphyseal-epiphyseal junction of the radius.

The patient injured his wrist during a pugilistic encounter and very soon thereafter developed a tumefaction of the area. This became red and was finally incised with exudation of a small quantity of pus. The wound did not heal, and from time to time more purulent material exuded.

X-ray films revealed a cystic area the size of a bean in the distal lateral portion of the radius in which the bone trabeculations had been destroyed.

At operation this area was found to contain a thick purulent material, with some spicules of dead bone.

Culture of this material revealed a pure culture of the hemolytic streptococcus. The postoperative course was uneventful.

The author also adds a good bibliographical review of the subject, presenting the various phases of the controversial etiology.

CARLO SCUDERI, M.D.

The Diagnosis of Traumatic Lesions of the Menisci (Diagnóstico das lesões traumáticas dos meniscos) JOSE BOTTELDO, *Gen. med. Portuguesa*, 948, 503.

The diagnosis of traumatic lesions of the menisci must be based on the history of the accident, the objective and roentgen examination of the patient, and arthrocentesis. A good history is of fundamental importance. It reveals nearly always an initial injury which in from 50 to 60 per cent of the cases occurs during some sport, principally football, and in from 40 to 50 per cent during work or the activities of daily life.

The mechanism of these lesions is always a movement of flexion or extension superimposed on an internal or external rotation of the knee. In general, it is the internal rotation of the femur on the semi-flexed and fixed tibia which most frequently causes rupture of the fibrocartilage, especially on the medial side, but the same mechanism may also produce a lesion of the lateral meniscus in its posterior half. Much less frequent is the external rotation of the femur which then damages particularly the lateral fibrocartilage. From the beginning there may or may not be a block. Pain, functional disability and hyarthrosis constitute the symptomatology of the initial accident. The meniscal lesion is characterized by recurrence of the painful episode alternating with

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Treatment of Pseudarthrosis by Simple Onlay Bone Graft Without Removal of Callus. DALLAS B. PRUESTER. *J. internat. chir. Bruxelles*, 1948, 8, 713

It is widely believed that in pseudarthrosis the callus is so extensively altered that it cannot be made to ossify, and that in order to obtain bony union the false union must be broken down the callus removed and the fragments fixed, preferably by a bony transplant held rigidly by screws or wires.

A less traumatizing and more biological operation is available. In a series of 80 cases it has been found that in cases in which the fragments are in acceptable position the fracture nearly always unites if a strong bone graft is applied to a denuded and leveled side of the fragments across the fracture line and held in place only by the soft parts sutured tightly over it leaving the callus which holds the ends together.

A longitudinal incision is made at the level of the fracture and the periosteum is separated from the side of the fragments sufficiently to create a bed for the bone graft. If the exposed surface is irregular, enough of the protruding bone and callus are chiseled away to create a level surface for complete contact with the graft. A strong whole thickness graft is cut usually from the tibia but sometimes from the ilium and applied to the exposed side of the fragments across the fracture line. In some instances two smaller whole thickness grafts are used especially if the fracture is near the end of the bone. Cancellous bone grafts are sometimes applied on either side of the cortical graft at the fracture line. In fractures of the large bones the length of the graft varies from 7 to 12 cm. for the midportion of the shaft and from 3 to 6 cm. for the ends of the shaft. The periosteum and soft parts are sutured tightly over the graft and then held it firmly in place. The remaining attached periosteum and the callus hold the ends of the fragments together. Neither fragments nor grafts become displaced. In some cases the intermediary callus has been extensively curetted out but usually it has been left intact, and the result has been the same in either case. After closure the extremity is immobilized in a plaster dressing for 2 to 3 months.

During this period the graft becomes united to the shaft by callus thrown out by both structures. Because the graft is not firmly fixed by screws the contraction of the muscles produces axial coaptation of the fragment ends and stimulates osteogenesis. Movement at the fracture line is gradually eliminated as union proceeds between the graft and the fragments. Bony union is usually solid in 2 to 3 months depending on the bone involved and the nature of the fracture. Further immobilization is rarely necessary.

If the displacement is great this operation is not used instead the fracture is reduced and the fragments are fixed by a strong onlay graft anchored with metal screws.

periods of recovery and always caused by a torsion similar to that of the initial accident. In these recurrences, block or sudden claudication of the knee may predominate, but pain and hydrarthrosis are always present.

Block exists in 50 per cent of the cases and occurs in semiflexion. Sudden arrest of the leg which is being extended can be caused only when a fragment of meniscus is interposed between the femur and tibia at a point anterior to the coronal plane of the joint. Thus only those meniscal lesions which extend beyond the plane of the lateral ligaments particularly the longitudinal lesions which extend in front of this plane, cause block.

Sudden claudication of the knee may be regarded as an equivalent of block. It is due to a lesion of the posterior half of the meniscus especially of the posterior horn. There is no typical block in these cases. The patient has the feeling of having an unstable knee, particularly when going down stairs.

Hydrarthrosis accompanies the meniscal accident and is proportionate to the amount of block or of its equivalent. It is a sign that the ligaments, capsule, or synovial membrane have been damaged but it is less so a sign of sprain of the knee than of meniscal lesion.

The typical pain of a meniscal lesion usually extends quite forward beyond the plane of the ligaments and in the lateral interarticular line. Lesions of the posterior horn cause pain that is vague and often within the joint without typical localization. The pain may be present only at the time of the accident or it may be vague and permanent, like grinding.

Objective examination reveals increase in volume of the knee and appreciable atrophy of the thigh muscles particularly of the quadriceps. The increase in volume of the knee is principally due to hydrarthrosis. However there is often no hydrarthrosis and the swelling is more apparent than real being due to the contrast between an atrophied thigh and a more or less normal knee. There is always some degree of atrophy and atony of the quadriceps, the internal vastus is first and more intensely involved. Limitation of movements, especially during flexion, is encountered with some frequency and is a sign of a lesion of the posterior horn.

Pain in the joint line is reproduced by certain positions of the tibia in relation to the femur and various authors have described different ways to induce it. This has introduced a series of signs which include those of Boehler, Rocher, Steinmann, Bragg, Payr, Graham, Apley, Turner and McMurray.

Routine roentgen examination has no practical importance for the diagnosis of meniscal lesions. Exceptionally calcification of the fibrocartilages may afford some information. The value of roentgen examination lies in the demonstration of lesions of the bones and to the ligaments when they are made in forced varus or valgus positions. Arthropneumography is discussed in another article.

RICHARD KNEEL, M.D.

If there has been previous infection of the fracture the graft should be introduced through an incision away from the healed scar and applied to the opposite side of the fragments. Because of the lesser danger of infection, this operation may safely be done weeks or months earlier than one in which the approach is through the old field of infection and the pseudarthrosis is broken down.

The operation may be quickly performed with little damage of tissues, little blood loss, a low incidence of shock and wound infection, and without the use of plates, wires and screws.

RODOLPH S. REICH, M.D.

Rupture of the Biceps Brachii, with Report of a Case of Bilateral Rupture of the Long Tendon
H. K. CHRISTIE. *Austral & Zealand J Surg* 1948, 8:37

The author reports an unusual case of bilateral rupture of the long tendon of the biceps brachii, occurring in the left biceps in 1945 while lifting a log, and in the right biceps in 1946 while lifting a heavy case. The rupture in the right biceps was operated upon immediately the free end of the tendon being inserted into the pectoralis major tendon, looped around and sutured to itself, the forearm being held in full flexion during the procedure and for a period of 3 weeks after operation. Passive movements were started after 3 weeks, and by 6 weeks full range of elbow motion was restored. The left biceps was operated upon 4 months later (about 18 months after occurrence of the injury). The result was excellent.

The typical syndrome of traumatic rupture of the biceps includes a sudden snap when lifting, associated with acute pain and loss of power. Local swelling and synovial effusion occur. Most characteristic is the egg-shaped tumor caused by the disinserted muscle belly. If the long head ruptures, the muscle belly descends toward the elbow, and if the common tendon of insertion is ruptured the muscle belly ascends. A tear in the belly of the muscle can be felt as a gap or depression. These signs are increased by attempts at muscular contraction.

DANIEL H. LEVINTHAL, M.D.

The Treatment of Severe Scoliosis. Resection of the Spinal Column (Tratamiento de las escoliosis graves. La resección de la columna). MARCELO J. FITTA, LUIS A. GONZÁLES, and ANTON BRACCO. *Bol. Acad. argent. cir* 1948, 31:566.

For the correction of severe forms of scoliosis, especially those of the lumbar or thoracolumbar region, the authors recommend resection of the spinal column. The method was originally developed by Volkmann. The operation is performed under cyclopropane-oxygen anesthesia. Morphine, barbiturates and atropin are administered preoperatively and a blood transfusion is given during the operation. Surgery is performed with the patient lying on his side, the convexity of the spine pointing upward. If the curvature is low an incision resembling that for nephrectomy is employed. The incision extends

from the corresponding anterior superior iliac spine to the costovertebral articulations of the eleventh and twelfth ribs and from there 3 or 4 cm. upward along the lateral border of the long spinal muscles. It may be necessary to resect the eleventh and twelfth ribs. As a rule, 5 vertebral bodies are exposed. The corresponding intervertebral discs and wedge-shaped portions of the vertebrae are removed. Care must be taken not to injure the kidney. Hibbs technique, utilizing portions of the tibia, is employed to stabilize the spine. A special hinged corset is employed for further correction of the scoliotic curve.

A follow-up study of 2 children operated upon more than 1 year prior to this report showed excellent results: one of them was 12 and the other 13 years of age.

JOSEPH K. NARAI, M.D.

Factors Favoring Successful Transmetatarsal Amputation in Diabetes. HOWARD F. ROOT. *N. England J. M.* 1948, 339:453.

Although the emergency character of infectious or early gangrenous lesions of the toes and feet of diabetic patients has long been recognized by most physicians, a new aspect of this problem is presented by the demonstration that in many diabetic patients a useful and serviceable foot can be preserved through the proper use of the transmetatarsal amputation.

One hundred and thirty three transmetatarsal amputations were carried out on 122 different diabetic patients in the New England Deaconess Hospital, Boston during the period between 1944 and September 1947. In 22 cases, failure to heal is recorded but in 3 of these thigh amputation was not necessary.

Gangrene of one or more toes was present in 78 cases, and in these cases the pathological report also mentioned osteomyelitis. In another 19 cases osteomyelitis alone was recorded. In 36 cases the lesions were described as chronic ulcerations in the feet, with defective circulation or a neurotrophic disturbance of sensation. In all cases some type of trauma had been present. The commonest lesion was an infected callus with extension into the bone or joint. The invasive lesions numbered 62 and the localized lesions, 7. Success was not dependent upon the presence or the lack of the active invasive type of infection.

This group of patients was composed of mild cases of diabetes of long duration in patients who had formerly been extremely obese. It is evident that serious foot lesions in mild diabetic patients depend in part upon an antecedent obesity and in part upon metabolic changes associated with great losses of weight due in a large measure to relatively uncontrolled diabetes.

The condition of the circulation, both general and local, is in many cases a chief factor in determining operative success. Although the patients in both groups showed slightly high blood pressures the series as a whole was characterized by moderate

joints, so that the author is unable to state what the best procedure is. Resection is unsatisfactory especially in the case of the ankle joint. Fusion does not achieve a good result. The most rational treatment for the ankle joint appears to be removal of the astragalus in conjunction with subsequent palliative treatment.

In numerous cases of rib tuberculosis the results were good following wide resection with removal of the entire soft tissue tumor.

JOHN L. LINDQUIST, M.D.

Interilioabdominal Amputation (Amputación interilioabdominal) JULIO PIÑEIRO SORONDO and ROSALDO L. FERRER. *Am. J. Surg.* 1943 1: 143.

With the authors' method interilioabdominal amputation can be performed without great shock in about 2 hours. The patient is placed on the uninjured side and operated upon simultaneously by two surgeons. Blood or plasma is administered by the electric knife is used to coagulate the vessels has been used in 4 patients with malignant tumor of the hip or femur all stood the operation well and had only a slight ileus for 2 or 3 days. One patient died from local recurrence after 9 months and 1 from pulmonary metastasis after 10 months while 2 patients are living without apparent recurrence 1 of them about 2 years after the amputation.

The causes of shock in this amputation are the excessive time required by the operation when it is performed by one surgeon the change of position of the patient during the operation the great loss of blood the lack of blood transfusion during the operation the excessive and unnecessary injury to the peritoneum by retractors the omission of novocainization of the nerve trunks before ligation and section the stretching of the nerve trunks by sudden maneuvers and the use of hammer and chisel instead of a Gigli saw to cut bone. These factors are carefully avoided in the present technique which thus becomes indicated in malignant tumors of the hip bone (including certain chondromas) in some malignant tumors of the lower extremity requiring disarticulation of the hip and in chronic grave and rebellious osteitis and osteomyelitis of the hip bone when partial resection of this bone is insufficient or ischiolateral arthrodesis is impossible. The patient or his family should be told that the operation excludes the possibility of wearing an artificial limb.

Technique. The customary intestinal preparation is done and preanesthetic drugs are used. If spinal anesthesia is contraindicated pentothal is used during the first 60 or 90 minutes and then inhalation anesthesia. The anus is closed by a pursestring suture which is removed after the operation. The operation includes eight ventral stages performed by one surgeon and eight dorsal stages performed simultaneously by another surgeon.

The ventral stages consist of (1) incision of the skin and subcutaneous cellular tissue parallel to and about 3 cm. below the iliac crest anterosuperior iliac

spine crural arch and genitocrural fold with supplementary incision over the pubis if its contralateral portion must be resected (2) section of the abdominal muscles (3) retraction of the peritoneum and subperitoneal tissue the bladder ureter spermatic or ovarian arteries rectum and uterus (4) section of the seven elements which cover the front of the sacroiliac joint (5) freeing and retraction of the internal iliac vessels and the lumbosacral nerve trunk (6) section of the pubic symphysis (7) section of the sacroiliac symphysis or of the sacral ala (8) closure by suture of the posterior flap in one plane over the wound one or two rubber dam drains being left in the anterior part of the wound for 24 hours.

The dorsal stages include (1) incision of the skin and subcutaneous cellular tissue and formation of a dorsal flap the lower extremity of which must reach the great trochanter while the base must pass about 3 cm. below the ischium and gluteal fold (2) section of the major gluteal muscle and exposure of the sacroiliac joint (3) ligation of the gluteal and ischiatic vessels (4) section of the pyramidal muscle the major and minor sciatic nerves and the sacrotuberous ligament (5) freeing of the internal pudendal vessels section of the sacrosacral ligament freeing of the corpus cavernosum and middle perineal aponeurosis and entry into the ischioanal fossa (6) section of the ischiococcygeal and levator ani muscles (7) section of the sacroiliac symphysis and (8) closure as stated for the last ventral stage. The dressing is held by a moderately compressing bandage. The bowels are not allowed to move for the first 2 days. On the fourth or fifth day an enema is given reinforced if necessary by an injection of proctigmine. All or nearly all sutures are removed on the eighth day and the patient is allowed up with crutches on the tenth day or even earlier.

RICHARD KIMMEL, M.D.

The Posttraumatic Physiology of the Joint (La fisiología post traumática de la articulación) TIBO MARTI. *Helv. chir. acta*, 1948 15 Suppl. 5.

For the guidance of Swiss physicians who are interested in the treatment and the estimation of disability of accidents of industrial work and disease in professional workers Marti presents a thorough study of the posttraumatic physiology of the normal and pathologic joint, based on his own experience and on that of numerous principally Swiss authors. From the actual knowledge on this subject he has endeavored to establish simple biologic rules for the treatment of traumatic lesions of the joint.

He stresses the importance of treating the periarthritic edemas the hematomas and the irritating elements keeping in mind that the first two cause also an inflammatory reaction which is favorable to cure. Therefore, the edema should be treated by immobilization of the joint in correct physiologic position, but massage is contraindicated at least in the beginning. Puncture is indicated only if the hematoma is important, and is not performed before the fourth or the fifth day a compressive bandage is

then applied. All distortions should be treated like reduced luxations but with shorter immobilization. In intra articular fractures, the bone and the cartilage must be replaced in their original position, the cartilage especially must be carefully reduced because it heals only with connective tissue, which may become an irritative element for the opposite articular surface. Muscular atrophy is combated by active mobilization and massage is used only after the peri-articular inflammatory irritation has disappeared. The duration of immobilization will depend on the nature and gravity of the lesion: even prolonged immobilization in correct position does not present much danger of ankylosis. Attention must also be paid to the posttraumatic reactions of the tendinous insertions and of the apophyses. Absolute rest may be completed by the use of analgesics and substances capable of modifying and regulating the local vascularization. Marti prefers infiltrations of 1 per cent novocain to which he adds acetylcholine because of its remarkable vasodilator effect.

The medicolegal problems arising from the articular disorders are discussed on the basis of the Swiss legislation concerning compulsory insurance against accidents.

RICHARD KIMMEL, M.D.

The Occurrence and Management of Reflex Sympathetic Dystrophy (Causalgia of the Extremities)
JAMES W. T. UREY, *J Bone Surg* 94B, 50-A 883.

This study is based on experience with 31 cases. The most prominent symptom of causalgia is a mit nervous burning pain in the extremities. There

may be signs of vasoconstriction or vasodilatation. The obvious signs are coldness, increased sweating, pallor or cyanosis of the skin, and swelling of the hand or foot. The advanced cases may resemble rheumatoid arthritis.

The x-ray examination shows either spotty or generalized decalcification. The pain may appear right after the injury or it may begin weeks or even months after the injury. Nerve injuries injuries to the blood vessels or crush injuries are known to cause causalgia very frequently. It was shown that the pain increases in both degree and extent and is liable to change the entire personality of the patient. The treatment consists of injections of procaine into the

trigger points or into the appropriate segments of the sympathetic chain, i.e. the stellate ganglion, or the second and third thoracic ganglia or a par vertebral sympathetic block may be done. A simple negative peripheral block should never be accepted as a true diagnostic sign because of the possibility that the ganglion was missed. Sympathectomy was done in patients who had temporary relief from procaine blocks.

The best results following this operation were obtained in the younger age group. Good or excellent results were obtained in approximately two-thirds of the patients operated on. It was found that patients who had had causalgia for a long time responded less favorably to this procedure than those whose symptoms had been of shorter duration. Etamon chloride was used instead of procaine with satisfactory results.

GEORGE L. REISS, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Thromboangiitis Obliterans. J B KIMMONT
Lancet Lond. 1948, 2 717

Seventy-seven patients with thromboangiitis obliterans were studied. Intermittent claudication superimposed vasospastic attacks and ulcers seemed to improve after sympathectomy. Prophylactic sympathectomy in some early cases of unilateral Buerger's disease did not give complete protection although it possibly delayed the onset of symptoms. The effects of sympathectomy and the prognosis are best when the small vessels are the first to be involved.

ROBERT A. NABATOFF M D

Traumatic Rupture of Normal Aorta. LARS THORÉN
Upsala läk. fören. förh. 1948, 5 207

As compared to rupture of pathologically involved aortas traumatic rupture in a normal aorta is considered rather unusual. After a brief survey of those pathological conditions which usually cause rupture 4 cases of traumatic rupture in a normal aorta are described. The usual sites of rupture are discussed as are the various theories concerning the pathogenesis of these lesions. An estimate based on the literature reveals that from two-thirds to three-fourths of all ruptures occur in the ascending aorta. Apart from direct laceration of the wall, the majority of ruptures probably arise as a result of longitudinal tension on the wall plus an intravascular increase in pressure. The theory that a normal aorta may rupture merely as a result of an increase in blood pressure following violent strain "appears to be unlikely. Uncomplicated partial ruptures offer the most favorable prognosis but if a dissecting aneurysm develops from a partial rupture the prognosis becomes considerably less favorable.

The treatment of these conditions is discussed and it is noted that the clinical picture of partial rupture with dissecting aneurysm may resemble an acute condition of the abdomen.

ROBERT A. NABATOFF M D

Saddle Embolus of the Aorta. JOHN L. KEZLEY Ann
Sw 5 1948 128 257

A 52 year old woman recovering from her second episode of cardiac decompensation for which she had been receiving digitalis and who was known to be suffering from auricular fibrillation displayed vague rapid onset of coldness pain and paralysis of both lower extremities accompanied by pain in the lower abdomen and sacral region. Pulsations of the aorta were absent beyond the sacral promontory save for weak pulsations in the region of the left femoral artery. A diagnosis of saddle embolus was made and a transperitoneal embolectomy was performed with in 6 hours of embolism.

Through a 2 cm. incision in the aorta at its junction with the right common iliac artery the obstructing clot together with a 6 inch tail thrombus in the right iliac artery was removed and the arterial defect was closed with an everting running mattress stitch. The administration of 100 mgm of heparin was begun at this time. Operation required 115 minutes. Pulsations were immediately present in the peripheral vessels except for the left dorsalis pedis artery in which it was not detected until the fifth postoperative day. Adjunctive therapy consisted of procaine lumbar sympathectomy block on the first postoperative day, pontocaine spinal anesthesia on the second through the sixth days intermittent venous constriction and anticoagulant therapy. Dependent edema of the legs disappeared after 6 weeks. In the peroneal group of muscles has persisted as has the fibrillation. Cardiac compensation has been maintained.

A discussion of the recognized etiologic factors together with diagnostic and therapeutic features follows the case report. The author states that embolectomy is the only lifesaving treatment for a patient with an aortic embolus. The choice of operative procedure—a direct attack upon the involved vessel or an indirect approach whereby the iliac or femoral arteries are exposed and the clot removed from below—is decided by the condition of the patient.

ALLAN D. CALLOW M D

Accidental Intra Arterial Injection of Drugs.
S M COHEN *Lancet* Lond., 1948 2 361 409

The present article is concerned with the tragedies following accidental intra arterial injection of some substances commonly employed in anesthesia, and such procedures as arteriography pyelography and cholecystography. Additional instances of occasional catastrophes following improper injection of occasional amine quinine ethanalamine bismuth and Hartmann's solution are provided. Detailed case reports of 12 instances in which thiopentone (pentothal sodium) was injected intra-arterially and the clinical features pathologic lesions treatment and suggestions for prevention constitute the larger portion of the article.

Eight of the patients suffered the loss of some part of the extremity 3 made what appeared to be complete recoveries. 1 patient suffered disabling residua consisting of weakness and sensitivity to cold. The author estimates that a fair figure for the incidence of major thiopentone tragedies in his country is probably 1 case in 55 000 cases. He feels that such an accident can happen to anyone and is not a reflection upon the competency of the anesthetist. The variable anatomy of the arterial tree upon the front of the elbow upper arm and forearm is discussed and

a knowledge of these variations is held to be a *must* for the competent anesthetist.

The clinical features following intra arterial injection of thiopentone are listed as burning pain ("the hand felt like a flaming branch") color changes in the hand and forearm which may progress to mottling edema, muscle necrosis changes in nerve function and in one case rapid loss of consciousness following the injection of a very small amount of thiopentone. The pathogenesis is largely dependent upon immediate thrombosis following damage to the intima by the highly irritant, strongly alkaline thiopentone. The circulation may be finally arrested by one or several of the following mechanisms: (1) arterial thrombosis, (2) arterial or distal arteriolar spasm, (3) extensive diffuse venous thrombosis, (4) extensive venous spasm, (5) mechanical blocking of the arterial tree due to protein flocculation or precipitation of the drug, and (6) arteriovenous communications enabling retrograde spilling-over of intravenous fluid into the arterial circuit.

The treatment of choice is held to be immediate arteriotomy with removal of the clot. Delayed surgery is of no help. Arterectomy is held to be without advantage. Antispasmodics such as papaverine, aspirin, alcohol and others have not brought dramatic improvement. If surgery for the original lesion must be continued the author recommends general anesthesia, preferably cyclopropane deep enough to produce vasodilatation, but light enough to prevent a fall in blood pressure. Brachial block is advocated in preference to sympathetic block. Local measures such as protection by sterile wraps are advised in addition to maintenance of body warmth immersion of the opposite limb in warm baths (112 degrees F) elevation of the affected limb, and the generous use of morphine for the relief of pain.

Certain measures designed to aid the anesthetist in the prevention of such errors as accidental intra arterial injection of drugs are listed. These include checking the vessel to be injected for pulsation, selection of a vein beyond the antecubital fossa, injection of a trial amount and waiting for the development of pain a reluctance of a too tight venous tourniquet as well as hyperextension of the elbow and a detailed knowledge of the anatomical variations encountered about the elbow joint. Further experimental work on animals is held to be desirable.

ALLAN D. CALLOW M.D.

Arterial Embolism. J. R. LEARMONTH. *Edinburgh M J* 1948, 55: 449.

The points of origin of arterial emboli are described. Three essential factors in the treatment of arterial embolism are: (1) the preservation of adequate blood volume, (2) the preservation of adequate general blood pressure, and (3) adequacy of the collateral circulation. The availability of the collateral channels depends upon the anatomic arrangement of the vessels at the involved site, arterial spasm, consecutive thrombosis, and the structural changes in the walls of the adjacent vessels.

First aid treatment of arterial embolism should include: (1) heparin, (2) placing the involved part at rest at a temperature from 15 to 20 degrees, (3) relief of pain, (4) inducement of sleep to aid vasodilatation, and (5) if arteriolar fibrillation is present digitalis should be withheld unless there are signs of cardiac failure. The clinical types of arterial embolism are described and clinical examples are presented. If the patient is seen within 10 hours the author awaits the result of treatment with heparin. If this is of value unmistakable improvement will occur within about 3 hours. If there is an unprofitable interval, arterectomy is performed. The ultimate result will depend largely upon the exact site of obstruction and upon the architecture of the arterial tree in each particular case.

ROBERT A. NARATOFF M.D.

Arterectomy in Pains of Vascular Origin (L'artériectomie dans les douleurs d'origine vasculaire). J. AOUTIN. *Rev. chir. Par* 1948, 67: 293.

After a series of intravenous calcium injections the author's patient developed a syndrome first diagnosed as phlebitis, but which cleared up after 40 days of immobilization. A month later however the patient complained of attacks of severe pains in the cubital space which irradiated to the shoulder and forearm and exacerbated at night. A mass of hazelnut size could be palpated. There was hyperhidrosis of the palm and cyanosis of the fingertips.

As 5 novocain infiltrations of the stellar ganglion were unsuccessful the humeral artery was resected for a length of 6 cm. The operation was followed by prompt recovery and cessation of all pathological signs although the resected artery appeared normal histologically.

The author believes that the extra venous injection had caused an irritation of the adventitia and continuous spasms of the artery which were responsible for the cyanosis and hyperhidrosis as well as for the pains. No signs of an old phlebitis were found at the operation the cubital veins were not thrombosed.

WERNER M. SOLMITS, M.D.

Results of 94 Arteriotomies (Résultats de 94 artériectomies). C. MENTHA. *Lyon chir* 1948, 45: 1-4.

The author reports the results of 94 arteriotomies done on the service of Professor Leriche from March 1942 to January 1947. These operative procedures were done for senile and presenile arteritis in 80 patients. All of the patients were more than 45 years of age, 76 were males and 4 were females.

Although arteriography for the localization of arterial thrombi or the use of postoperative anti coagulant therapy was impossible during wartime the results were very favorable.

In 35 patients arteriotomy alone was done either unilaterally or bilaterally. In the 45 other patients this procedure was combined with unilateral or bilateral lumbar sympathectomy. The results were classified as excellent in 75 per cent and good in 26.25 per cent, some improvement was obtained in

22.5 per cent. The results were slightly better in the patients who had arteriectomy combined with sympathectomy than in the patients who had arteriectomy alone. The patients were followed up for from 1 to 5 years.

The author concludes that arteriectomy either alone or combined with lumbar sympathectomy is the most efficient method for the treatment of chronic obliterative arteritis of the presenile and senile types.

EDWARD W. GIBBS, M.D.

BLOOD TRANSFUSION

Chronic Leg Ulcer in Diseases of the Blood. BENJAMIN R. GRENDEL, *Blood*, 1948 3 1283

Chronic leg ulcers may occur as a complication of (1) sickle cell anemia (2) congenital (hereditary) hemolytic anemia (3) splenomegaly associated with Banti's syndrome (4) idiopathic thrombocytopenic purpura, (5) pernicious anemia (6) Gaucher's disease and (7) chronic hemolytic polycythemia.

He reports two cases. The first patient, a 52 year old white man presented a typical hemolytic anemia, the earliest symptom of which was the leg ulcer 27 years previously. This was successfully treated by skin grafting and splenomegaly. The second patient, a 60-year-old white man, at autopsy proved to have cirrhosis of the liver and congestive splenomegaly (Banti's syndrome).

The pathogenesis of the leg ulcers accompanying these diseases of the blood has not been satisfactorily explained. The common denominator would seem to be related to the spleen. It is suggested that the association of leg ulcer with these various diseases of the blood is related in an unknown manner to either splenomegaly or hyperfunction of the spleen (hyperplenism). LARRY J. KLEINBAUER, M.D.

Are Universal Donors Dangerous? (Les donneurs universels sont-ils dangereux?) M. P. ROBERT, P. H. BONNET, AND H. PERROT *Presse med.* 1948 62 691

The authors discuss the advantages and disadvantages of using the universal donor in blood transfusions. They deemed it useful to reinvestigate the problem by studying the blood modifications taking place in the recipient at the site of the injection.

A series of experiments were conducted in which 50 c.c. of whole fresh blood from a Rh positive donor (with average or high agglutinin levels) were injected into a wrist vein of Type A recipients. The vein selected had no collateral drainage from the wrist to the elbow. Two trocars were placed in this vein at 10 cm. and 20 cm. proximal to the injection site and samples of blood were withdrawn at intervals during the transfusion. The transfusion was given rapidly and two samples were taken from each trocar after each 10 c.c. had been given or every 12 seconds. Sodium citrate was added to the first sample and the second was allowed to clot. In the citrated samples agglutination of the cells was looked for microscopically and in the clotted

samples the titers of the alpha and beta agglutinins were determined.

The authors were able to show that the titer of the foreign agglutinin alpha declined rapidly upon entering the recipient's vein. Very little was present at the 10 cm. trocar and practically none at the 20 cm. trocar. The titer of the agglutinin beta declined in a similar manner. These changes persisted throughout the transfusion. They explain the rapid disappearance of the agglutinins as follows:

1. Partial fixation in the vessel wall.
2. Partial though almost inconsequential loss through the combination with the recipient's red blood cells.
3. Absorption by the blood serum of the opposing agglutinins.

The authors proved the third explanation in the following manner:

The plasma from 20 c.c. of oxalated blood type A was mixed with an equal quantity of serum O (titer of alpha = 1/64; titer of beta = 1/64). Washed cells from the A blood and foreign B cells were then added. The foreign B cells controlled the beta agglutinins. There was a definite reduction of agglutinin alpha from 1/64 to 1/16 in 30 minutes and to 1/8 in an hour while the titer of the beta agglutinin did not vary.

The authors conclude that foreign agglutinins from the universal donor are rapidly neutralized at the transfusion site but the neutralization is accompanied by slight agglutination with resulting slight hemolysis which, most likely would be detrimental to weak anemic patients.

JOHN H. FLYNN, M.D.

LYMPH GLANDS AND LYMPHATIC VESSELS

Surgical Management of Thoracic Duct Injuries. G. B. HODGE and HUNTER BRIDGES, *Surgery* 1948 24 805

Traumatic chylothorax is a rare but not uncommon condition which is due either to direct or indirect violence or to operative injury. Traumatic injury such as that due to crushing bullets or stab wounds on the chest and hyperextension of the vertebral column are often encountered.

Operative injury to the duct with chylothorax or chylothorax is a more frequent occurrence than one is led to believe from reports in the literature. The cervical portion of the duct is often injured in operations on the left side of the neck for tumor or enlarged lymph nodes. If unrecognized or not treated chylothorax will develop and if the pleura is opened chylothorax may occur. In injuries to the intrathoracic portion of the duct, chylothorax with its attendant high mortality will occur unless the injury is promptly recognized and treated.

Injuries to small tributaries or collaterals of the thoracic duct often become sealed without serious consequences. However injury to a large tributary with chylothorax may be present and not clear up for several days.

Fig. (Hodges and Bridges) Technique of implantation of the thoracic duct into the azygos vein.

The symptoms in chylothorax are those due to pressure and loss of chyle. The pressure symptoms may be relieved by frequent thoracentesis, but the loss of chyle if allowed to persist will result in inanition and death. With the loss of the constituents of chyle, marked deficiency state develops, characterized by weakness, hunger, intense thirst, emaciation, apathy, and death which is due to starvation. The lymphocyte and eosinophilic blood count are reduced.

The treatment of chylothorax has been medical, surgical, or combined. In the medical management a proper diet low in fats and rich in protein and vitamins, is given. Blood transfusions, plasma, glucose, saline solution, intravenous infusion of aspirated chyle and thoracentesis have been employed. These supportive measures may maintain the patient's nutritional status until spontaneous or operative repair of the injury is carried out.

In operative injuries it is paramount that the injury be recognized at the time and appropriate treatment carried out. The authors have investigated a method of repair of a traumatized thoracic duct on dogs and satisfactory results were obtained in those cases in which the thoracic duct that was excised was ligated and in those cases in which the thoracic duct was implanted into the azygos vein. It was interesting to note that of the dogs in which a segment of the thoracic duct was excised and the divided ends left open, 4 recovered and 2 died. The autopsy on these animals revealed that closure of the open ends of the duct and collateral channels and lymphaticovenous anastomosis developed.

The authors concluded that in injuries of the lower part of the thoracic duct ligation is unsafe. If a primary repair of an injured or severed duct cannot be accomplished, then implantation of the thoracic duct into the azygos or other suitable vein should be carried out. This treatment is the most physiological if primary repair cannot be accomplished.

A case report was presented by the authors in which the thoracic duct was implanted into the azygos vein with complete recovery. The technique of the implantation into the azygos vein is illustrated in Figure 1.

JOHN E. KARABIN, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Major Surgery Hematocrit Values, Plasma Protein Determinations, Protein Fraction (Grosschirurgische Eingriffe, Hämatokritwert, Plasma Eiweißquantum, Eiweißfraktion) I DISCHERT W. W. W. mod. Wschr., 1948 98 394.

Using the Kjeldahl method the author made 1 240 plasma protein serum protein and fraction protein determinations on 233 patients.

The plasma protein value was sometimes higher than normal when the body weight corresponded to the body height or the ratio was abnormally high. Only malignant myelomas revealed an exception in spite of a great loss of weight, the plasma protein may be as high as 14 gm. per cent instead of the normal 6.5 to 8.0 gm. per cent. Hypoproteinemia was found in accident cases and was probably due to the effect of shock, a similar condition was noticed also in patients with chronic inflammatory processes, chronic suppurative conditions such as empyema or phlegmons, also nephrosis complicating surgical conditions of the kidneys, grave gastrointestinal lesions such as ulcerative colitis echinococcus disease certain cases of carcinoma, malnutrition and in patients with Witzel's fistula.

An increase of globulins was found in patients with phlegmons and certain patients with pulmonary tuberculosis. Only 25 per cent of 24 patients with bronchial carcinoma showed a decrease in the albumin-globulin ratio. The hematocrit values were found increased in idiopathic and symptomatic polyglobulia resulting from peripheral stasis or dehydration following vomiting diarrhea, or burns. An acute rise of hematocrit values in patients who had not received a blood transfusion was a sign of a fatal outcome.

A rise of gamma globulins was observed after the extirpation of an echinococcus cyst from the upper lobe of the right lung.

Numerous observations on patients who underwent pneumonectomy showed a diminution of plasma proteins reaching 1.75 gm. per cent. An exception to this rule may be found only in relatively young patients.

Unless there are great blood losses or a considerable fall of the blood pressure during the operation plasma protein and hematocrit values usually return to normal levels after a transfusion of approximately 600 c.c. of blood. A transfusion of much larger amounts may embarrass the circulation and prevent the reticuloendothelial system from an intensive formation of antibodies because the system may become exhausted by phagocytosis of foreign erythrocytes brought into the organism with the transfused blood. Unless a transfusion is given for the purpose of replacing considerable losses of blood its aim is to stim-

ulate the bone marrow. This task is accomplished by bilirubin or urobilin liberated from phagocytized erythrocytes. The stimulated plasma cells in the bone marrow form plasma proteins especially globulins, thus the rise of globulins after a transfusion is explained.

The operative shock is responsible for a fall in plasma proteins. Furthermore a loss of proteins by muscles of a bedridden patient after the operation leads to a loss of proteins in the blood.

Contrary to the statement of some American writers plasma protein contents as low as 5.5 gm. per cent never caused edemas in the author's material of 235 patients, no matter whether they were operated on or not.

A protein rich diet combined with the administration of large amounts of fats and carbohydrates proved to be the most efficient remedy to combat the postoperative hypoproteinemia.

The author recommends a blood transfusion 2 or 3 weeks after pneumonectomy if the postoperative course is uneventful, in order to raise the plasma proteins, because as a rule the patient shows a fall of such proteins. JOSEPH E. NARAT, M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Primary Tendon Repair JOSEPH L. POSEH, SURG. Clin. N. America 1948 38 1323

The author reviews the treatment of 187 cases of injuries of the tendons and nerves of the hand and wrist at the Detroit Receiving Hospital, Detroit Michigan during 1947. Case histories representative of the various types of injuries are presented in detail. In general the principles outlined by Koch, Mason and Allen were followed.

Emergency room care consisted of establishment of the diagnosis without interference with the wound. Tetanus antitoxin was administered and the patient was prepared for admission to the operating room. Although the author states that general anesthesia is preferred the majority of patients were operated upon under brachial block or local infiltration of novocain.

Cleansing of the wound with soap and water was performed in the operating room. A bloodless field was maintained by the use of a blood pressure cuff inflated to 250 mm. of mercury, which is released every 155 hours during the procedure. Adequate exposure without incising across skin creases is stressed. Tendons were approximated with No. 60 cotton suture by the technique developed by Mason and Allen. Because of the difficulties in its use, the Bunnell pull out wire technique was abandoned although the author states good results were obtained in the few cases in which it was used. Splinting was maintained by the use of plaster molds and pressure dressings.

When possible, the primary dressing was not changed for a period of 10 to 14 days.

When the flexor tendons were found to be divided within the sheath, only the profundus tendon was repaired, the sublimis tendon being excised. Both tendons were repaired when the laceration was in the palm or wrist. Of 43 patients with severed tendons at the wrist, 22 had associated nerve injury.

Of the extensor tendons, the extensor pollicis longus caused the most difficulty in care. Secondary tenorrhaphy was necessary in 5 of 8 cases in which primary repair had been carried out. The author attributed the cause for failure to premature removal of the splint. For extensor tendons, he advocates the application of a splint at night for 3 weeks following removal of the original splint at 3 weeks postoperatively.

Only 3 patients were operated upon later than 6 hours after injury; the majority of the operations being performed in 4 to 6 hours after the trauma. Penicillin, if used, is given intramuscularly, and its use locally is condemned by the author. From the experience of the Hand Clinic at Detroit Receiving Hospital primary tendon suture is recommended.

JOHN L. BELL, M.D.

Some Observations on Anemia in Patients with Burns. F. BRANTERWHITE and F. T. MOORE. *Brit J Plast Surg* 1948, 8.

The object of this article is to draw attention to the importance of the nutritional factor especially protein depletion in anemia resulting from burns. Most patients during the period of their recovery from burns show diminution in their blood hemoglobin values. The patients whose burns are less severe can, with dietary assistance, correct the anemia. In contrast, the patients whose burns are more severe need careful observation, prolonged treatment, and repeated blood transfusions. The important feature which separates these two classes is the extent of the total skin loss.

The first blood change to be noted as a result of burning is hemoconcentration. Following the intravenous infusion of plasma, hemoconcentration is controlled within 3 or 4 days. The hemoglobin of patients whose area of total skin loss is less than 10 per cent falls to 85 to 90 per cent return from this level is usually spontaneous and complete before the second week has elapsed.

The anemia arising from burns, associated with a percentage area of total skin loss greater than 15 per cent, is persistent and reacts only to transfusions of whole blood. Healing of the burned area is really the key to the situation, but the anemia will not be relieved until the burn is healed, and the burn will not heal until the hemoglobin is over 60 per cent. Repeated transfusions are the only solution and are the routine measure applied.

Attention is drawn to the anemia that follows plasma infusions given when the patient is at the stage of hemoconcentration. There is no direct relationship between the amount of plasma infused to

prevent hemoconcentration and the subsequent degree of anemia. A marked hemoconcentration is not necessarily followed by a marked degree of anemia. Hemoconcentration bears a relationship to the total area burned, but the subsequent anemia bears a relationship only to the extent of the total skin loss.

The anemia that follows the phase of recovery from hemoconcentration is directly related to the extent of the raw areas. The more extensive the area of total skin loss, the more profound is the ensuing anemia. This is in effect an alternative way of saying that the significant factor in the subsequent anemia is the area of granulation tissue that arises as a result of skin loss.

It has been shown by Cope (1943) that during recovery from burns, a period of negative nitrogen balance occurs and during this period of protein catabolism the protein stores of the body are depleted.

In a patient suffering from extensive skin loss due to burns the daily excretion of urinary urea rapidly rises and is coincident with a rapid fall in the blood hemoglobin and the plasma proteins. Blood transfusions may control the decreasing blood hemoglobin if given in sufficient quantity. Four of the patients seen with severe burns developed a picture resembling that found in tropical nutritional anemia or sprue. They showed a variety of types of anemia without leucopenia, asthenia, wasting, sore tongue, diarrhea or bulky fatty stools.

Cases are presented which suggest that the resistant anemia that occurs after the initial stages of a burn is closely related to and runs parallel with disturbances of the nutrition. In the first group the protein loss was the most operative factor. In the second group a spruelike syndrome had added to the difficulties of the patient in absorbing and retaining the factors needed for red-cell formation. Hematinic factors liver iron, or vitamin B will not perse suffice to correct this anemia. The evidence suggests that the operative factor is loss of protein.

Whipple and his co-workers have produced much experimental evidence stressing the importance of adequate protein intake for hemoglobin formation. They have found that the globulin necessary for hemoglobin synthesis is found in most meats, and in classical experiments showed that liver by mouth, especially beef and chicken livers had a more important influence on hemoglobin production than any other protein-containing food and all the work since then has suggested that it is factors other than antianemic liver factors used for pernicious anemia that are of importance. Liver is a rich source of amino acids experiments by Whipple and others point to lysine as the important factor others are important for plasma production, but practical experience has proved that plasma infusion will not correct the anemia of burns.

The reason for the development of the spruelike syndrome in 4 patients is not clear but the administration of 30 gm. of sulfonamide might have interfered with the intestinal synthesis of vitamin B.

Leucopenia did not occur so that an inhibition of marrow activity by sulfonamide cannot be postulated as a cause of the anemia. Hemolysis as a cause of anemia relates to the early stages of the burn; no evidence has been produced showing that in the later stages hemolysis occurs. There is thus a good body of evidence pointing to the importance of protein intake that is to say food protein with serious burns. The practical effect is that patients suffering from severe burns must be given a high mixed protein diet that the hemoglobin must be maintained above 60 per cent, if healing is to occur and that hematitics alone cannot be expected to correct the fall in the blood hemoglobin.

FRANK F. KANTHAK, M.D.

Infection Through Soaked Dressings. LEONARD COLLEBROOK and A. M. HOOD. *Lancet* Lond. 1948, 2: 682.

To investigate the possibility that outside contamination could traverse several thicknesses of an intact, sterile, moist dressing and infect an underlying wound the authors constructed a model wound which consisted of a section of brass tubing with several holes drilled near one end. Wicks of gauze were placed through these holes to facilitate seepage of fluid from gauze which had been moistened and placed loosely within the tube. A sterile dressing was bandaged over the holes and the tubing was laid horizontally on a piece of filter paper placed within a copper container and the entire apparatus was autoclaved.

In simulating wound contamination the innermost gauze was saturated with a mixture of plasma and nutrient broth and the outside of the dressing was infected by adding cultures of bacteria to the filter paper. The model was incubated and cultures taken from the inner gauze showed that infections of the *Pyococcus*, *Staphylococcus aureus*, *Proteus*, diphtheroid bacillus, *Streptococcus hemolyticus* and coliform bacillus readily traversed the dressing. Motile organisms passed through in a few hours; streptococci and staphylococci took up to 48 hours to penetrate. It was found that a plaster of paris shell over the bandage did not interfere with the passage of organisms but that cellophane or other impervious plastic was an effective barrier.

The authors suggest that some hospital cross infections may occur in a manner similar to their experiment. A plastic sheeting which is pervious to water but impervious to bacteria is undergoing further investigation as a possible barrier to infection which might be incorporated in dressings.

WAYNE FIELD CARMON, M.D.

Penicillin in Tetanus. R. S. DIAZ RIVERA, LUIS R. DIAZ, and JOSÉ BERRIO-SUÁREZ. *J. Am. M. Ass.*, 1948, 138: 191.

Because of inadequate methods of therapy tetanus remains one of the most dangerous of wound infections. It has been shown that tetanus antitoxin is of limited value after a large amount of toxin has been fixed by the central nervous system.

Fig. 1 (Colebrook and Hood) Apparatus used in experiment described in text.

Between July 1945 and March 1947 the authors treated 59 patients at the San Juan City Hospital, Puerto Rico (2.4 per cent of total admissions). The known incubation periods varied between 1 day and 3 months, with an average of 8.4 days for the total group and an average of 5.7 days for the cases in which the outcome was fatal.

Generalized tetanus developed in 56 patients and cephalic tetanus in 3. All but 18 patients had convulsions. Leucocytosis was present in 35 per cent of the cases. Therapy consisted of the intravenous administration of 100,000 units of antitetanic serum upon admission and frequently in addition intramuscular injections of 100,000 units. Wherever possible local excision of the port of entry was performed after injection of the surrounding tissues with 20,000 units of antitetanus serum and open wound treatment with H_2O_2 was instituted. For a period of 1 to 3 days 5,000 to 10,000 units of antitetanus serum were given intramuscularly. 5 per cent dextrose in isotonic sodium chloride was given intravenously and a stomach tube for nutrition was used in the patients who were more seriously ill. Phenobarbital sodium injected hypodermically in doses of 1 gr (0.13 gm) every 2 to 3 hours helped to control convulsions. ether in oil by rectum was used also. Penicillin in doses of 15,000 to 20,000 units was given intramuscularly every 3 hours.

The mortality rate was 20.3 per cent. The average hospital stay for the whole group was 19 days and the average total amount of penicillin received was 1,800,000 units. The patients who died had received an average of only 796,000 units of penicillin. The duration of the convulsions was not shortened by penicillin nor by tetanus antitoxin.

A short incubation period and the rapid onset of convulsions are bad prognostic signs. This is true also when the port of entry is in the head. The causes of death in 12 patients were respiratory paralysis and toxemia in 7, bronchopneumonia in 4 and extreme dehydration in 1 patient. Severe serum sickness was considered a contributory factor in 1 patient.

The results are evidence of benefit from large doses of tetanus antitoxin in several cases of well established generalized tetanus. However, penicillin seems to have contributed to a reduction in mortality. Although it had no effect on the incidence of complications it may have altered the multiplication of Clostridium tetani. It also had a beneficial effect on complicating pneumonias.

ARM. J. LEAS, M.D.

On the Treatment of Actinomycosis with Sulfadiazine and Penicillin. C. A. W. and J. A. H. S. W. Brit. med. Jour. 1945, 3, 3

Sulfadiazine and penicillin are known to affect actinomycetes in vitro. The authors present the case of a 40-year-old patient who suffered from pulmonary actinomycosis and who had received penicillin therapy without success.

Chemotherapy consisted of the administration of sulfadiazine at a maximum of 12 g. daily and of penicillin at 100,000 units per day. No injury to the kidneys was observed. Within 4 days of the start of treatment the patient was able to get up and walk. The patient was discharged after 4 months of treatment.

Further studies of the treatment of actinomycosis are being carried out. The authors are hopeful of recurrence.

ARM. J. LEAS, M.D.

ANESTHESIA

Relationship Between Hypoparathyroidism and Tetanizability of Anesthetic Agents. A Preliminary Report. C. H. L. D. and C. T. C. H. W. Brit. med. Jour. 1945, 3, 3

White rats were selected as animals suitable for the study of the relationship between hypoparathyroidism and tetanizability of anesthetic agents. A preliminary study of the relationship between hypoparathyroidism and tetanizability of anesthetic agents was carried out.

It was found that the tetanizability of anesthetic agents was increased in the hypoparathyroid rats. The tetanizability of anesthetic agents was increased in the hypoparathyroid rats. The tetanizability of anesthetic agents was increased in the hypoparathyroid rats.

M. H. W. and C. T. C. H. W.

Our Experiences with Peridural Anesthesia (Case Report). H. H. W. and C. T. C. H. W. Brit. med. Jour. 1945, 3, 3

For the past 15 years Ohlring has used Dogliotti's peridural anesthesia in all serious abdominal operations including kidney and bladder operations and pericardial operations. The only contraindication being severe respiratory failure such as occurs for instance in chronic bronchitis.

In the beginning he used quinine solution but changed over to pantocain-gelatin solution. Each c.c. of pantocain 0.5 white gelatin 5 plus 10 large salt solution to 100. This solution is sterilized and kept in well-sealed brown bottles. The solution is used in a 1:1000 solution.

On the evening before operation, 0.5 to 0.75 gm. of novocain is given subcutaneously. On the morning of operation, 1 c.c. of novocain is injected intravenously so that the patient is already in a half-awake condition. He is brought into the anesthetic room if needed for complete unconsciousness and then 0.5 to 1 c.c. of novocain is then injected. The only difficulty of the method is in correct puncturing of the lumbar space. On this point we reached a good understanding of the method. The patient is placed in a prone position and the lumbar space is punctured. The patient is placed in a prone position and the lumbar space is punctured. The patient is placed in a prone position and the lumbar space is punctured.

The patient is placed in a prone position and the lumbar space is punctured. The patient is placed in a prone position and the lumbar space is punctured. The patient is placed in a prone position and the lumbar space is punctured. The patient is placed in a prone position and the lumbar space is punctured. The patient is placed in a prone position and the lumbar space is punctured.

From September 1945 to September 1946, peridural anesthesia was used in 140 abdominal operations. Anesthesia was incomplete in 4.3 per cent of these cases and the anesthetic was added some local anesthetic at a maximum of 1.5 cubic centimeters of 1 per cent solution. The fact that not enough time was allowed to obtain complete anesthesia and also that the technique was being used for the first time was the cause of the incomplete anesthesia. The fact that not enough time was allowed to obtain complete anesthesia and also that the technique was being used for the first time was the cause of the incomplete anesthesia.

Peridural Anesthesia in Children (Die Periduralanästhesie im Kindesalter). H. H. W. and C. T. C. H. W. Brit. med. Jour. 1945, 3, 3

Applying the principles worked out for adults, the authors have extended the use of peridural anesthesia in children and have obtained good results. They have used a 0.33 per cent aqueous solution of

pantocain and a 0.5 per cent pantocain-0.6 per cent periston solution with 1 drop of 1 to 1,000 suprarenin solution per 5 c.c. The body weight of the child was used as a practical guide to the dosage of pantocain aqueous solution of pantocain in children of from 0 to 12 years weighing from 2 to 35 kgm. ranged from 2 to 12 c.c. and that of the 0.5 per cent pantocain-0.6 per cent periston solution in children of from 6 to 12 years weighing from 20 to 35 kgm. ranged from 6 to 8 c.c.

No preparation was used for infants. Very restless children were given from 0.2 to 0.5 c.c. of luminal sodium in the first year of life and from 0.5 to 1 c.c. in the second to the fifth year only after the sixth year was from 1 to 1.5 c.c. administered regularly 1 hour before anesthesia.

Puncture is usually performed in the sitting position with a needle 3.5 cm. long graduated in centimeters and having a point bevel of 45 degrees. In the nursing the depth of the puncture is usually less than 1 cm. in children of from 5 to 7 years it is about 2 cm. The adaptability of the circulation of children to peridural anesthesia is extraordinary and prophylactic measures against circulatory changes are unnecessary. The aqueous solution of pantocain is indicated in children under 6 years the pantocain periston solution is used in appropriate cases after the age of 6.

In the beginning the authors did not use the method in children with severe peritonitis nursings with ileus and the newly born. At present practically all interventions below the xiphoid are performed under peridural anesthesia even in nursings and the newly born the only exceptions are those for spasm of the pylorus, anal atresia, and myelomeningocele which are done under local anesthesia. The use of the peridural method is recommended particularly in orthopedics since it provides ideal muscular relaxation.

Peridural anesthesia is valuable as a therapeutic measure without subsequent operation in ileus of nursings. In incarcerated hernia it causes relaxation of the abdominal wall with enlargement of the hernial opening, reduction of the hernia by simultaneous stimulation of peristalsis then occurs spontaneously in some cases and is facilitated by taxis in others. Recent intussusception can be reduced manually through the relaxed abdominal wall.

RICHARD KIMMEL, M.D.

Experiences with Procaine Administered Intravenously CHARLES M. BARBOUR and RALPH M. TOWELL. *Anesthesiology* 1948, 9, 514.

In the present article, the authors recount the history of the intravenous administration of procaine hydrochloride and report their personal experience with the use of this therapeutic measure in a weak concentration (0.1% solution). It has been used for numerous purposes. The intravenous administration of procaine provided adequate analgesia for the transportation of battle casualties and produced

alleviation of pain during surgical dressings of burns. It has been effective in combating deleterious cardiac arrhythmias in the presence of an emergency and as a prophylactic measure immediately before and during the operative procedures involving intrathoracic structures likely to produce these untoward cardiac effects. It serves as a substitute in many instances for morphine in the control of postoperative pain and for patients suffering from spastic diseases and arthritis. It has been adopted by others for use in patients who present rapid irregular cardiac rates before and during general surgical procedures. In weak solutions procaine hydrochloride has been employed during operations within the neck when such syndromes as bradycardia, hypotension and progressive cyanosis appear. For the treatment of cardiovascular emergencies the employment of analeptics has been discarded for the use of intravenous administration of glucose in distilled water or saline solution whole blood or blood fractions to assure adequate cardiac filling together with the intravenous use of procaine in 0.1 per cent concentration to reduce futile activity associated with excess irritability. Intravenous procaine is of therapeutic value in the management of patients suffering from pruritus associated with jaundice, contact dermatitis and exfoliative dermatitis. The relief from itching has lasted from 4 to 18 hours following an infusion. The optimum time to administer the drug is in the evening thus permitting sound sleep. Preliminary skin tests are performed.

Procaine has been used successfully for the treatment of urticaria associated with the administration of blood. The management of patients suffering from burns offers the anesthetist a real opportunity to contribute to the comfort of these people irrespective of the severity of the burn.

The sympathetic effect is in early and definite action of procaine. For these sympathetic effects it is used in the treatment of thrombophlebitis. Though not extensive the results with this agent in the treatment of skeletal muscular spasm have been encouraging.

It must be remembered that the drug is convulsant. Its use in concentrated solutions or rapid injection of dilute solutions may cause untoward reactions that will not only jeopardize the patient's life but will bring this method and agent to disrepute.

MARY KARP, M.D.

Pentothal-Curare Solution. Observations on Its Use in 500 Cases. JOE W. BAIRD. *Current Res Anesth.* 1948, 27, 336.

Pentothal-curare solution in combination with 50 per cent nitrous oxide and 50 per cent oxygen seems adaptable to almost all types of operations and for all age groups. One of the greatest advantages of this type of anesthesia is the complete elimination of the fire and explosive hazard.

Because of the minimal alteration of the normal physiology by the various components of this anes-

th the agent. It is recommended as the anesthetic of choice for debilitated and poor risk patients. It is believed that this type of anesthesia is indicated in very mild stages of disturbances of the cardiac conduction mechanism. It has been found especially useful when there is danger of postoperative bleeding or injury from excessive tracheal intubation. The urinary is at least 30 minutes and requiring no muscular relaxation pentothal curare anesthesia is not as adaptable as for the longer and more type of surgery.

When use of respiratory depressants are not indicated the respiratory movement must be maintained by manually compressing the bellows bag on the gas machine. It is recommended that this type of anesthesia be administered only by a trained anesthesiologist who has adequate facilities for providing artificial respiration.

MARY FRANCES FINE, M.D.

Pentothal Need During Surgical Anesthesia. (Quantitative and Pneumographic Studies Relating to the Physiology of Respiration.) J. A. C. M.C. *Current Anesthesia* 1948 27: 302-314

The purpose of studies both quantitatively and pneumographic have been carried out in patients peritoneal surgery that anesthesia. The quantitative studies showed a direct relationship between the anesthetic effect of the anesthetic and the unit in the respiratory system of patients in the anesthetic unit. The results of the study showed that the factors which influence the need for the pentothal during anesthesia are the

function of surgical and the anesthetic, the age of the patient, the duration of operation, anatomic site of operation, and obliteration of pain impulses by spinal anesthesia procaine hydrochloride.

In the onset of anesthesia pentothal is found to vary from 0.25 to 1.0 gm. with 76 per cent of patients requiring between 0.25 and 0.5 gm. This induction of surgical anesthesia, however, requires from 0.25 to 1.0 gm. of pentothal.

When administered at fixed rates of 150 mg. of 1 per cent solution per minute pentothal had to be administered for periods of from 30 to 37 per cent of the operating time. There was an additional calculated rate of drug need for each 10 minute increment in the operating time, from 48 mg. per minute for a 30 minute operation to 18 mg. per minute for a 2 hour operation.

In both periods about 50 per cent of the total amount of the drug administered as a 15 per cent solution. In two of the cases only 37 per cent of the total amount of drug administered was used for induction. No significant correlation could be made between the anesthetic weight and utilization of the drug. The use of bellows was found to reduce the need of pentothal by 30 per cent.

Pneumographic studies revealed trends concerning the respiratory mechanism to be used to maintain a constant, and observations were made on the relationship to the establishment of regular respiration by pentothal. Variations in respiratory rate types of patients and the use of various alterations in rate and a plethysmograph. MARY FRANCES FINE, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Some Observations on the Roentgen Diagnosis of Nonopaque Foreign Bodies Aspirated into the Bronchi
SÖLVE WELIN *Acta radiol. Stockh.* 1948, 39: 539

During the last 4 years 13 cases of aspiration of organic foreign bodies have been found at the Caroline Hospital in Stockholm, and although such foreign bodies are commonly classified as nonopaque to roentgen rays the effort was made to visualize the aspirated body roentgenographically through the use of heavily exposed posteroanterior and oblique views the latter so angled as to throw the air column of the main bronchus of the affected side into relief against the gray shadow of the mediastinal structures, and thus obtain an air bronchogram. The technical factors recommended for adults were 80 to 90 kilovolts 0.05-0.1 seconds 300 milliamperes while for children the exposure time may vary from 0.03 to 0.8 seconds. A stationary Lysholm grid has been needed except in the case of the youngest children.

By this method it was possible, in 7 cases to demonstrate a single foreign body directly. These cases also showed roentgen evidence of valvular obstruction, but not of atelectasis. At bronchoscopy the aspirated body proved to be a nut kernel in 3 instances, a bit of fruit, vegetable or gristle in 3 others, and resin crystals in the seventh case.

In 3 other cases there was atelectasis of a whole lung secondary to obstruction of a main bronchus by a mass showing a rounded configuration of its air illuminated superior surface, at once giving the impression of a rounded foreign body. One of these cases showed in addition, a small rounded mass outlined against the main air column about 1 cm. proximal to the point of total obstruction. At bronchoscopy two peas were taken from the latter patient and one pea was taken from the other.

The remaining 4 cases showed only a sharp straight line interruption of the main bronchial air column with associated atelectasis of one lobe or portion of a lobe. Although the straight line appearance was not so suggestive of foreign body the history of sudden onset of obstructive symptoms supported that possibility and confirmation was obtained at bronchoscopy in each instance with removal of a pea in 2 cases and of an ear of wheat in 2 others.

Except for one woman of 40 these patients were all young children aged from 1 to 7 years. Two of the cases came to attention within 24 hours but some had been undiagnosed for more than a month. In view of the risk of secondary infection in such cases prompt diagnosis is of great value and in the author's experience the method outlined above has proved of distinct help in some instances in rapidly establishing a diagnosis.

LILLIAN DONALDSON M D

Studies of Roentgenologic Images of the Gastro-Intestinal Mucosa. Particular Appearances of the Mucosa of the Cecal Portion of the Ascending Colon in the Syndrome of the Right Lower Abdomen (Studi sull'immagine radiologica della mucosa gastro-intestinale. Particolare aspetto della mucosa del ceco-ascendente nella sindrome addominale destra). A. MONTALE CASATI. *Radiol. med. Milano* 1948 34: 593.

A method for examining the mucosal markings in the gastrointestinal tract has been described in previous communications. This has consisted essentially in the administration of 100 to 160 c.c. of an aqueous 20 per cent solution of colloidal barium sulfate (Molteni) by mouth after a cleansing enema and followed after 2 hours by a light meal. The pictures are taken about 15 hours after the ingestion of the shadow casting material. In this report the author gives his experiences with cases of painful syndromes in the right lower quadrant many of the patients had been appendectomized with persistence of pain.

The usual finding has been stippled circles of shadow in the partially (naturally) distended cecum. These circles have been of various sizes but usually small or about the size of a large grain of barley. This circular mottled appearance is ascribed to a tumefaction or hypertrophy of the intestinal lymphatic system induced by an interference with the excretion of bacteria or their toxins into the bowel lumen at this point. The lymphatic system here exercises a cushioning effect between the inner and outer surfaces of the bowel wall and connects up with the lymphatic system in the retroperitoneal tissue which may also be affected.

The author believes that his method, which he designates the method of scarce filling can be used to find the residual or even silent colonopathia in these cases and that a carefully taken anamnesis and his method of visual palpation with the aid of the sigmoidoscope will differentiate between the involvement of the bowel wall itself and that of the neighboring lymphatic structures. However he leaves the delimitation and analysis of the clinical applications of this method to a future communication.

JOHN W. BRENNAN M D

Tuberculosis of the Stomach and Duodenum. HERMAN W. OSTROM and WILLIAM SERBER. *Am. J. Roentg.* 1948 60: 315

Gastric and duodenal tuberculosis are uncommon lesions. When found they are usually associated with tuberculosis elsewhere in the body, although not necessarily the pulmonary type. The incidence of gastric lesions as reported by various groups is from 1 case in 21,000 autopsies to 0.34 per cent reported by the Mayo Clinic. Duodenal disease is

afterward and continued at intervals until the terminal ileum was filled. A cobblestone appearance of the mucosal pattern of the terminal ileum was noted in every case. None of the children had any tenderness or a palpable thickening of the terminal ileum.

In one case, a child 11 months of age died of acute laryngotracheobronchitis. At autopsy, numerous lymphoid cell collections were found in the terminal ileum, projecting above the level of the surrounding mucosa. Roentgenograms of a specimen of the terminal ileum after barium was smeared on its mucosal surface exhibited a typical cobblestone appearance. It is pointed out that the child died only 12 hours after the onset of the disease. Autopsy after a chronic illness with wasting may not lead to such good visualization of the pattern since the usual normal amount of lymphoid tissue is considerably reduced.

Golden described a similar cobblestone appearance of the terminal ileum in adults but in his cases there was evidence of right lower quadrant pain and condition to inflammation. He attributed the tender ileum was palpable. He attributed the condition to inflammation.

Further investigations are necessary to establish the age at which the cobblestone pattern of the normal ileum in children is no longer produced.

T. LEUCUTIA, M.D.

Roentgen Ray Diagnosis of Malignant and Potentially Malignant Lesions of the Colon and Rectum. JOSEPH C. BELL and JAMES B. DOUGLAS. *Radiology* 1948, 51: 297.

The authors state that in the past few years it has been noted that patients with cancer of the lower bowel are reporting earlier for examination than was the case 10 years ago. For this reason the problem of diagnosis is correspondingly more difficult.

According to Whitehead, 17 per cent of all deaths caused by cancer are traceable to cancer of the colon or rectum. That much can be done to prevent or postpone many of these deaths is shown by the statistics of Rankin and Johnston who in a series of 453 patients operated upon for cancer of the colon obtained 52.6 per cent of 5 year cures. When the lymph nodes were not involved the percentage was 25 per cent higher than among those in whom the nodes had been invaded.

Boehm and Hanson in reviewing 1,457 cancers of the large bowel found that the site of the lesion in 5 per cent of the total number of patients was located in the sigmoid, rectosigmoid and rectum approximately 50 per cent being in the rectum.

The authors emphasize that in making a roentgen examination of the colon a preliminary physical examination including digital rectal exploration is important. The history taking must list in order of importance: (1) recent change or absence of change in bowel habits; (2) abdominal discomfort or pain indicating interference with passage of material through the bowel; (3) rectal bleeding; its character, duration and amount; (4) indigestion and (5) evidence of progressive anemia. Since 65 to 75 per cent

of all cancers of the colon and rectum can be visualized with the sigmoidoscope and biopsy secured this procedure also should precede roentgen examination whenever possible.

In addition to the roentgen technique generally employed the authors use a film variant which is made possible by a three-contact quick change-over switch control attached in parallel with the change over switching apparatus in the spot film tunnel. This permits exact exposure on the film of any fluoroscopic image of interest. Serial exposures often proving of inestimable value especially in differentiating a stricture secondary to a diverticulitis from a cancer. Even in cases in which a preliminary sigmoidoscopic examination reveals the presence of a cancer polyp or other abnormality a roentgen study of the entire colon is indicated.

A defect due to an organic lesion is constant therefore whenever there is any doubt about its nature the roentgen examination should be repeated after a thorough cleansing of the bowel.

The double-contrast examination is of great aid in the demonstration of polyps and to a lesser degree in the diagnosis of early cancer or when a cancer is located in the right side of the colon. It is not a good procedure to follow a routine barium enema with a double contrast enema and it is best to do them separately since they require entirely different techniques. These techniques are described in detail. The article is illustrated with some unusual roentgenograms obtained by both the barium enema and the double-contrast enema techniques.

T. LEUCUTIA, M.D.

Congenital Valvular Formations in the Urethra. SIGVAARD JORUP and SVEN ROLAND KJALLBERG. *Acta radiol. Stockh.* 1948 30: 197.

The authors present 6 cases of congenital urethral valves which is a relatively uncommon condition. The patients were between the ages of 3 weeks and 37 years.

The method of demonstration of the condition is to inject the urethra with opaque contrast material which is soluble in water. Roentgenograms are taken during the injection of the material and on micturition. The valves appear as thin fin-shaped defects in the contrast study. The prestenotic posterior urethra is usually greatly dilated with an inferior convex or slightly conical surface of limitation. The thickness of the valve cannot usually be determined. On account of the obstruction in the passage only a thin ribbon of contrast medium is observed in the urethra below the valve formation. Early diagnosis of congenital urethral valves is urged to avoid urinary tract enlargement.

Lens. Results of surgical treatment of congenital cataract, 6

Letterer-Siwe disease. Bone lesions in eosinophilic granuloma, Hand-Schüller-Christian disease and, 533

Leucemia. Acute and pregnancy 58 skeletal lesions in, 87

Leucotomy. Operation of prefrontal, cordotomy and, 400

Ligamentotomy. Obstetrical sequelae of, by Doleris-Pelland technique, 53

Ligatures. New material for surgical sutures and (Ipsamid B) 83

Lip. Recurrent epithelioma of, 389

Lipoidoma. Localized, 64

Liposarcoma. Clinical and histological considerations of, 381

Liver. Differential diagnosis between medical and surgical jaundice by laboratory tests, 340 testicular trophy accompanying chylomas of, 350 on surgically treated hepatitis, 4 6 effect of procaine on function of experimental and clinical study 456 hepatic coma, 5 by distal disease of and lung surgical treatment, 558

Lobotomy. Transorbital, 33

Lumbar disc. Anatomical studies on degeneration of, 364

Lungs. Pulmonary valvulotomy for congenital pulmonary stenosis, 29 aortic pulmonary anastomosis, 29, certain images of striae in pulmonary fields, 78 volume of bronchial tree at various levels and its possible physiologic significance, 35 contribution to study of pulmonary hilum hilum of right upper lobe, 35 hernia of, 36 experiences in surgical treatment of pulmonary stenosis, 36 preoperative bronchoscopy in lobectomy for tuberculous, 36 pulmonary abscesses attended by pleural complications, 37 treatment of bronchocystitis, 37 roentgen appearance of chest in diseases affecting peripheral vascular system of conditions associated with increased vascular permeability, 81 some considerations of roentgen diagnosis of silicosis and conditions that may simulate it, 83 transthoracic anesthesia for bronchoscopy, 6 chronic nonspecific suppurative pneumonia, 6 pulmonary decortication in treatment of early pyogenic empyema, 6 studies in abscess of etiology of abscess of, 2 7 non-malignant intrathoracic lesions simulating bronchogenic carcinoma, 7 diagnosis and operability of bronchogenic carcinoma, 8 treatment of inoperable bronchogenic carcinoma with methyl-bis, 2 8, radical clippings and primary closure of deep thoracic fistulas, 9 9, parietal complications of collapse therapy 334 pulmonary decortication for chronic posttraumatic hemothorax constricting pleura, 335 improved method of resection of segments of, 335 syndrome of bronchial obstruction in permeable membrane, filtration of air 403 echinococcal disease of, surgical treatment, 403 solitary abscess of treated by primary resection of, 403 streptomycin in surgical infection abscess of and empyema, 403 bronchial adenoma, 404 cytological diagnosis of pulmonary cancer 404 solitary calcification of thologic aspects, 458, histopathologic fibrosis of roentgenologic findings, 458 pathology of pulmonary fibrosis, including chronic pulmonary sarcoidosis, 46 management of pulmonary cystic lesion, 407 primary pulmonary malignancy 498 role of pleural excision in infection following pneumothorax 498, some observations on roentgen diagnosis of nonopaque foreign bodies aspirated into bronchi, 35 streptomycin treatment of pulmonary tuberculosis, 558 hyaline disease of liver and, and surgical treatment 558

Lymphangioma. 3

Lymphodema. Treatment of, 45

Lymphogranuloma venereum. Anurocydia, 454

Lymphopenia. Observations upon, of x-ray irradiation, 463

Lymph system. Connections of in subarachnoid space, 1 radiation therapy of Hodgkin's disease, 8 contribution to study of pulmonary hilum hilum of right upper lobe, 35 experimental contribution to study of behavior of renal lymphatic system following partial, subtotal, or total block of lymph flow and its significance in pathogenesis of renal infections, 213 Hodgkin's disease from 1838 to 1947 276

Lysosyme. Vaginal autodeposition: present status of problem and its possible development; biologic significance of lysosyme in the vaginal secretions, 150 demonstration of in amniotic fluid, 116 reference to bactericidal power of amniotic fluid 41

MALFORMATIONS. Analysis of, of heart amenable to Blacklock-Taussig operation, 404 anencephaly, as cause of jerking of knee joint, 441

Malignancy. Intestinal changes secondary to irradiation of pelvis, 47 vascular malformations and aneurysms of gastrointestinal tract, collect a review 281 clinical classification of malignant thyroid tumors, 350 discussion of multiple tumors, 381 lesions of breast, statistical review with results of therapy, 402; tumors of testes, 430 treatment of lip (tumors) with emetine, 453 treatment of deep-seated tumors with multiple port techniques simulating rotation therapy 461 energy mechanisms in tumors in relation to chemotherapy, 470 primary pulmonary 498 anterior resection for of upper part of rectum and low part of sigmoid, 5 roentgen-ray diagnosis of lesions of colon and rectum, 553 definition of inoperability of cancer, 56

Mandible. Anesthetic management of patients with fracture of, 83 mandibular bone grafts, 484 fractures of, in children, 488

Mastectomy. Radical, 402

Mastitis. Is chronic cystic, a precancerous lesion year follow up study of 26 cases, 27

Mastoid. Radical operation on, 328

Mastoidectomy. Surgery of aural suppuration after radical, 8

Mandibular antrum. Treatment of cancer of, by radium, 84

Mediastinum. Fibrosis of with syndrome of Pancoast, 40

Megacolon. Colectomy in, 59, resection of rectum and rectosigmoid with preservation of sphincter for benign spastic lesions producing, 229, surgical treatment of congenital, 509

Megastigmoid. Clinical and surgical considerations in 50 cases, 39

Melanoma. Of vulval tract, 7 primary of vagina, with review of literature, 234

Melioration. Two cases of, 63

Meninges. Malformations of as cause of jerking of knee joint, 441 diagnosis of traumatic lesions of, 34

Mercury. Renal decapsulation in nephrosis due to, 353

Mercury bichloride. Case of anuria due to poison cured by intra-cavitary injection of novocain, 61

Mesentery. Vascular occlusion of, 31; lymphangioma of, 3

Mesonephros. Mesonephric remnants in cervix, 43

Metabolism. Research on glucose, in pregnancy 48; study of, of burn cases, 84 protein response to trauma collective review 473

Metastases. Occult bone, 87 colloid, lead orthophosphate associated with deep roentgen therapy in bone, from cancer of breast, 370 is radiological appearance of spine (and skeleton) 274 75 diagnostic of osseous, from cancer of prostate (and from other cancers), 437 neoplastic, to heart, 500

Radiation, I testicular changes secondary to irradiation of pelvic malignancies, 47; treatment of cancer of maxillary antrum by, 82; statistical, pathogenetic, and clinical considerations on radiotherapy of mandibular bone, 70; therapy of malignant intracocular neoplasms, 324; cytology of neoplasms of female genital system before and after treatment, 116; studied by apposition method, 347; precision dosage in interstitial irradiation of cancer of cervix uteri, 555.

Radium therapy, Technique for cancer of teres cervix, 54.
Radius, Functional substitution in irreparable radial nerve paralysis of, 68; tendon plastic for surgical treatment of dislocation of head of, 44; unusual localization of Brodie abscess in bone distal diaphyseal epiphysis of, 334.

Rectosigmoid, Transplantation of ureters into, and cystectomy, 433.

Rectum, Which is better surgical treatment for cancer of, 30; blastoid cords of region of anus and considerations on cases, 5; experimental contribution to implantation of ureters into, according to Bergsheim's technique, 64; proctitis of, 8; evaluation of colorectectomy and immediate anastomosis of, 8; resection of and rectosigmoid, 116; preservation of sphincter for benign apasic lesions producing megacolon, 290; cancer of and preservation of function, 290; surgical management of carcinoma of colon and, 45; rare injury of soft tissues to spontaneous delivery, 429; anterior resection for malignant lesions of upper part of and lower part of sigmoid, 5; experiences with operation for carcinoma of, with preservation of sphincter, 5; roentgen-ray diagnosis of malignant and potentially malignant lesions of colon and, 333.
Reiter' disease, Study of 344 cases observed in Finland, 559.

Renal, Artificial kidney of, 9; synthetic new antacid for treatment of peptic ulcer, 3.

Respiration, Neuron area of clinical significance in laryngology, 3; peritoneal need during surgical anesthesia quantitated, and pneumographic studies relating to physiology of respiration, 550.

Respiratory tract, Importance and discussion of connective tissues of upper, 9.

R (neuroploasmyo) sarcoma of teres cervix, 35.

Retina, Review of 100 cases of detachment of, 37; other atonias on pulse and arterial pressure of, 30; histological findings in case of angiod streaks, 344; atrophic glaucoma choroiditis and atrophy of, 486.

Rhinosarcoma apparently cured by strychnine, 303.

Ribs, Significant anatomic relations in syndrome of scapular muscles, 13; primary tumors of, 405.

Rickets, Roentgen diagrams of associated with other skeletal diseases of infants and children, 86.

Roentgenocardiography, Studies on circulation by, 87.

Roentgen irradiation, Observations upon lymphopenia of, 46; effect of radiation on hemopoiesis, 405; complications following, of thyroid gland, 489; gastroscopic picture in gastritis due to, 554.

Roentgenograph, Intravenous cholecystography with tetraiodophthallic fluorescent, 40; accessory pancreas posing as benign tumor of stomach, 43; osteoperiostitis simulating tumor, some remarks about radio-diagnosis, 63; localized osseous lipiodosis, 64; treatment of spontaneous precocious aneurysm of subclavian artery, 7; certain images of striae in pulmonary fields, 78; jejunoscopic intussusception, rare complication of operative stomach, 78; case for functional cholecystography compared studies on aqueous oral and Brouwer tests, both administered to same normal healthy subject, 70; roentgenologic

changes in urinary bladder and distal portion of ureters in spermatocystitis, 70; roentgenographic points of view on spinal tumors in children, 80; changes produced by diffuse torulosis in newborns, 8; celiac obstruction in upper extremity (Paget Schroetter's syndrome), collected review, 89; radiological and histological studies on aseptic osteomyelitis, which is associated with vascular disturbances, 116; exceptional report of familial case of total loss of bone of toe of foot, 116; asymmetrical atrophy of all other toes, 170; phlebography in localization of laccompent communicating clots in patients with arthritic clots, 78; obstruction of alimentary tract in infancy, 87; appearance of chest in diseases affecting peripheral vascular system of lungs conditions associated with increased vascular permeability, 85; some considerations of diagnosis of sifilosis and conditions that may simulate it, 85; diagnosis of rickets associated with other skeletal diseases of infants and children, 86; separation of capital femoral epiphysis in adolescence, 93; exploratory thoracotomy in management of intra-thoracic disease, 5; practical application of peritoneography to clinical obstetrics, 38; urology, 243; fractures of ankle, analytic historical survey as basis of new experimental, roentgenologic, and clinical investigations, 26; pneumothoraxography of knee joint with particular reference to meniscus cartilage, 26; general theory of stratigraphy, 260; radiology of persistent thyrogland duct, 7; angiocardiology in diagnosis of congenital heart disease, 27; method of contrasting localization of brain abscesses, 33; operative cholangiography, 34; diagnosis in gynecology and obstetrics, diagnosis in gynecology, 346; diagnosis in gynecology and obstetrics, diagnosis in obstetrics, 35; immediate and remote descending pyelography in renal contusion, 353; importance of information furnished by preoperative urethrography and results of urethroscopy on immediate repair of urethra, in course of diffuse perineal phlegmon, 356; diagnosis of suprapelvic tumors by pneumocystography, 378; pathologic gall bladder, 378; contribution to radiological study of simultaneous skin and bone manifestations in leprosy, 378; state of immediate urethrography and immediate reconstruction of urethra over support in traumatic ruptures of membranaceous and perineal urethra, 435; is radiological appearance of spine (and skeleton) always diagnostic of osseous metastasis from cancer of prostate (and from other cancers), 437; examination of paramedian masses, 116; particular reference to frontal sinuses, 458; pneumocystography in diagnosis of cerebellar atrophies, 458; idiopathic pulmonary fibrosis, 458; acute obstruction of small intestine, 459; aspect of prostatic cancer on urethrography, 459; study of uterine cavity and of total permeability in fetus by method of hysteromphography, 5; some observations on diagnosis of non-specific foreign bodies aspirated into bronchi, 55; studies of images of gastrointestinal mucosa, particular appearances of mucosa of cecal portion of ascending colon in syndrome of right lower abdomen, 55; tuberculous of stomach and duodenum, 55; tumors of upper third of stomach, 554; mucosal pattern of terminal ileum in children, preliminary report, 554; diagnosis of malignant and potentially malignant lesions of colon and rectum, 553; congenital valvular formations in urethra, 553; visualization of patent ductus arteriosus botalli by means of thoracic aortography, 553; visualization of coronary arteries, 554; rubber cassette with intensifying screens designed for examination of operatively exposed organs, 553.

- Röntgen therapy. Radiation therapy of Hodgkin's disease, 81 effect of, on experimental ocular vaccinia in non immune and in partially immune rabbits, 130 for extensive epithelioma of larynx results in 230 cases, 188 of malignant tumors of testis, 188 pleurocent genotherapy of bladder tumors, 245 some considerations in treatment of hemangioma in infants and young children, 269 statistical pathogenetic, and clinical considerations on radionecrosis of mandibular bone, 270 laryngeal chondronecrosis following, 270 radiation therapy of malignant tumors of testis, 272 of carcinoma of female urethra and vulva, 273 decade of experience with pleuro, in tumors of skin and mucosa, 279 colloidal lead orthophosphate associated with deep, in bone metastases from cancer of breast, 379 of pituitary tumors, 460 treatment of deep-seated malignant tumors with multiple port technique simulating rotation therapy, 461 cancer of cervix uteri, 464 cancer of larynx, 5 year results of, 554
- Roux Y. Use of in extending operability of carcinoma of stomach and of lower end of esophagus, 224
- Rubella. Theories of etiology of congenital deformities collective review, 1
- SACRUM. Internal fixation for lumbosacral fusion, 66 total and subtotal sacrococcygeal agenesis, 370
- Saliva. Lytic action of on gastric mucin from patients with ulcer in relation to pathogenesis of gastric ulcer, 146
- Salivary gland. Tumors originating in, 18
- Salt. Alimbral balance during brief starvation effect on serum electrolytes and mineral balance of maintaining intake of certain mineral constituents, 279 significance of urine chloride determination in detection and treatment of dehydration with depletion of, 451
- Sarcoidosis. Pathology of pulmonary fibrosis, including chronic pulmonary, 461
- Sarcoma. Osteogenic, of kidney, 53 primary of esophagus, 466 prognosis of of choroid, 486 mesenchymal nephroma in adults, 523
- Schistosomiasis. Infection treatment of esophageal varices due to Manson's preliminary report, 405
- Sciatica. Diagnostic puncture of intervertebral discs in sciatica, 212 caused by herniation of intervertebral disc late results of operation in 115 cases, 371
- Scoliosis. Treatment of severe resection of spinal column, 536
- Scopolamine, Pethidine and, in labor, 520
- Screening test. Use of vaginal smear as, 234
- Secale cornutum. Experiences with new semusynthetic alkaloid of in obstetrics and gynecology, 516
- Sex. Diagnosis of during pregnancy, 428
- Shock. Obstetrical, and pituitary ischemia, 49 death from inhibition and its relation to, 100 hyperthermia in association with, 278 biologic studies of surgical paroxysmal arterial hypertension following any tissue trauma is due to adrenalin secretion by suprarenal gland, 471
- Shoemaker Billroth I operation. Gastric resection, 506
- Shoulder. Neuritic amyotrophy syndrome of girdle of 65 consecutive surgical treatment of painful syndrome caused by anomalous joint, 66 statistical considerations of 337 dislocations of including posterior luxations and nerve complications, 259 fracture subluxations of, 259 calcifying tendinitis of, 363
- Sigmoid colon. Megacolon clinical and surgical considerations in 36 cases, 39
- Silicosis. Some considerations of roentgen diagnosis of and conditions that may simulate it, 185
- Silver carbonate. Application of stain of for diagnosis of uterine cancer by vaginal smear method, 233
- Sinuses. Tumors of nose and, 328 roentgen ray examination of paranasal, with particular reference to frontal, 458 osteoma of frontal and ethmoid, 487
- Skeleton. Roentgen diagnosis of rickets associated with other diseases of in infants and children, 186 lesions of, in leucemia, 187
- Skin. Operative technique for umbilical hernia utilizing grafting of, 32 pigmented precancerous and cancerous changes in, 88 calcifying epitheliomas of (type Malherbe) 191 spreading ulceration of associated with idiopathic ulcerative colitis, 226 contribution to radiological study of simultaneous manifestations of and bone in legs, 378 decade of experience with pleurocent genotherapy in tumors of and mucosa, 379 effects of various amino acids on peripheral blood flow and temperature of, 381 lesions of, due to pitch and tar, 468 acanthosis nigricans and plastic surgery, 469 on transmission through of visible and ultra violet radiation, 556 subcutaneous transplantation of, 562
- Small intestine. Urea clearance by perfusion of intact, 531
- Smears. Special methods for diagnosis of tumors in laboratory, 87 use of vaginal as screening test, 234
- Smith-Petersen operation. Osteotomy of spinal column, 366
- Sodium. Effectiveness of various diuretic agents in causing excretion of in pregnant women, 158
- Sodium alginate. Toxicity of in cats, 286
- Spasm and fibrosis of sphincter and due to reflex action, 39
- Spectacles. Green, prescribed in glaucoma, 306
- Spermatozoa. Roentgenologic changes in urinary bladder and distal portion of ureters in, 79
- Sphincter and Spasm and fibrosis of due to reflex action, 39
- Spinal cord. Case of vertebral hemangioma with paraplegia, 22 contribution to knowledge of conus and filum terminale, 21 diagnostic puncture of intervertebral discs in sciatica, 212 bladder in injuries of, 211 lumbar herniations of nucleus pulposus analysis of 106 operative cases, 33 cysts of sacral roots, 368 discussion on rupture of intervertebral disc in cervical region, 198 surgical experiences with extramedullary tumors of, 464
- Spine. Internal fixation for lumbosacral fusion, 66 experimental intervertebral-disc lesions, 70 anomalies of in anomalies of viscera and constitution, 80 roentgen diagnostic points of view on tumors of in children, 80, vacuum intervertebral discs, 80, chronic lesions of vertebral column and accidents of work, 202 value of faradocutanous sign of hyperaesthesia about the paravertebral region, 203 2 cases of vertebrae chumosa of apparently primary origin, 260 lumbar herniations of nucleus pulposus analysis of 90 operative cases, 331 anatomical studies on lumbar disc degeneration, 364 osteotomy of vertebral column, Smith-Petersen operation, 366 total and subtotal sacrococcygeal agenesis, 370 in radiological appearance of (and skeleton) always diagnostic of osseous metastasis from cancer of prostate (and from other cancers), 457 criteria for fusion of following removal of protruded nucleus pulposus, 448 treatment of severe scoliosis resection of, 536
- Splanchicectomy. End results of unilateral for hypotonic conditions of bile ducts, 41
- Spleen. Tumors of and pseudotumors of, 231 panhematopenia of, 420 adult Gaucher's disease, with special reference to variations in its clinical course and value of splenic puncture as aid to diagnosis, 557
- Splenectomy. When is it indicated, 420
- Spondylolisthesis. Chronic lesions of vertebral column and accidents of work, 262 as complication of childbirth, 519

- Spondyloids, Chronic lesions of cervical column and accidents of, 26
- Spur, Juxtaosseous insufficiency relation to syndrome, 508
- Staphylococci, Phegmonous gastritis due to partial gastrectomy massive sacral ulcer caused by postoperative pyemia, failure of penicillin therapy 339
- Starvation, Mineral balance during brief effect on serum electrolytes and mineral balance of maintaining vital of certain mineral constituents, 279
- Stellate ganglion, Effects of novocainization of contra lateral, on pain in limbs and amputation stump, 26
- Sterility, Pregnancies after treatment, of long standing, 24 comparative physiology of fertilization and application to study of in man, 353 on female, due to congenital obliteration of abdominal aperture of tube surgical intervention subsequent pregnancy 415
- Sterilization, Restorative operation follow-up, 157 review of problems of air contamination in operating rooms and of diverse procedures of air 47
- Stomach, Chemoablation (new) recognizing acute spontaneous dilatation of 33 study of gastric mucosa in various diseases affecting upper part of gastrointestinal tract 33 accessory pancreas posing as benign tumor of 4 Juxtaesophageal intussusception, a rare complication of operation, 78 lytic action of alkali on gastric mucosa from patients with ulcer in relation to pathogenesis of gastric ulcer 46 ill criteria of report of 26 new cases, 1 nocturnal gastric secretion studies on normal subjects and on patients with duodenal ulcer gastric ulcer and gastric carcinoma, 3 results following subtotal gastrectomy for duodenal and gastric ulcer 24 case of Roux's Y in extending operability of carcinoma of and of lower end of esophagus 24 acicular malformations and acicular tumors of gastrointestinal tract colic review 48 gastric mucosa after agotomy for peptic ulcer gastroscopic study 538 clinical considerations of mesial gastroduodenal hemorrhages, 340 agtonic gastric colic stimulating perforated gastric ulcer 407 surgical treatment of peptic ulcer 408 surgical treatment of ulcer 400 gastric polyps adenoma, 4 end-to-end anastomosis after gastrectomy technique of suture following hemicolectomy, 4 1 follow-up of agotomy plus gastroenterostomy or pyloroplasty for ulcer 504 gastric resection Schoemaker Billroth, I operation 506 appraisal of patients after resection of during war 506 pyloric stenosis caused by ingestion of coralline substances report of case, 507 tuberculosis of, and duodenum, 55 tumors of upper third of 55 gastroscopic picture in posttraumatic gastritis 354
- Stratigraphy General theory of 369
- Streptococci, Suppurative fascitis as essential feature of hemolytic gangrene due to, 373
- Streptomyces, Dermatitis in horses due to, 84, intra-treous, toxicity and diffusion, 204 in surgical infections Infections of soft tissues, 266 penicillin, dicummaril, and, and blood coagulation thromboplastic properties 1 penicillin, 280 experimental study of toxic effects of on cellular apparatus of cat central nervous system, 393 rhinoceroses apparently cured with, 393 in surgical infection lung abscess and empyema, 403 in treatment of chronic infections of bone, 338 treatment of pulmonary tuberculosis with 358

- Tuberculosis, Chronic hypertrophic stenosing (pseudotumoral) of ileum, 37 genital, in female, 46 radical operative treatment of hip involved by, report of 113 cases, 66 experimental studies of ocular failure of penicillin to affect course of experimental ocular preoperative bronchoscopy in lobectomy for, 136 in children, 256 anatomoclinical study of 5 cases of priapism of striated muscles, 305 is present or not histologic examination or inoculation, 383 laryngeal oblique, 395 renal, in child, 433 significance of calcareous glands due to, in abdomen in relation to urinary tract, 531 short review of methods and results in management of bone and joint, in Novaggio Military Hospital during last 10 years, 538 of stomach and duodenum, 551 streptomycin treatment of pulmonary 558
- Tumors, Pseudocystic bladder 57 treatment of bladder of small intestine, 148 indications in laboratory 87, surgery of bone, 173 voluminous myeloplaxic, of tendon sheaths of ankle with secondary osseous lesions, 177 roentgen therapy of malignant, of testis, 183, removal of orbital, through inferior route with Kuhn

Symptomatic repair of ectopic, 105 differential diagnosis of at cerebellopontine recess, 20, contribution 1. Knowledge of corpus and filum teres, 20, 21 of spleen and pseudotumors of spleen, 23, 24 of ovary 11th report of 15 cases and review of literature, 23 contribution to study of ectopic chorio-epithelioma, 21 pleurocystic/therapy of bladder, 245 tendency toward conservatism in removal and subsequent repair, 11 surgery of bone, of articular extremities 1 knee joint, 57 some considerations in treatment of hemangioma in infants and young children, 269, radiation therapy of malignant of testis, 272; acicular malformations and vascular 1 gastrointestinal tract collect review 281; of nose and sinuses, 323 recurrent epithelioma of lip, 320 trial classification of malignant thyroid, 320 breast, 11b local malignancy (plant fibrosarcoma, so-called phyllodes adenomas and recurring adenomas), 324 cytology of neoplasms of female genital system before and after radiation treatment, studied by apposition method, 347; 8 observations of bilateral bite of knee, 365 diagnosis of suprasellar by pneumoencephalography 378, decade of experience with pleurocystic/therapy 11, of skin and mucosa, 379 discussion of multiple, 383 clinical and histological considerations of liposarcoma, 383 of lower lip 390 esophagojejunostomy and esophagogastronomy in isopericardic, of esophagus and cardia, 410 correlation study of adenocarcinoma and pelvic endometriosis, with special reference to hormonal reaction of ectopic endometrium, 4 treatment of inflammation of adnexa by Douglas puncture and colpocystomy 420 malignant of testes, 439 irradiation of pituitary 460 energy mechanisms in malignant in relation to chemotherapy 470 attempts at production of experimental by injection of thorax 47 pneumographic study of temporal horn, 11b special reference to, 12 temporal region, 49 surgical experiences with extra medullary of spinal cord, 494 primary rib, 495 management of pulmonary coin lesion, 497 benign polypoid, of esophagus, 502 Brenner with predominance of muciniferous and granulocytic elements, 54, paraganglioma, 5 mesodermal nephroma in adults, 53, of bladder with particular attention to their clinical classification and prognosis, 52 of upper third of stomach, 55 case of desmoid, in unusual location, 560 chondromyxoid fibroma of bone distinctive benign tumor likely to be mistaken especially for chondrosarcoma, 560

ULCER. Surgery of duodenal, 36 chronic colitis 11b, 37, surgical treatment of colitis with, 38 lytic action of saliva on gastric mucin 10m patients 11b, in relation to pathogenesis of gastric, 46 relation of pancreatic secretion to formation of peptic effect of pancreatic tomy ligation of pancreatic ducts, and diabetes on production of histamine-induced, 12 dog, 246, present day therapy of thrombolysis (streptococcal) coils, 51 colectomy in colitis 11b 5 neurohumoral aspects of formation of peptic, 51b synthetic resin new antacid for treatment of peptic, 2 penicillin in postoperative treatment of peptic, with perforation and appendicitis 11b perforation, 23 nocturnal gastric secretion studies on normal subjects and on patients with duodenal, and gastric, and gastric carcinoma, 3 indications for emergency operation in severe hemorrhage from gastric or duodenal, 241 results following subtotal gastrectomy for duodenal and gastric, 241 spreading of ulcers associated with idiopathic colitis 11b 26 gastric mucosa after vagot-

omy for peptic gastroscopic study 328, clinical considerations of massive gastroduodenal hemorrhage, 340 atrophic gastric ulcer bleeding perforated gastric, 407 gastrojejunal chemical features and late results, 408 surgical treatment of peptic 408, surgical treatment of, 409, duodenal follow-up study of 305 1 tumor discharged because of, 4 2 1 lactical deslites, 468, follow-up of gastrectomy plus gastroenterostomy or pyloroplasty for 504 management of nasal artery bleeding peptic, 5041 prognosis and treatment of massive hemorrhage from gastric and duodenal, 505 considerations on pyloric stenosis for gastroduodenal perforations, 505 appraisal of patients after gastric resection during 1st 506 chronic leg, in diseases involving blood, 543

Ulna. Resection of lower extremity of, 365

Ultra. Islet radiation, On transmission through skin of 11b and 356

Umbilical cord. Short or shortened, as indication for cesarean section and other obstetrical operations, 39

Urethra. Cancer of 33

Urea. Clearance of by perfusion of intact small intestine, 35

Uremia. Clinical considerations of problem of extracorporeal excretion peritoneal lavage, 90 dialysis of blood for treatment of, 248

Ureter. Ectopia of 35 retroca 11, 56 ureteropelvic obstructions, 56, roentgenologic changes in urinary bladder and distal portion of, in spermatocystitis, 79 injury of from gunshot wounds, 103 carcinoma of 64, experimental contribution to implantation of, lat rectum according to Berghem's technique, 64, fistulous affection of 243 ureterocutaneous transposition, 244 malformation of bladder and, in genital prolapse, 340 wounds caused by firearm, 354, surgical intervention in calculi of 433 transplantation of, into rectum and cystostomy 453 late results of surgical and non-surgical treatment of calculi of, studied with excretion urography 526

Ureterogastrostomy. Indications and immediate and remote results of, 64

Urethra. Stress incontinence, 44, construction of glandular, in hypospadias, 58 congenital diverticulum of anterior 58, treatment of stenosing and inflammatory fistulous perurethritis (strictures with fistula formation), sequelae of acute recurring perurethritis by urethrectomy and external perineostomy 58, roentgen therapy of carcinoma of female, and 11 4, 273 importance of information furnished by preoperative urography and results of urethrectomy on immediate repair of, in course of diffuse perineal plegma, 556 deformities of male, 435 also of immediate urography and immediate reconstruction of over support in traumatic ruptures of membranaceous and perineal, 435 management of injuries of 529, should operate on urethral structure, 529 observations on hypospadias, 53 congenital alular formations in, 553

Urinary tract. Stress incontinence, 44, stress incontinence in female, 46- ureteral ectopia, 55 retroca 11 ureter 56 ureteropelvic obstructions, 56 treatment of stenosing and inflammatory fistulous perurethritis (strictures with fistula formation), sequelae of acute recurring perurethritis by urethrectomy and extensive perineostomy 58, dissociation of urinary calculi, 61 fundamental operative methods of repair of urinary fistulas in women, 57- indications and immediate and remote results of ureterogastrostomy, 64 experimental contribution to implantation of ureters lat rectum according to Berghem's technique, 64, re-percussion of vesical neck by cystoscopy, above incision,

- 165 resin artificial kidney 192 complications in of surgery of left colon 227 urokinography, 243 ureterocutaneous transplantation, 244 artificial kidney clinical application in treatment of traumatic anuria, 248 wounds of ureter caused by firearms, 354 operation for excessive bladder hypertrophy 355 importation of information furnished by preoperative urethrography and results of urethrotomy on immediate repair of urethra in course of diffuse perineal phlegmon, 356 effects of rate of administration of amino acid preparations on wastage in, of amino acid nitrogen in man, 381 ureterocystostomy incident to cesarean fibroma developing retrocavitally in, rare form of absence of 1 kidney 431 surgery of upper 434 deformities of male urethra, 435 value of immediate urethrography and immediate reconstruction of urethra over support in traumatic ruptures of membranous and perineal urethra, 435 transurethral resection in childhood 436 genitourinary injuries, 439, spontaneous rupture of bladder 527 management of injuries of urethra, 529 should we operate on urethral stricture, 529, congenital absence of penis, 529 diptheritic cystitis and urethritis following prostatectomy 530 significance of calcareous tuberculous glands in abdomen in relation to, 531 cancer of urachus, 532 our experiences with peridural anesthesia, 548
- Urine, True bacterial pyuria, 532
- Urography Late results of surgical and nonsurgical treatment of ureteral calculi studied by means of excretion, 526
- Uterine tubes, Results of operation for restoration of patency of 345 concerning symptom of hydrops tubae profluenta and significance in recognition of primary carcinoma of, 424 treatment of blocked, by pressure in due to congenital obliteration of abdominal aperture of surgical intervention subsequent pregnancy 425 study of uterine cavity and of permeability in fetus by method of hysterosalpingography 517
- Uterus, Rupture of with extraperitoneal, mediastinal and subcutaneous emphysema, 43 changing concepts in cervical biopsy 43 menorrhagic remnants in cervix 43 carcinoma of cervix, 43 Labhardt operation in obstetrical sequelae of ligamentotomy by Doleris Pellanda technique 53 primary dysplastic involving myofibroblasts of 154 technique of radium therapy for cancer of cervix of 154 reticuloplasmosis of cervix of, 155 methods of management and results in primary inertia of 160 contribution to study of glutination of cervix of 161 application of silver carbo-nate stain for diagnosis of cancer of by vaginal smear method, 233 dysfunctional hemorrhage of vaginal prolapse of vaginal parietes and of etiology, pathological clinic of University of Turin, 235 contribution to study of neoplastic utero-ovarian association in women with fibromyomas of 345 fibromyoma of during pregnancy and in puerperium, 433 relations between development of carcinoma and colposcopically demonstrated atypical epithelium of portio, 422 prob-lem of early diagnosis of cancer of body of and cervix, 423 cancer of cervix of 464 age, incidence, and distribution of 463 cases of carcinoma of cervix, 513 study of cavity of and of tubal permeability, 513 by method of hysterosalpingography 517 precision dom-age used in interstitial irradiation of cancer of cervix of 555
- Uvula, Structure function and importance of 209
- VAGINA Rare indication for cesarean section thrombotic varicosities in 49 autodegeneration of present status of problem and its possible development biologic significance of lysozyme in the vaginal secretions, 156 emphysematous of 156, abdominal colpocysto-pexy for complete prolapse of and bladder 156 pri-prolapse of parietes of and of uterus etiology, pathogenesis, and treatment with report of cases from ob-stetrical clinic of University of Turin, 235 influence of gonadotropic hormones on biology of physiologic bases, 345 influence of gonadotropic hormones on bi-ology of pathology and therapy 346 fibromyomas of, 346 report of 5 cases operated upon for vesicovaginal fistulas, complicated in 1 case by functional urinary incontinence, 426 gynatresia 3 uncommon clinical types, 514 cleavage planes in reconstructive plastic surgery of 515
- Vagotomy Gastric mucosa after vagotomy for peptic ulcer gastrocystic study 338 response to in idiopathic ulcerative colitis and regional enteritis, 414
- Varices, Injection treatment of esophageal due to Man-son's schistosomiasis preliminary report 405 dis-cussion on primary treatment of 440
- Veins, Obstruction of in upper extremity (Paget Schroet-ter's syndrome) collective review 89 phlebography in localization of incompetent communicating, in pa-tients with varicose, 178 experimental portacaval anastomosis, 179 surgery of arterial injuries and prob-lem of transplantation of 373 discussion on primary treatment of varicose, 449 anatomy pertaining to pararenal, 523
- Vena cava, Injury of during nephrectomy 433
- Viscera, Anomalies of spine in anomalies of and constitu-tion 80
- Vitamins, Hypervitaminosis A report of 2 cases in infants, 466
- Vocal cord Open approach to arytenoidectomy for bilateral abductor paralysis, with report of 23 cases, 489
- Volkman's disease, Discussion of physiotherapy of paw in experimental study of contracture provoked by means of intra-arterial injection of organic iodine product, 176
- Volvulus, Of transverse colon, 415 of cecum, 414 certain considerations of acute, of cecum, 414
- Vulva, Aspects in treatment of carcinoma of cervix and 233 roentgen therapy of carcinoma of female urethra and, 273
- WAR, Eighty-seven abdominal wounds due to 42 numerous tetanus cases during last phase of and their treatment with antitoxin (tetanus-formol-toxoid) 182 blast injuries of ears, 206 visual protection in aerial 344, wounds of ureter caused by firearms, 354 pigment nephropathy in battle casualties, 469 follow-up study of men with penetrating injury to brain, 491 battle wounds and injuries of heart and pericardium, 499 appraisal of patients after gastric resection during 506
- Waris, Simultaneous evolution and involution of breast carcinoma and, of mammary region, 496
- Water Permeability of human placenta to and supply of to human fetus as determined by means of deuterium oxide, 521
- Whipple's disease, Case of Intestinal lipodystrophy simu-lating Boeck's sarcoid, 225
- Wilms' tumor 55

INTERNATIONAL ABSTRACTS OF SURGERY

Wire, Stainless steel, for abdominal incisions and hernias, 43
 Wounds, Eighty-seven abdominal war 4 injury of rete
 from gunshot, 163 of common carotid arteries, report
 of 17 cases from World War II, 78 battle wounds
 and injuries of heart and pericardium, 499
 Wrist, Observations and experiences with tenoplasties for
 improvement of function in drop of 69 corrective

osteotomy and capsulectomy in treatment of mal-
 union of metacarpal fractures, 537 primary tendon re-
 pair 545

XANTHOMA, Benign giant-cell synovialoma and its rela-
 tion to "xanthoma," 383
 Xeroderma pigmentosum with affection of eye, 15

graphy the authors summarize the technical disadvantages of the practice as follows:

While angiography offers fine visualization of the right chambers of the heart and the pulmonary artery, after the medium passes through the pulmonary section of the circulation the dilution increases to such an extent that visualization of the left chambers and of the aorta is incomplete. This particularly complicates the diagnosis of patent ductus arteriosus because when the opacity of the medium has reached its maximum in the aorta there is still so much opaque substance left in the pulmonary vessels that the outlines of the aorta become difficult to distinguish, and for this reason a communication between the pulmonary artery and the aorta becomes impossible to localize.

In a previous article in the same journal the authors have described their technique for thoracic aortography by catheterization from the right radial artery. In the present article they illustrate and describe 3 cases of patent ductus arteriosus accurately visualized preoperatively by this technique. They express the opinion that thoracic aortography is more helpful than angiocardiology and hope to develop the technique so as to render possible an accurate determination of the length and width of the ductus preoperatively.

JAMES C. MACMILLAN, M.D.

Visualization of the Coronary Arteries. GUNNAR JOHNSON. *Acta radiol. Stockh.* 94B, 50, 150.

In order to study the great vessels of the upper thorax in patients with such conditions as patent ductus arteriosus, at the Södersjukhuset Clinic and the Sabbatsberg's Hospital in Stockholm, Sweden, the author used the method of thoracic aortography through catheterization of the radial artery as described by Radner and by Brodén, Hansson, and Karnell in 1948. An incidental finding in 5 of the patients was visualization of one or both coronary arteries. The films of 3 of these patients, aged 27, 46, and 33 years respectively, are reproduced chiefly in lateral view and show the coronary arteries clearly over a large extent of their main channels. No untoward symptoms resulted from the injection and the electrocardiogram in each case had the same appearance before and after the roentgen examination.

The author points out that in order to get opaque substance into the coronary arteries in adequate concentration for visualization the injection should be done with the catheter inserted far down in the ascending aorta, preferably with the tip resting near the semilunar valves. The latter were well visualized in all 5 cases.

LILIAN DONALDSON, M.D.

Cancer of the Larynx. Five-Year Results of Radiotherapy. MAX CUTLER. *Radiology* 94B, 5, 500.

The efficiency of radiation therapy was studied in 107 consecutive cases of cancer of the larynx.

In recent years there has been a trend in some institutions to treat early laryngeal carcinoma by rad-

iation therapy with a 5 year survival rate of from 50 per cent (Blady and Chamberlain) to 85 per cent (Kramer).

A plea is made for a more careful anatomical classification of tumors. The use of intrinsic and extrinsic lesions leads to confusion.

In all cases, a total dose of from 6,000 to 7,000 roentgens is given in an 18 day period. Early lesions are given 100 roentgens twice daily which are gradually raised to 150 roentgens. More extensive lesions are given 85 roentgens twice daily which are gradually raised to 275 roentgens. In both instances, there is a gradual diminution of the portal size with an intensity rate of 6 to 7 roentgens per minute at a tube target distance of from 75 to 110 cm.

Of the group of 107 unselected cases, more than half were inoperable and the 5 year cure rate was 35 per cent. In this group the 5 year cures of operable cases was 53 per cent and in early operable lesions 60 per cent, whereas in inoperable lesions it was 20 per cent.

The author is of the opinion that radiotherapy is indicated when the cords are freely movable or partly fixed. Laryngectomy is indicated if there is fixation of the cords. With improvement in radiation technique as well as early diagnosis, the need for total laryngectomy should be diminished further.

MAURICE D. SACKS, M.D.

The Gastroscopic Picture in Postirradiation Gastritis. EMMET D. PALMER. *Am. J. Roentg.* 94B, 60, 360.

The author presents what is believed to be a new gastroscopic entity—postirradiation gastritis—as observed in 13 patients who were treated for malignant conditions while in the Armed Forces. The histopathological diagnosis in each case was as follows: retroperitoneal retrocolic sarcoma in 1 case; seminoma in 4 cases; malignant teratoma in 3 cases; and embryonal carcinoma of the testis in 1 case.

Radiation therapy was given with factors of 1,000 kilovolts, 3.6 mm. lead, 3 milliamperes, 70 cm. distance through five portals constant in size and position in all patients. The gastric area was included in two of these portals—a 10 by 10 cm. epigastric portal and a 10 by 15 cm. lumbodorsal portal. The total skin dose to each field varied from 4,800 to 5,600 roentgens given over a period of 49 to 76 days in 13 patients and from 2,400 to 3,800 roentgens administered over a period of 3 to 55 days in 2 patients.

Only those areas of the stomach which had been directly in the path of roentgen irradiation showed changes demonstrable by endoscopy. These relatively constant and characteristic gastric changes consisted of marked edema with tubular deformity and fixation of the antrum, similar fixed patulousness of the pylorus, and clean deep chronic ulcers which healed without contracture. Pathologic and roentgenographic studies in general corroborated the gastroscopic findings.

The radiation dosages used in 11 of these patients were from two to three times that believed necessary

(by most therapists) to destroy lymph node metastasis from such radiosensitive tumors. In fact, the findings are those which might be anticipated following such intensive irradiation of the gastric mucosa. The department of radiation therapy at this hospital has now succeeded in balancing the minimum effective dose against the maximum safe dose so effectively that the gastrointestinal section does not expect to see any more postirradiation gastritis.

JOHN H. FREED M.D.

Precision Dosage in Interstitial Irradiation of Cancer of the Cervix Uteri. JAMES A. CORSCADEN, S. B. GUSBERG and CHARLOTTE P. DONLAN. *Am J Roentg* 1948 60 522

The authors have devised an arrangement of needles to deliver adequate radiation to the cervix and the paracervical and lateral parametrium. Expressed in the terms of gamma roentgens it is commonly accepted that 7,000 gamma roentgens or more applied to a cancer cell will destroy it without severely injuring the normal tissues. With 15,000 gamma roentgens all tissues are destroyed and a slough is created. The problem thus in the treatment of carcinoma of the cervix is to deliver to all accessible regions a dose adequate to destroy cancer without causing excessive injury to the normal tissue. By the use of the precision stereoscope the location of the radium units can be accurately determined; the distances between them measured and the dose calculated. The authors learned that needles could be introduced with a considerable degree of accuracy into the positions previously planned. Therefore an arbitrary pattern was devised which delivers apparently adequate radiation to all points in the uterus and parametrium. In this pattern 3 mgm. tubes are placed end to end in the intrauterine tandem. About this tandem eight 3.2 cm. needles were placed in stockade fashion for a radius of 1.5 cm. One and a half centimeters lateral to this and 1 cm. apart two 3.2 cm. needles were placed parallel to the axis of the uterus in the sagittal plane. One and a half centimeters lateral to these or 4.5 cm. from the cervical canal five 6 cm. needles were placed parallel to the pelvic wall 1 cm. apart. With this pattern 21,010.8 gamma roentgens will be delivered to the cervical mass. To the paracervical region 14,346.7 gamma roentgens will be delivered and to the lateral parametrium near the pelvic wall 10,803.1 gamma roentgens will be delivered. It was found that the needles could be placed with considerable accuracy through a vagina which was not greatly deformed. The precision stereoscope is used to determine the distribution of the radium and the dose of radiation received by the tissues is calculated. Deficiencies in dosage may be determined and corrected.

The principal objection to the method is that it is blind and that radium needles are likely to injure the intestines, bladder and ureter. It requires precise knowledge of the anatomy of the pelvis, some degree of surgical dexterity and a knowledge of the

Fig. 1 (Corscaden et al.) Diagram to show arrangement of needles to deliver apparently adequate radiation to the cervix, the paracervical region, and the lateral parametrium. Cervical mass—11,010.8 r. Lateral pelvic wall at W—10,803.1 r. Paracervical area at P—14,346.7 r.

principles of irradiation technique. Clinical results are not presented in detail. All of the patients treated by this method had extensive involvement of the parametrium and were classified as being in stage 3 (League of Nations). The immediate results in the use of this method are striking and unmistakably superior to those following the use of intracavitary technique.

FRANK L. HURSEY M.D.

Rubber Cassette with Intensifying Screens Designed for Roentgen Examination of Operatively Exposed Organs. OLLE OLSSON. *Acta radiol* Stockh. 1948 30: 91

Although the roentgenologic examination of the kidney at the time of operation is not a new procedure the attention of the reader is directed to a refinement of the procedure involving the adaptation of intensifying screens in a film package to be used at the time of nephrotomy. In this manner definite x-ray assistance can be obtained in the removal of renal calculi and fragments of calculi.

The author has devised a cassette consisting simply of a flat rubber bag provided with an air withdrawal spout. The screens used are of the type designed for industrial use; they are supplied in standard sizes and are characterized by the fact that the fluorescent coating has been applied to a flexible material. The cassette can be sterilized along with the other rubber articles used at operation. An assistant with sterile gloves loads the cassette in the dark room of the operating department and the mouth of the cassette is closed with a single pair of resection

Fig. (Olsson) Cassegrain telescope and air withdrawn. Illustration shows flexibility of the cassette

tongs which serve as handles for introducing the cassette into the operative field and holding it during exposure (Fig. 1)

Directors of the Surgery Clinic in Lund Sweden believe that the x ray study of the cases with calculi should include

1. Plain roentgenograms of the urinary tract with excretion urography
2. In almost all cases a roentgenogram made just before the operation to check the position of the calculi prior to operation.
3. A roentgenogram of the exposed kidney in every case at least before the termination of the operation.
4. Complete roentgenological examination including excretion urography before the patient is discharged from the hospital

JAMES C. MACMILLAN, M.D.

On the Transmission Through Skin of Visible and Ultraviolet Radiation. G. HANSEN. *Acta radiol. Stockh.*, 948, Supp. 7

The purpose of this study was to determine by measuring the absorption of radiation by mouse and human skin in vivo and in vitro whether any specific biological effect can be attributed to any wavelength between 500 μ and 300 μ

In chapter I a short account is given of the normal histology of mouse and human skin and the difference in structure between these two types of skin. Chapter II is devoted to a review of the earlier important experimental work done by other authors in this field with a discussion of their methods and results. In chapter III the more commonly used sources of ultraviolet radiation, such as carbon arc lamps and mercury arc lamps, are tested. The Philipp a super high-pressure mercury arc lamp was finally chosen as the best source of ultraviolet radiation for this absorption study because of its relatively constant supply of ultraviolet rays (when cooled with distilled water) which gave a quasi-continuous spectrum.

The author gives an account of the method of measurement employed in determining the degree of transmission of glass and liquid filters for different wave lengths. In the next chapter the photographic method of determining the degree of transmission with either filtered or spectrally resolved radiation together with the possible sources of error are discussed and the apparatus used in this study is described and illustrated.

Chapter V gives a short account of the method used in preparing frozen sections and microscopic mounts from skin. Although it is shown by experiments on mouse skin that the degree of transmission is changed markedly during storage, nevertheless the main course of the transmission curve may for all practical purposes be regarded as independent of the method of storage. Within the wave length region between 500 μ and 300 μ the course of the transmission curve is the same for live mouse skin and for skin excised shortly after death. All transmission curves show a minimum at 415 μ which is attributed primarily to the presence of hemoglobin and perhaps also to cytochrome and myoglobin which are all present in the preparations used and have a characteristic absorption-band at 415 μ . A series of transmission curves is reproduced for a large number of layers of mouse and human skin.

The results of the investigation show that the transmission of radiation through skin, both (depilated) mouse skin and human skin of both types of different layers (frozen sections) of both types of skin, decreases uniformly with the wave length from 500 μ to 300 μ . Apart from the absorption of the various layers of skin do not disclose any characteristic features as regards the absorption of radiation and there is nothing in the results of the measurements of transmission through skin, as per formed for the purpose of the present investigation, which indicates that there is any wave-length region between 500 μ and 300 μ to which a specific biological effect on skin tissue can be ascribed

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Adult Gaucher's Disease, with Special Reference to the Variations in Its Clinical Course and the Value of Sternal Puncture as an Aid to Its Diagnosis. J. GROFF and A. H. GARRER. *Blood* 1948 3 1221

Gaucher's disease is a rare often familial disease distinguished by the presence of characteristic cells in the organs of the reticuloendothelial system. The protoplasm of these cells has a typical cytologic appearance due to the presence of a special lipid the so-called Gaucher substance or kersin.

Helpful clinical signs are splenomegaly enlarged lymph glands peculiar yellow pigmentation which in some cases, develops on the face and in the conjunctivae in the form of wedge-shaped pingueculae characteristic pigmentation on the lower legs a peculiar malar flush and the occurrence of myopia.

The hematologic picture which is not necessarily diagnostic, consists of a hypochromic anemia with leukopenia and thrombopenia normal or low cholesterol of the blood and a hemorrhagic diathesis.

The roentgen examination may be useful in cases in which there are enough accumulated Gaucher cells in bones to produce macroscopic areas of bone destruction. The head and neck as well as the lower end of the femur may be involved.

Despite the presence of these signs the diagnosis may be difficult, and sternal puncture is of importance in the detection of the disease particularly in the detection of subclinical manifestations. Nine cases are reported in which the diagnosis suspected on clinical grounds was definitely established by the detection of the Gaucher cells in the smear of the sternal marrow.

The authors found a marked variability in the clinical picture. Usually the disease is progressive although there may be spontaneous remissions. The rate of progress varies and the patient is usually unaware of its early presence. The earlier the onset, the more rapid the course.

Although the spleen and the liver are the most prominently involved only rarely is the bone marrow spared in Gaucher's disease. Involvement of these organs however does not mean there will be evident roentgen changes. Rare sites of involvement are the lungs the kidneys and the brain. Complications are frequent and vary with the site of involvement. Splenectomy does not seem to alter the course of the disease and need only be done if the spleen itself gives rise to symptoms. Treatment with a purely vegetarian diet appeared to be just as unsatisfactory as splenectomy.

The authors believe that sternal puncture is the only method that will enable the clinician to establish a positive diagnosis of Gaucher's disease. The only

difficulty that may arise is that of differentiating the cells from the large cells that occur in Niemann Pick's disease however the protoplasm in the Gaucher cells is characterized by a fibrillar meshwork whereas the Niemann Pick cells have a foamy appearance. LE ROY J. KILINSKASKE, M.D.

South American Blastomycosis Associated with Hodgkin's Disease: Anatomoclinical Considerations on a Case (Blastomycose sul-americana associada à moléstia de Hodgkin. considerações anatomo-clínicas sobre um caso) CARLOS DA SILVA LACAZ, J. LOPES DE FARIA, and ROBERTO A. DE ALMEIDA MOURA. *Hospital, Rio* 1948 34 313.

A man of 34 in poor general condition had noted about a year before admission that he was developing some swellings in the neck which gradually became larger. Other swellings appeared in the axillary and inguinal regions and increased slowly in number and volume. From 1 to 2 months ago he began to have difficulty in speaking and swallowing because of some ulcerated lesions on the lower lip and on the gums. Painful mastication compelled him to take only liquid food. Examination disclosed ulcerations on the mucosa of the lower lip gums hard and soft palate and epiglottis. A diagnosis of Hodgkin's disease and of South American blastomycosis was made. He was treated with aminogenol transfusions and glucophysiologic serum and sulfadiazine. He died 10 months later and autopsy confirmed the diagnosis. The blastomycotic lesions involved the tonsils (productive lesion) the larynx (exudative-productive lesion with formation of pseudomembrane) and the liver while the lesions of Hodgkin's disease were found in the right lung the cervical axillary, inguinal lumbar and hepatohilar lymph nodes and the spleen.

It is difficult to determine exactly the port of entry of the *Paracoccidioides brasiliensis* in this case, but the authors believe that the initial lesions occurred in the tonsils. The exudative reaction is explained by the action of the parasite on a debilitated organism with low resistance. It resulted in the deposition of fibrin and the formation of a pseudomembrane. This type of pseudomembranous lesion has apparently not yet been reported in the blastomycosis in general, nor in South American blastomycosis in particular. This case emphasizes the necessity of histologic examination of the tonsils in South American blastomycosis even when they are macroscopically normal and atrophied. It is interesting to note that the lungs and the skin were free of infection.

No paracoccidioidic granuloma was found in the lymph nodes only lesions of Hodgkin's disease. This is also strange since the nodes should not have escaped invasion by the fungus which was probably disseminated by the hematogenous route to reach

intradermally. A positive reaction is manifested in from 6 to 12 hours by painful infiltration at the site of injection. The reaction was positive in 90 per cent of the cases.

2 The blood count shows anemia and eosinophilia from 5 to 15 per cent.

3 X-rays give most valuable help not only in demonstrating the cysts but also in giving information as to their size, location and number.

The most important complications are suppuration and rupture. Suppuration takes place through invasion by micro-organisms. This blood borne suppuration is often seen in cases with intercurrent diseases. The organisms are usually, staphylococci, streptococci, and colon bacilli. Rarely anaerobic bacteria are the causative agents. Rupture may be spontaneous or the result of puncture or trauma. It is a most serious complication with a clinical picture and course varying with the organs into which the rupture has taken place. A hydatid of the liver may rupture into the bile duct, abdominal cavity or pleura. A lung hydatid may perforate into the pleural cavity, pericardium or bronchus. Perforation into the vena cava and pulmonary artery have been reported. The great mortality is due to sepsis, anaphylactic shock, hemorrhage or asphyxia.

Treatment is surgical and consists of the removal of the parasitic cyst and drainage of the adventitious capsule, i.e. marsupialization. The procedure can be done under local anesthesia. Care must be taken to prevent the cyst fluid from escaping into the pleural or peritoneal cavity. The cyst is punctured and drained and then 10 c.c. of a 2 per cent formalin are injected into the cavity to destroy the hydatid elements. The cyst is then separated from the adventitious capsule and removed. The adventitious cavity must be thoroughly cleaned and dried. When the cyst is in the liver the adventitious cavity is then sutured with interrupted catgut sutures to the peritoneum and muscles of the abdominal wall. A small drainage tube is inserted. In the lung the adventitious cavity is thoroughly dried and cleaned and then closed with interrupted catgut sutures, the sutures being fixed to the thoracic wall. This fixation serves 2 purposes: (1) it secures the suture line against any opening and (2) it causes the formation of adhesions so that subsequent drainage, if necessary, can be done without danger to the pleural cavity.

Postoperative complications include anaphylactic shock, dispersion of the hydatid elements, hemorrhage and secondary infection. All are rare except the latter and that is readily controlled with penicillin.

REY ELLIOTT LAMAR, M.D.

Reiter's Disease. A Study of 344 Cases Observed in Finland. ILKARI PARONEN *Acta med. scand.* 1948, 137: Suppl. 312.

The author presents an excellent historical review of Reiter's disease with its various aspects and states that articular complications following dysentery were even known to Cassilius Aurelianus at the beginning of the fifth century. In connection with this

disease he discusses the history of arthritis urogenital involvement, lesions of the nervous system, cardiac involvement, the respiratory system, digestive system, and other lesions. He further considers fever, blood studies, pathoanatomical changes, treatment, diagnosis and differential diagnosis, prognosis, duration and recurrence and the etiology and pathogenesis of the disease.

On the basis of his review of the literature the author seeks an answer to the following questions:

1 What is the clinical picture and prognosis of Reiter's disease?

2 Does the available material throw additional light on its etiology and pathogenesis?

The author presents a series of 344 cases, the great majority of which are from the Defense Forces of Finland and were observed in 1943 and 1944.

In about 70 per cent of the cases the complete triad (articular, ocular and urethral manifestations) was present, about 25 per cent showed two of the essential symptoms and 5 per cent showed only one of them.

Articular manifestations were observed in 325 cases (97.3%) of which 316 (97.2%) were polyarthritic and only 9 cases (2.8%) were monoarthritic. The joints of the lower extremities were affected more frequently than those of the upper extremities or the vertebral column—the knee more frequently than the ankle joint. Besides the joints the muscles and tendons were sometimes involved.

Eye affections with conjunctivitis at the onset, occurred in 89 per cent of the cases, iritis (in 22 cases) and keratitis (in 27 cases) appeared later. The conjunctivitis was characterized by a deep cranberry red color and a velvety surface.

The urogenital organs were involved in 79.3 per cent of the cases, urethritis being the most common manifestation. Cystitis was present in 22 cases (10 of these unaccompanied by urethritis). Nephropathy was present in 9 patients, in 6 of whom it appeared in the form of a mild symptomatic nephrosis, pyelonephritis developed in 2 patients and nephritis in 1 patient. Penile lesions were present in 87 cases (10 of these unaccompanied by urethritis). The testes and epididymis were affected in 11 patients. In 6 of these there was only testicular pain and tenderness without noticeable swelling, but in 3 there developed a unilateral orchitis and epididymitis leading to swelling and induration. In 1 patient a bilateral epididymitis and in 1 a unilateral orchitis.

Dry circumscribed pleurisy was definitely diagnosed in 26 cases (7.8 per cent) and this diagnosis seemed very probable in 48 other cases.

Carditis was observed in 23 cases. In 4 of these there were symptoms and signs of myocarditis and 1 pericarditis. In 16 cases there was evidence of only myocarditis and in 3 cases only pericarditis.

Less common findings were stomatitis and rupia. In one man a bilateral mastitis developed and lasted for a period of 4 months.

Fever was present in 81.3 per cent of the patients. The duration of the fever varied from a period of one

by the periosteum and the overlying parosteal connective tissue. Along its inner surface the tumor was bordered by a smaller or larger zone of sclerosed and often distinctly grooved osseous tissue.

These various gross features found their reflection in the roentgenographic shadow to which they imparted a certain distinctiveness at least when the lesion was in a long bone and had attained appreciable size. However, even here and certainly when in other sites, the exclusion of bone cysts, enchondromas or of foci of fibrous dysplasia may be difficult on the basis of roentgenographic appearance alone.

The authors interpret the lesion to be a peculiarly differentiated connective tissue tumor which exhibits in the course of its evolution certain chondroid and also myxoid traits microscopically. It is composed basically of cells lying loosely in a myxoid intercellular matrix which as the tumor matures may undergo substantial collagenization. The tissue of any particular specimen may also come to simulate cartilage tumor tissue in some or many fields and in its gross appearance it likewise bears a certain resemblance to cartilage. The presence in the tumor tissue of smaller or larger numbers of cells exhibiting nuclear atypism may give an ominous appearance to the cytologic picture of the lesion, which explains why it may come to be misinterpreted as a malignant tumor particularly as a chondrosarcoma.

As indicated the tumor is apparently entirely benign and does not tend to recur after curettage even without supplementary irradiation. Thorough curettage of a large lesion may of course make filling of the bone defect with bone chips or a bone graft desirable.

DAVID H. LYNN, M.D.

The Definition of Inoperability of Cancer. GEORGE T. PACK. *Ann. Surg.*, 1948, 127, 1105

The greatest margin of error in reporting the end results of treatment for cancer may be found in the classification by the reporter of a regional or histologic type of cancer as operable or inoperable. Three factors interplay in the pronouncement of a given cancer as nonresectable by the surgeon: namely, (1) the condition of the patient as regards his age, the existence of degenerative diseases and the complications attendant on the presence of the cancer; (2) the extent of the disease; and (3) the philosophy, moral point of view, and the courage and experience of the surgeon.

The definition of inoperability has an important influence on end results. A distinction should be made between absolute inoperability due to distant dissemination of the cancer and obvious incurability and relative inoperability due to local technical difficulties. No surgeon should perform an exploratory operation unless he is qualified to proceed with the actual removal of the tumor if encountered. Old age should not be a contraindication in itself for surgical exploration. Palliative surgery is recommended when it promises relief even though cure is not technically possible.

Case reports are incorporated to illustrate the arguments presented including also the fact that some patients may be entitled to a second exploration. This may be in spite of the abandonment of a first operation and pronouncement of incurability by a former surgeon because of technical difficulties.

W. FOSTER BLOOMERY, M.D.

EXPERIMENTAL SURGERY

Identification of Pregnanolol in the Urine of 2 Subjects Having Gynecomastia; Its Value as a Test of Hyperfolliculinism in Man (Identification du prégnandiol dans les urines de deux sujets atteints de gynécomastie: sa valeur comme test d'hyperfolliculinisme chez l'homme). JACQUES DECOEUR, MAX F. JAYLE and J. M. DOUMIC. *Ann. endocr., Par.*, 1948, 9, 395.

From the clinical point of view the 2 subjects observed by the authors had developed gynecomastia after puberty. In the first who was 19 the swelling was moderate and seemed to be regressing; he had no other signs of feminism except some increase in the width of the pelvis. In the second who was 46 the swelling was more marked and associated with moderate adiposity of feminine character which had appeared after the age of 25; he showed a more marked degree of feminism. In both the genital organs were normal, the volume of the testes being even above the average. In the first subject the sella turcica was large without other signs of tumor or hyperfunction of the hypophysis.

From the chemical point of view the 17 ketosteroid rate was abnormally low in the first subject but without clinical signs of male hormone insufficiency it was normal in the second. The excess of phenolsteroids definite in the latter was found in only one of three determinations in the former. However in both the dominant biologic anomaly was represented by the appearance of large amounts of pregnanolol-glycuronate which was chemically identified in the second subject.

Comparison of the elimination of steroids in the 2 subjects with the average obtained in normal persons showed that (1) the hormonal elimination of gynecomastic individual is characterized by a change in the estrogen androgen relationship which rises by increase of the numerator or decrease of the denominator; (2) the ratio of total steroid glycuronates (pregnanolol glycuronate tenfold) toward one because of the appearance of pregnanolol glycuronate of 1/10th in normal subjects it is about four and the fraction, insoluble in acetone, may be considered as being formed by steroids thrown down in the precipitate and not by pregnanolol glycuronate.

The identification of pregnanolol glycuronate of sodium in the urine of man has not yet been mentioned in the endocrinologic literature. The fact that this substance was repeatedly found in subjects with hyperfolliculinism lends to it the value of a real biochemical symptom in this endocrine condition. As an explanation the authors advance the hypoth-

INTERNATIONAL ABSTRACTS OF SURGERY

sis of an anomaly of the intermediary metabolism of a steroid hormone deriving from allopregnane. In the normal subject, the latter would be converted into acetone soluble steroid glycuronate leaving in the urine only some practically unrecognizable traces of pregnandiol-glycuronate. The intervention of folliculine would modify this metabolism and cause the appearance in the urine of sufficient pregnandiol glycuronate to make it possible to isolate, identify and determine the amount of the substance. Inverse ly the fraction soluble in acetone decreases and the ratio of total steroid-glycuronates to pregnandiol glycuronate tends toward one.

From the double clinical and biologic point of view gynecomastia and the other minor anomalies observed in the 2 subjects seem to be less the expression of an insufficiency of their male sexuality than of a sort of bisexuality by the addition of hormonal secretions of a female nature.

RICHARD KROCK, M.D.

Th Subcutaneous Transplantation of Skin. STEUART GORDON. *Brit J Plast Surg* 948, 3

Many surgeons have implanted skin into the subcutaneous tissues with varying results. A brief outline is given of the experimental and clinical work that has been done including the work of Peet and Paddock, Zimches and Wasiljew, Maur Harkins, and others. The conclusions seemed to be that

burned cuts grafts (1) heal rapidly and well (2) have great vitality (3) are able to survive under adverse conditions (4) develop a good blood supply (5) gradually assume the function of the parts replaced and (6) are readily available. Conflicting reports indicate cyst formation due to inclusion of the epidermis.

To clarify his own ideas the author experimented with rabbits using thick split-skin grafts and dermis. To obtain the dermis, 65/1000 cm. grafts were taken with a dermatome and, with the graft still on the drum 20/1000 cm. of the epidermis was removed. Lumbodorsal fascia was replaced on one side of the rabbit with a thick split-skin graft, and on the other side with a dermis graft, in one series. Burned bits of skin and buried bits of diced dermis were used in a second series. Dermis was used in a fourth experiment, dermis was frozen on dry ice and rapidly thawed in warm hypotonic salt solution. This procedure was repeated three times freezing the graft each time until it was boardlike.

The conclusions reached were that the burying of autogenous skin or dermis in the rabbit will result in cyst formation in from one fifth to one-third of the number done that the use of dermis alone reduces the incidence of cyst formation about one-half and that the use of treated (frozen) dermis may pre cat cyst formation.

- Aurocyanin, 376 454
- BACK, Lateral fixation for lumbo-sacral lesion, 66**
- Bacteriologic, Demonstration of lysocyme in amniotic fluid, regarding power of amniotic fluid as a, 24
- Barium, Interoesophagus in children, diagnosis and therapy with omeal, 4
- Bartholin's, Treatment of chronic; new treatment procedures; their superiority over chemical therapy; question of recurrence, 485
- Bed sores, Ischial decubitus ulcer 468
- Beta-glucuronidase, Levels of, in serum during toxemia of pregnancy 158
- Beta irradiation in glaucoma, 206
- Biceps brachii, Rupture of, with report of case of bilateral rupture of long tendons, 336
- Bile, Quantitative and qualitative control of flow of and relation to biliary tract surgery 417
- Bile ducts, End results of unilateral splanchnicectomy for hypotonic conditions of, 411; conservative therapy of residual calculi following operations on common, 130; operative cholangiography 341; hepatic duct syndrome, 34; reconstruction of, 417
- Bilharziasis, Affecting of ureter 243
- Biliary tract, Experimental repair of common duct defects utilizing free vein graft over Blakemore-Lord tubes, 30; conservative therapy of residual calculi following operations on common bile duct, 30; operative diagnosis of indurations of duodeno-pancreas, 390; acute pancreatitis: critical analysis of 15 cases, 231; experimental peritonitis due to, 37; anatomopathologic and functional changes in biliary system following cholecystectomy, 340; acute torsion of gall bladder 34; hepatic duct syndrome, 34; strictures of common duct, 34; use of defunctionalized loop of jejunum in surgery of pancreas and, 413; external choledochoduodenostomy 4, 6, quantitative and qualitative control of bile flow and relation to surgery of, 417; reconstruction of bile ducts, 47; 4 years after reconstruction of common duct with rubber tube, 418; late results following surgery of 418; chronic relapsing pancreatitis, analysis of 7 cases associated with disease of 4; operative treatment of gallstone disease in light of ultimate results, 313
- Biopsy, Changing concepts in cervical, 43
- Bladder, Pedunculated tumors of 57; treatment of (tumors of, 57; total cystectomy, 57; roentgenologic changes in urinary and distal portion of ureters in spermatozoitis, 70; abdominal colposcopy for complete prolapse of vagina and, 56; supercussion of cervical neck of urethra on urinary tract above lesion, 56; in spinal cord injuries, 211; neurogenic, 141; vesical dysfunction in paraplegia, 245; pleurocentesis of tumors of 245; cystitis of trigone in women, 348, and ureteral malformation in genital prolapse, 349; operation for excessive hypertrophy of 335; report of 5 operations for vesico-vaginal fistulae 1 case complicated by functional urinary incontinence, 436; transplantation of ureters into rectosigmoid and, 433; transurethral resection in childhood, 436; spontaneous rupture of urinary 537; contribution to treatment of diaphragm of, 537; pathologically displaced upper femoral epiphysis as foreign body in urinary 57; tumors of, 11th particular attention to their clinical classification and prognosis, 538; carcinomas of urinary bladder 538
- Blacklock, Tanning operation, Analysis of malformations of heart amenable to, 404
- Blast injuries of ears, 206
- Blastomycosis, Of anorectal region, considerations on 3 cases, 51; involving prostate, 158; South American, associated with Hodgkin's disease: anatomoclinical considerations on case, 557
- Blast trauma, Minimal shock pulse trauma to cochlea, acute and chronic, 13
- Blood, Changes in distalness and lipase of, in acute pancreatitis, 43; study of intra-vascular thrombosis with some new conceptions of mechanism of coagulation, 73; acute leukemia and pregnancy 153; further studies on anticoagulants, 60; dialysis of, for treatment of uremia, 243; hemolytic transfusion reactions, 364; penicillin, streptomycin, dicummarol, and coagulation of thrombolytic properties of penicillin, 360; toxicity of sodium alginate in cats, 380; experimental study of transfusions of, 374; prothrombin activity, 375; effects of altered arterial tension of carbon dioxide and oxygen on cerebral flow of, and cerebral oxygen consumption of normal young men, 58; effects of various amino acids on peripheral flow of, and skin temperature, 38

SUBJECT INDEX—ABSTRACTS—VOLUME 88

- SUBJECT INDEX—ABSTRACTS—VOLUME 88
- Bone, Studies on insufficiency pelvis (gravidarum et puer perarum) 52 changes in and joints in hemophilia, with report of cases of so-called hemophilic pseudotumor 63 osteopetrosis simulating tumor some remarks about radiodiagnostics, 53, 2 cases of melorheostosis, 63 localized lipiodioses, 63 evaluation of penicillin therapy in acute hematogenous osteomyelitis, 68 occult metastases of 87 relationship of trauma to development of acute gastroosteodental lesions in experimental animals and man, 144 evolution and causes of Jungling's disease, 168 radiological and histological studies on aseptic osteolysis with exceptional symmetrical atrophy of all other toes, 170 indications and technique of surgery of tumors of foot with vascular disturbances which is associated with familial case of total loss of, one toe of foot with vascular disturbances with exception report of data observed in Kuentzsch maling 172 recent ad at Surgical Clinic of University of Innsbruck additional myeloplastic tumors of tendon sheaths of ankle with secondary osseous lesions, 177 roentgen diagnosis of rickets associated with other skeletal diseases of infants and children, 186 skeletal lesions in leucemia, 189 syndrome called osteitis fibrosa, 250 tendency toward conservation in removal and subsequent tetra clunus, 257 lengthening of articular extremities of apparently primary origin, 260 ste radial pathogenetic, and clinical considerations on radionecrosis of mandibular 270 aseptic necrosis of femoral head, 260 narrow of an sternal aspiration in study of simultaneous manifestations of skin and legs, 378 treatment of discrepancies of skin and, in extremities during growth 443 intravenous infusions in infants 452 mandibular grafts, 484 hyperplastic callus formation with or without evidence of fracture in osteogenesis imperfecta, 533 lesions of fracture phile granuloma, Hand-Schüller-Christian disease and Letterer-Siwe disease, 533 unusual plasmacytomas of renal changes, 533 solitary plasmacytoma 534, treatment of distal diaphyseal osteomyelitis, graft of treatment of pseudarthrosis of radius, in treatment of chronic infection of callosity by simple onlay methods and results in management of tuberculosis of joints and, In Novaggio Military Hospital during last 20 years, 538 chondromyxoid fibroma of likely to be mistaken especially for chondrosarcoma, 550
- Bones, Management of whole thickness bars with involve-ment of and tendons, 75
- Brain, Lymphatic connections of 134
- treatment of subdural hematoma 22 actinomycosis, 133, treatment of thoracogenic abscess of 133 trans-orbital biopsy, 133 differential diagnosis of tumors leucomyoma 210 Cushing's disease with hypofrontal basophil cell tumor of hypophysis, 211 method of contrasting visualization of abscesses of 211 method of suprasellar tumors by pneumoencephalography 318 effects of altered cerebral tensions of carbon dioxide and oxygen on cerebral blood flow and cerebral oxygen consumption of normal young men, 381 surgical pathology of abscess of 397 cordotomy and lenotomy, 400 pneumoencephalography in diagnosis of cerebellar atrophies, 458, follow up study of with penetrating injury to brain, 401 study of syndrome, 491
- effect of oral caronamide on plasma penicillin levels following large intramuscular doses of penicillin, 382, plasma penicillin levels after oral penicillin with and without oral caronamide, 382 splenic panhematocytosis of radiation on hemopoiesis, 465 relationship between heparin dosage and clotting time, 467 cir-culating anticoagulant as cause of hemorrhagic dia-themose, 470 some aspects of problem of hemorrhages in new born, 520 chronic leg ulcer in diseases of 543 major surgery hematosit values, plasma protein determinations, plasma fraction, 545 some observa-tions on anemia in patients with burns, 546 relation-ship between hypoprothetemia and toxicity of ana-thectic agents, preliminary report, 548
- Blood pressure, Discussion on surgical treatment of hyper-tension 24 observations on pulse and retinal arterial pressure 130 tonocardiography after exercise, 264; anesthetic block of vagus and phrenic nerves and of sympathetic trunk at neck in thoracic surgery, its protective effect on arterial experimental study on dogs, 406
- Blood sugar, Metabolic study of burn cases, 84
- Blood transfusion, Various articles concerning, and cardio-vascular disturbances in surgery 73 hemolytic trans-fusion reactions, 264 death following autotransfusion, 350 experimental study of 374 are universal donors dangerous, 543
- Blood vessels, Vascular fundus disease with especial refer-ence to classification of Gifford and Macferson, 16 pulmonary valvulotomy for congenital pulmonary stenosis, 20 aortic pulmonary anastomosis, 29 mesen-teric vascular occlusion, 31 treatment of spontaneous resection aneurysm of subclavian artery 71; prog-nosis, hypertension II(C) on peripheral vascular diseases, hypertensive I(C) on peripheral vascular venous obstruction and circulation in patients, 86 Schrotter's syndrome) collective review 89 con-traction to study of pulmonary hilum bilium of right upper lobe, 135 experiences in surgical treatment of pulmonary stenosis, 136 anomalies of derivatives of aortic arch system, 138 phlebography in localization of incompetent communicating veins in localization of various veins, 178 wounds of common carotid ex-ternes report of 17 cases from World War II 178 experimental studies in vascular repair comparison of reliability of various methods of end-to-end arterial anastomosis, 179 studies on circulation by portacaval anastomosis, 187 tonocardiography after exercise, 264 vaso-motor action of some local anesthetics, 268, vascular malformations and vascular tumors of gastrointestinal tract collective review 261, vascular surgery of phelebitides and contribution to biochem-ical study of phelebitides and surgical treatment, 268-various veins, 273 discussion on primary treatment of varicose veins, 449, biologic studies of surgical shock peroxanalar arterial hypertension following any tissue trauma is due to adrenalin secretion by suprarenal glands, 471 revascularization of heart, 500 surgical treatment of infarct type of constriction of aorta, 500 thromboembolic obliterans, 541; arteriectomy in limbs of vascular origin, 542 results of 542
- Bock, S. A., Visualization of patent duplex arteriovenous fistula by means of thoracic aortography 533
- Bock, S. A., Case of intestinal lipodystrophy 533
- Bombing, Ocular lesions following atomic, 15
